***Methacholine Chloride,** U.S.P., *Mecholyl Chloride;* acetyl-β-methylcholine chloride. Very soluble in water. Dose, hypodermically (never intravenously!), 10 mg., increased cautiously to 25 mg.; oral dose, 0.05 to 0.5 Gm.; two or three times daily in water or milk. It is used especially for ion transfer. *Methacholine Chloride Capsules,* U.S.P., usual size, 0.2 Gm. *Methacholine Chloride Injection,* U.S.P., aqueous; usual size, 10 mg. in 1 cc. *Mecholyl Bromide,* N.N.R., is less hygroscopic and is convenient for oral use as tablets, 0.2 Gm., one to three tablets two or three times daily.

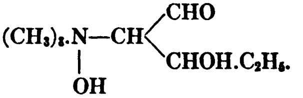
Carbachol, U.S.P. (Carbamylcholine Chloride, *Doryl*), is very soluble in water (1:1). Average dose, oral, 3 mg.; hypodermic, 0.25 mg. *Carbachol Injection,* U.S.P., available as 0.25 mg. in 1 cc. *Carbachol Tablets,* U.S.P., available as 2 mg.

◆

MUSCARINE

Muscarine, an organic ammonium base found in the poisonous fly mushroom (but not in most other poisonous fungi), and a similar base prepared synthetically from choline, produce typical peripheral stimulation of the parasympathetic system and also a nicotine and a curare action. The most characteristic effect of muscarine is a vagus standstill of the frog heart.

Constitution.—Muscarine was isolated by Schmiedeberg and Koppe, 1869, from the fly agaric, Amanita muscaria. Harmson, 1903, obtained 0.016 per cent from the fresh fungus. It is a substituted ammonium base related to choline. Its constitution was established by Kögl, Duisberg and Erxleben, 1931, as



$$(CH_3)_3.\underset{\displaystyle\overset{|}{OH}}{N}—CH\begin{cases}CHO\\CHOH.C_2H_5.\end{cases}$$

Schmiedeberg and Harnack, 1876, who had set up an erroneous formula for muscarine, obtained a compound by the supposed oxidation of choline which they thought identical with natural muscarine, but Boehm, 1885, showed differences in physiological action, and it was then called "*synthetic muscarine*" or "*pseudomuscarine.*" Ewins, 1914, showed that this is not an oxidation product, but a nitrous ester of choline. Its physiologic properties were further studied by Dale, 1914. They agree qualitatively with those of natural muscarine, but exhibit quantitative differences. Weinhagen, 1920, found that slight and accidental variations in the method of its preparation cause differences in the composition of synthetic muscarine.

Muscarine Action on Frog's Heart.—Muscarine causes slowing, with diminished systolic and increased diastolic excursions, and finally *stoppage in diastole.* These effects resemble those of electric vagus stimulation (also the electrocardiogram; Samojloff, 1913); and the results of submaximal vagus stimulation and muscarine are strictly additive, in frogs (O. Loewi), in turtles (Fleischhauer, 1912), and in mammals (Schott, 1911). Muscarine also produces additive results with pilocarpine. Large doses of both paralyze the vagus (Loewi) and the ganglia (Schott). The muscarine effect is more persistent than electric vagus stimulation, and occurs even in calcium-poor hearts, in which ordinary vagus stimulation is ineffective (Loewi, 1912). The refractory period of the heart to artificial stimulation is shortened by weak muscarine, as by vagus stimulation (Raaflaub, 1914). The effect of muscarine on the electric response of the heart was investigated by Mines, 1914. *Perfusion* of the excised frog heart with very dilute muscarine in Ringer's solution produces simultaneous weakening and slowing. If it is perfused in blood, it may also slow without weakening; while perfusion of muscarine blood through the isolated ventricle may give weakening without slowing (Raaflaub, 1914). In *turtle heart,* muscarine increases the auricular tonus waves (Gruber and Markel, 1918). Muscarine causes acceleration of the *crab's heart,* although a well defined inhibitory mechanism exists in these animals.

Location of Action.—In mammalian hearts, muscarine causes no inhibition if the auriculoventricular bundle is cut (Cullis and Tribe, 1913), or in ventricular strips (Leetham, 1913); but in frogs, the muscarine standstill occurs also in the isolated apex, showing that the stimulation is peripheral to the ganglia; and since it can be abolished by atropine (Schmiedeberg and Koppe), the action can not be on the muscle. It is therefore assumed that it stimulates those endings which atropine paralyzes. If muscarine and atropine are exhibited at the same time or successively, their respective quantities determine which predominates, but atropine is much the stronger. The heart may be started by substances which stimulate its muscle directly, *e. g.*, physostigmine, veratrine, digitaline, aniline, camphor, guanidine. The type of contractions under muscarine differs in some respects from those of vagus stimulation (Rhodius and Straub, 1905). In guinea pigs it may cause *bronchial spasm,* similar to that of anaphylactic shock (Modrakowski, 1912). It has no effect on lacteal secretion (Ott and Scott, 1912).

Excretion.—In toads, this occurs quantitatively by the urine (Fuehner, 1908 and 1909).

Central Actions.—Muscarine is reported to cause acute excitement and violent delirium. The fly agaric is said to be used in Siberia as an intoxicant, with effects similar to those of cannabis.

Muscaria poisoning differs from that by other poisonous mushrooms in its relatively rapid course, which is run in one to three hours, and by the phenomena of parasympathetic stimulation. The mortality is not high. *Treatment* consists in gastric lavage, saline purge and atropine.

MUSHROOM POISONING

Many fungi contain poisonous constituents, varying in the different species. Ford, 1913, found that the principles toxic to man belong mainly to three classes: (1) muscarine, which is confined practically to the fly mushroom, Amanita muscaria; (2) substances producing degenerative changes in internal organs (especially Amanita phalloides); (3) substances producing gastro-enteritis.

The toxic effects of *Amanita phalloides* are due entirely to phalloidin, which was isolated as crystals by Lynen and Wieland, 1937. Marked resistance to this can be induced by immunologic technic (M. Vogt, 1938). The several actions were formerly attributed to distinct constituents. Rabe, 1911, claimed to have isolated an alkaloid with muscarine actions. Glucosidal hemolysins were reported in several related varieties, especially in Helvella esculenta (Ford, 1913). They are easily decomposed by heat and digestion and are therefore not concerned in poisonous effects. *Agglutinins*, perhaps glucosidal, are also widely distributed; some of these are not destroyed by boiling, but they are probably not pathogenic (Ford and Rockwood, 1913). Practically all species of Amanita slow or stop the frog heart on direct application. In A. phalloides, this is not due to muscarine, but to inorganic salts (Ford and Brush, 1914).

Poisoning by Amanita phalloides is said to be the cause of ninety per cent of the mushroom deaths in the United States. The *symptoms* set in after a latent period of six to fifteen hours, with sudden abdominal pain, vomiting and diarrhea, stools containing blood and mucus; rapid loss of strength; cyanosis; death in two or three days. The mortality is about 50 per cent; extremely ill patients may recover, or improvement may be followed by fatal relapse. Histologic examination shows extensive necrosis and fatty degeneration of the liver parenchyma, somewhat less of the kidneys. The brain may be edematous (Ford, 1913; Vander Veer and Farley, 1935). Uremia, from greatly impaired kidney function, may be responsible for part of the symptoms (Clark, Marshall and Rowntree, 1915). Dogs and rabbits show marked drop of blood sugar (to 0.028) and decrease of chloride. Rabbits go into hypoglycemia convulsions (Binet and Marek, 1936). The *treatment* comprises evacuation, rest, opiates, liquid diet of high carbohydrate content and intravenous injection of 10 per cent dextrose in 0.9 per cent chloride, 500 to 1000 cc. every six to eight hours.

Phenomena from other poisonous mushrooms vary with the species, but they generally include enteritis and hepatitis. More or less common features are: abdominal pain, nausea, vomiting, violent diarrhea; variable pulse; labored respiration; consciousness unaffected, or delirium; coma or convulsions. Some cause fatty degeneration of the liver and kidneys. Many mushrooms produce abdominal symptoms simply by being indigestible. The *treatment* would be as for phalloides. The chance of poisoning may be somewhat diminished by prolonged boiling, as some of these substances are decomposed in this manner, but reliance on this would be dangerous. Drying does not diminish the toxicity. Verrill, 1914, reported symptoms of inebriation (not dangerous) from eating Panaeolus papilionacens (Maine).

Edible Mushrooms.—The food value of mushrooms is popularly supposed to lie in a large percentage of assimilable nitrogen, but they contain no more than potatoes. As the fiber of mushrooms is also quite indigestible, their dietary value is as a relish rather than as food.

◆

QUATERNARY AMMONIUM BASES

The organic derivatives of ammonium are strikingly similar in their action. They produce a curare effect, *i. e.*, paralysis of the nerve endings of striped muscle (Brown and Fraser, 1869); some also effect muscular tremors in frogs; and those having three or four methyl groups cause a muscarine effect, *i. e.*, peripheral stimulation of the cardiac vagus; and a nicotine action, *i. e.*, paralysis of sympathetic ganglia. The curare effect evidently depends on 5-valent nitrogen; or rather, on the stereochemic configuration, for the same characteristic is shown by the corresponding phosphorus, arsenic and antimony compounds. The various actions differ in degree with the various derivatives in ways not easily explainable by their constitution (Burn and Dale, 1915).

Tetra-methyl ammonium chloride produces typical curare effect in mammals and frogs. Ammonium convulsions occur in mammals, but not in frogs, being prevented in the latter by the more powerful curare paralysis. The *circulation* shows a fall of blood pressure, generally with slowing of the heart, by peripheral vagus stimulation and peripheral vasomotor depression. The *respiration* is temporarily paralyzed by intravenous injection; in decerebrated animals, this is preceded by respiratory stimulation. The paralysis is due to a curare effect on the phrenic nerves (Marshall, 1913). Loevenhart, 1914, believes, however, that the respiratory action is entirely central; *i. e.*, primary stimulation and later depression of the medullary centers.

Tetra-Ethyl Ammonium Chloride.—In frogs, this produces irregular muscular contractions and tremors; first fibrillary, then tonic. With larger doses, these are succeeded by paralysis. Both actions are seated in the muscle nerve endings. Mammals also show increased excitability and depression of the endings. Burn and Dale, 1915, found no curare or muscarine action, but a good nicotine effect; but Acheson and Pereira, 1946, again confirm a curare effect on the cats' gastrocnemius, as well as blockage of autonomic ganglia, resulting in vasodepression (Acheson and Moe, 1946). It lacks muscarinic and antimuscarinic effects on the nictitating membrane (Acheson and Pereira, 1946). Dilute solutions (1:100,000) improve the working capacity of the heart-lung preparation; high concentrations produce ventricular fibrillation (Acheson and

Moe, 1945). Rabbits exhibit dyspnea, tremors, convulsions and arrest of respiration. In distinction to tetramethyl ammonium, there is no direct action on the circulation; the respiratory effects are also smaller (Marshall, 1914).

Methyl-Ethyl Ammonium Compounds.—The actions of these are, on the whole, intermediate, but without definite ratio to the alkyl radicals (Marshall, 1915; Burn and Dale, 1915).

Furfuryl trimethyl ammonium iodide (*"furmethide"*) acts on parasympathetic stimulant, producing marked sweating, and in larger doses salivation, defecation and vomiting (Fellows and Cunningham, 1944). It is proposed clinically as sudorific, faster and more certain than pilocarpine: 5 mg., hypodermically, cause sweating of the face, arms, thorax and abdomen, usually within two to five minutes. Side actions are rare and insignificant, and are readily controlled by atropine (S. A. Guttman, 1944).

◆

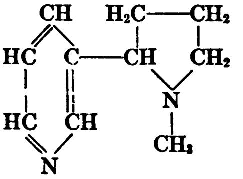
NICOTINE

Nicotine, the chief alkaloid of *tobacco*, has no therapeutic importance, but considerable scientific and toxicologic interest. Both the central and peripheral actions are important; they consist in short stimulation, followed by depression or paralysis. Centrally, small doses cause chiefly a respiratory stimulation; larger doses produce convulsions of the medullary type and arrest of respiration. The action is rapid, approaching that of hydrocyanic acid. Peripherally, nicotine paralyzes all autonomic ganglia, parasympathetic as well as sympathetic. The paralysis may be preceded by stimulation. The most important effects are on the circulatory and gastro-intestinal systems. The intestinal action is complex, and probably involves the muscle directly as well as the ganglia. This probably holds true for its other autonomic effects. Nicotine has several distinct actions on striated muscle, including fibrillary twitchings, curare action and tonus.

Location of Peripheral Autonomic Actions.—The typical paralytic effects of nicotine are exerted on the ganglia, for electric stimulation of the postganglionic fibers remains effective (Langley, 1890). The stimulant effects in many situations are also ganglionic, for they disappear after division of the postganglionic fibers, but persist after degeneration of the preganglionic fibers. The nicotine must therefore act on the "receptive mechanism" of the ganglion cells. These ganglionic effects are overcome by the drugs that act directly upon the receptive or contractile mechanism of the muscle. However, nicotine may also act in part directly on the muscle.

The chief importance of nicotine lies in its habitual use in the form of *tobacco* as an "enjoyment poison" ("Genussgift"), as a stabilizer and lubricator, as "oil on the troubled waters of life." The effects of tobacco are due practically solely to its nicotine. Limited tolerance to the acute toxic effects is soon acquired, after which it acts chiefly as a central sedative. Overindulgence produces chronic nicotine poisoning, with digestive disturbances, functional arrythmias, optic changes, etc. The differences in the various forms of tobacco habit are explainable by differences in absorption.

Nicotine,



a pyrrole derivative of pyridine, is a fluid, volatile, oxygen-free alkaloid, of strongly basic character. It is colorless and almost odorless when freshly prepared, but acquires a characteristic odor and a brown color on standing in the air. Tobacco leaves contain from 0.6 to 6 per cent and up to 15 per cent in some Algerian tobaccos. The natural levo-nicotine is considerably more potent than the dextro. Free nicotine is more potent than its salts because it is more quickly absorbed. Its volatility is not high; the prompt action is due to rapid absorption and high toxicity.

The **central actions of nicotine** consist in stimulation, followed by depression, of the whole cerebrospinal axis, from above downward. The symptoms from large doses resemble those of asphyxia or hydrocyanic acid.

The stimulation may be absent, especially with large doses, so that the animal may drop dead almost instantaneously, without other symptoms. But this is not common. Intermediate doses (in dogs, 1 to 5 mg. per Kg. by vein) produce *nicotine catalepsy* with postural plasticity, autonomic reactions and insensibility to pain (Gutiérrez-Noriega, 1942). The effects of small doses, such as are noticed in smoking, will be discussed under the habitual use. *Direct application to the motor cortex* produces clonus and generalized convulsions, as do caffeine and strophanthin (Rizzolo, 1929). In frogs, the action on the cerebral centers seems to be insignificant, for the effects are the same when the hemispheres are removed.

Medullary Centers.—The respiratory, vagus, vasomotor and emetic centers react strongly, even violently, partly through the carotid sinus and cardio-aortic reflexes.

Spinal Cord.—The motor cells are strongly stimulated, resulting in *convulsions*, with passage of feces and urine. If the nicotine is applied to a part of the cord, the convulsions remain confined to the muscles innervated from this area (difference from strychnine, which acts on the sensory cells). The stimulation is followed by paralysis. The nicotine convulsions are not seated exclusively in the spinal cord, but involve the hindbrain and medulla as well. They are much weakened by anesthesia. The *cutaneous reflexes* of frogs are depressed. Partial tolerance to this action is acquired by repeated administration (Howat, 1916). The *spinal posterior root ganglia* are not affected, even when a 1 per cent solution of nicotine is applied directly to them.

Respiration.—Relatively small doses produce strong but brief stimulation, followed by temporary acapnic inhibition, and with toxic doses by permanent arrest (Winterberg, 1900; de Almeida, 1920). The *hyperpnea* is chiefly reflex from the carotid sinus (Heymans *et al.*, 1931; Anitschkow, 1934) analogous to the hyperpnea of anabasine, lobeline, cyanide and sulfide. The *respiratory arrest* is the usual mode of death in acute nicotine poisoning. Experiments with crossed circulation show that the arrest is due primarily to peripheral (curare) action on the diaphragm and chest muscles (F. E. Franke, 1938). The respiratory center continues to discharge potential impulses through the phrenic nerves after the respiration has ceased, and these are usually increased by further injections of nicotine (H. Gold and Modell, 1936). The asphyxia is rendered more fatal by the preceding convulsions, and if these are prevented by ether, and artificial respiration is administered to give time for the disposal of the nicotine, the animal survives doses that ordinarily cause death (F. E. Franke and Thomas, 1933).

The *bronchial muscle* is constricted in surviving lungs (Baehr and Pick, 1913), but the effects are rather inconstant (Sollmann and Gilbert, 1937). The *ciliary movements of the bronchioles* are arrested by nicotine, but only with relatively high concentrations. In the *frog's esophagus*, they are first accelerated, then slowed and paralyzed, but also require high concentrations. The free alkaloid is about six times more potent than the acetate (Weatherby, 1940). They are markedly slowed by cigarette smoke (Dobrzanski, 1927), but this may involve other ingredients.

Circulation.—The effects of nicotine are complex. They include carotid sinus and cardio-aortic reflexes, direct actions on the vagus and vasomotor centers, stimulation and paralysis of the vagus, stellate, vasomotor and splenic ganglia, increased output of epinephrine and direct effects on the cardiac and vascular muscle. Together they result in initial slowing of the pulse (sometimes to temporary arrest), then acceleration of the heart and rise of blood pressure, which may reach a high peak and may then fall abruptly to shock level. In *smoking*, the effects are complicated by nausea or habituation. They will be discussed under the Habitual Use.

Heart Rate in Mammals.—With small doses of nicotine, the primary slowing is due chiefly to a carotid sinus reflex (Heymans *et al.*, 1931), but with large doses it involves also direct stimulation of the vagus center and of the vagus ganglia.

Arrhythmia.—With larger experimental doses, the slow heart beat is replaced suddenly by great *quickening* through paralysis of the vagus ganglia. The nicotinized heart may be slowed by muscarine, or stimulation of the sinus, but not by stimulation of the vagus trunk. According to Kose, 1904, the secondary acceleration involves ganglionic accelerator stimulation, which passes finally into paralysis. *Electrocardiograms* (dog) often show a nodal rhythm (synchronous action of auricles and ventricles), interrupted by extrasystoles; and other irregularities identical with those of stimulation of the vagi and accelerators, separately or together (Clerc and Pezzi, 1920). *Excised mammalian heart*, perfused with nicotine solution, shows typical vagus effects: first, diastolic standstill; then gradually resumption and finally acceleration above normal, with increased amplitude. The primary standstill is abolished by atropine. The secondary acceleration is probably due to accelerator stimulation (Clerc and Pezzi, 1912.(With *frog heart*, application of nicotine produces brief diastolic standstill (stimulation of vagus ganglia). The heart then resumes its beat and stimulation of the vagus trunk becomes ineffective. The cardiac effects were studied in 1868 by Truhart on intact frogs. Observations of Helt, 1920, on the excised heart by Straub's method show that the effects of increasing doses are (1) Vagus stimulation (diastolic tendency and slowing), spontaneously reversible; arrested by atropine. (2) Disturbance of conduction (partial heart block). (3) Diminished electric irritability. The nicotine is rapidly fixed in the heart and the action becomes irreversible. In *electrocardiographic studies on perfused hearts of frogs and turtles*, Barry (1921) found that the effects vary with conditions: strengthening or weakening; quickening or slowing; dissociation of the chambers; partial or complete arrest; or reversal of the beat (starting in ventricle). With *turtle's auricle*, nicotine, 0.03 to 0.05 per cent, increases the height of the contractions, without changing the tonus or the tonus waves. Concentrations of 0.1 to 1 per cent increase the tonus and the tonus waves; the contraction height may be increased or diminished (Gruber, 1921).

The blood pressure is raised by small doses, exclusively through the carotid body and aorta reflex (C. F. Schmidt and Comroe, 1940). This holds true also for lobeline, cyanide, sulfide, anoxia, CO_2 and alkalis (Heymans *et al.*, 1932). Larger doses stimulate also the vasomotor ganglia (Hoskins and Ransom, 1915). These actions, together with contraction of the spleen, increased epinephrine output (Gley, 1914), and the mechanical effects of the convulsions, drive the blood pressure very high. The nicotine rise is prevented, in cats, by intravenous injection of sodium *sulfathiazole* or of *thiamine*, suggesting transient thiazole blocking of the sympathetic ganglia and adrenal cells (E. P. Pick and Unna, 1946).

The central vasomotor stimulation may persist into death (Pilcher and Sollmann, 1915), but can not make itself felt when the vasomotor ganglia undergo nicotine paralysis. The carotid sinus reflex is then also abolished (Sollmann and Brown, 1912). There may also be direct depression of the arterial muscle. The vessels become dilated and the *pressure falls*. The dilatation can be seen in the intestinal vessels or the rabbit's ear. The vasomotor paralysis is rarely complete, so that direct or reflex stimulation, or a second injection of nicotine, again causes a short constriction. The heart muscle eventually wears out, mainly because of the lowered coronary pressure. Nicotine has no effect on excised *spleen*, but in living animals this contracts strongly, synchronous with the rise of pressure. It is due chiefly to stimulation of the celiac ganglion, and somewhat also to increased output of epinephrine (McCrae, 1930). The *coronary circulation* is slowed by the constriction of the coronary vessels, notwithstanding the raised blood pressure (Morawitz and Zahn, 1914). The *pulmonary and hepatic vessels* are constricted (Berezin, 1914). The outflow from the pulmonary vein is diminished, but the pressure in the pulmonary artery does not rise (W. E. Dixon and Hoyle, 1929). During the nicotine rise of blood pressure the volume of the normal *kidney* diminishes, by arterial vasoconstriction; the volume of a denervated kidney increases passively (Bariéty and Kohler, 1939). The blood pressure of animals in peptone or anaphylactic *shock* reacts but little to epinephrine, but rises sharply under nicotine ($\frac{1}{4}$ mg. per Kg.). This rise, however, is attributed essentially to the increased respiration (J. P. Simonds, 1916).

Peripheral Actions on Frog's Vessels.—By perfusion through decerebrated frogs, nicotine produces immediate vasoconstriction and muscular fibrillation. These effects disappear in a few minutes, during the perfusion, and can not be restored by further nicotine. Epinephrine is still effective. Tyramine suppresses the nicotine constriction almost completely (Handovsky and Pick, 1913).

Cerebrospinal fluid pressure follows the circulatory changes (Dixon and Halliburton, 1914).

The epinephrine output shows a brief increase, followed by marked and enduring decrease, presumably by stimulation and paralysis of ganglia. The epinephrine store of the gland is apparently unchanged (Stewart and Rogoff, 1919). Nicotine also increases the epinephrine output of perfused adrenal gland (Anitschkow, 1927).

The blood sugar level is first raised, then lowered by nicotine. The rise is attributed chiefly to the increased epinephrine output, but in dogs it produces hyperglycemia even after excision of the suprarenal glands (Burstein and Goldenberg, 1928; Hazard and Vaille, 1935). The fall may be due to paralysis of the ganglia or to the lowered blood pressure. Large doses of nicotine prevent the glycosuria which ordinarily follows the injection of caffeine and epinephrine; or on piqûre (Macleod and Dolley, 1905). In guinea pigs the rise may be double the normal level and persist for seventeen days after the last injection (Mosinger *et al.*, 1939).

Tissue oxidation is checked by nicotine. In slices of cerebral tissue the effect is chiefly on lactic and pyruvic acid, much less on dextrose, and practically none on succinic acid; with kidney and testis, dextrose oxidation is inhibited as much as lactic acid is (Z. Baker *et al.*, 1938).

Effects on Glands.—Secretion is generally stimulated through the ganglia. This is particularly prominent with the *saliva*. Small doses, however, change the response to stimulation of the chorda nerve, so that this diminishes secretion (Dale and Laidlaw, 1911). *Lacteal* secretion is not increased by nicotine (Ott and Scott, 1912). Large doses suppress for some hours (Hatcher and Crosby, 1927). A *local sweat response* is produced in man by intracutaneous injection of dilute solutions of drugs of the nicotine group (nicotine, 1:200,000; alpha lobeline, 1:2,000,000; acetylcholine, 1:40,000). It appears to be an axon reflex and is suppressed by adding procaine, 1:100,000 (J. M. Coon and Rothman, 1941).

Oviductal secretions of birds.—Nicotine has no effect on the output of shell material (Riddle and King, 1921).

Digestive Tract.—Nicotine produces nausea, emesis and violent diarrhea. The emetic action is mainly central, the intestinal mainly peripheral.

Nicotine emesis is probably due to medullary stimulation (Eggleston and Hatcher, 1915). It may be evoked by direct application of a minute trace to the medullary emetic center (Hatcher and Weiss, 1923). It is antagonized by atropine (Eggleston, 1916). *Excised stomach* is contracted in most mammals, but relaxed in a few forms (M. Smith, 1918). The effects on *mammalian intestine* are chiefly peripheral, *i. e.*, essentially alike in intact animals and in excised intestine. Small doses stimulate the muscle and slightly increase its tone. Larger doses produce violent stimulation, culminating in intense contracture (Nasse); but this is soon followed by inhibition of the movements and relaxation of the tone (Pohl; Ikeda, 1916). Dogs show relatively more stimulation and less depression. The contracture is abolished by atropine. The ganglia are also paralyzed, so that the responses to stimulation of the vagus or splanchnic are abolished (Mulinos, 1927).

In **urinary bladder** of cats, nicotine produces contraction followed by relaxation. The responses are not affected by section of the nerves or by atropine (Edmunds and Roth, 1920). G. B. Roth, 1917, found practically no effect on *excised ureter*. Macht, 1916, describes primary stimulation and secondary depression. The *retractor penis muscle* is stimulated by nicotine (Edmunds, 1920). As it does not contain any ganglion cells (Fisher), the action is presumably on the receptive mechanism. The effects on the *uterus* are described in the general discussion of autonomic poisons.

The pupils show both contraction and dilatation at different times, nicotine acting upon the ganglia of both the oculomotor and sympathetic fibers. There may even be a direct action upon the iris muscle. The effect is different in different animals: the dog and cat usually show dilatation; the rabbit first constriction and then dilatation.

Skeletal Muscle.—The injection of nicotine into frogs produces fibrillary twitching merging into tonic contracture (O. Kushima, 1919). The minor grades may cease temporarily on section of the nerve, but they return, especially on stimulation. They occur also in excised muscle and after degeneration of the nerve endings, so that they are intramuscular. Microscopic examination shows that the contracture may be confined to the region of the end-plates and that smaller concentrations of the poison ($\frac{1}{500}$) are effective at this region (Langley, 1913, 1914). This holds true also for other muscle poisons, for instance caffeine, and may mean that the sarcolemma is more permeable at this place; but it has been interpreted as evidence that the nicotine acts on a receptive substance assumed to be localized especially about the intramuscular "end-plate." The nicotine stimulation is mutually antagonistic with curare, atropine, cocaine and procaine (Frank and Katz, 1921; Schueller and Athmer, 1921). A number of other poisons produce essentially identical effects: namely, physostigmine, guanidine (Fuehner, 1920; Frank and Stern, 1921), acetylcholine (Riesser and Neuschloss, 1922), barium and probably veratrine. They also show essentially the same antagonisms. Physostigmine, guanidine and barium become ineffective rather early after nerve degeneration, which evidently induces intramuscular degenerations that interfere more with the response to these drugs than with those to nicotine and acetylcholine. As the stimulation by all these drugs is mutually antagonistic with curare, which does not paralyze the muscle to direct stimulation, it may be assumed that they and curare act on a "receptive mechanism" in the striped muscle.

The *muscle of fowls* is especially susceptible to the tonus (Langley, 1906; Edmunds and Roth, 1908).

Mammals also show fibrillar contractions, but of central origin. Excessive doses of nicotine do not produce these central convulsions, although they do not prevent strychnine convulsions (Langley, 1918).

Tobacco Smoking on Ergographic Response.—This produces a periodicity in the contractions, apparently due to central fatigue and depression (Raphael, 1920).

Curare Action.—Nicotine has a curare-like effect, which becomes prominent later. In the milder stages, equally strong or stronger current is required when the stimulus is applied to the nerve than when it is placed on the muscle. In the normal preparation the opposite is the case. The excitability and irritability of the muscle cells are also diminished by nicotine on direct application. The curare action may lead to paralysis of respiration in mammals (Thomas).

Invertebrates.—In the *squid* (Loligo) nicotine acts on the cerebral and not on the stellar ganglion (A. R. Moore, 1919). In *starfish* (Asterias) it produces ventral flexure, whereas strychnine produces dorsal flexure. When both drugs are used, the strychnine effect predominates (Moore, 1920).

Insecticide.—Nicotine is one of the most efficient insecticides, especially for soft-bodied insects, such as plant lice. It is generally sold as a 40 per cent solution of the sulfate, to prevent volatilization. About two million pounds of this solution are used annually in the United States (P. A. Neal *et al.*, 1941). It kills the insects by paralysis, ascending the ventral nerve cord from the abdomen to the brain. It produces structural changes in the nerve cells, analogous to those of oxygen deprivation (McIndoo, 1916). Both optical isomers are equally toxic (Gause and Smaragdova, 1939).

Antiseptic Action.—Tobacco juice and smoke are antiseptic, and Fullerton, 1912, claims that they tend to preserve the teeth. Common experience shows that they are not effective.

Local Actions.—Free nicotine is caustic by its alkalinity. Strong solutions paralyze the nerve fibers.

Fate.—Nicotine is *absorbed* rapidly from mucous membranes and especially from the lungs; more slowly from hypodermic injections. Serious poisoning has occurred from the intact skin (J. M. Faulkner, 1933). Absorption from "chewing" 10 Gm. of tobacco amounted to 5 mg. of nicotine in the first hour (D. Gaede, 1940). It is *excreted* only in small part (4.2 to 12.8 per cent; A. C. Corcoran *et al.*, 1939), mainly by the urine, where it can be demonstrated after smoking, through its catatonic effect on rats (Dingemanse and Freud, 1933), as well as chemically.

The urine of habitual smokers contains 1.4 to 9.8 mg. per twenty-four hours (A. C. Corcoran *et al.*, 1939). It disappears within three or four days after discontinuing the smoking. It appears to be responsible for the pressor effect of many urines (Helmer *et al.*, 1939). Smoking forty cigarettes in a day, 2 to 8 mg. of nicotine are excreted in the urine, representing 2 to 8 per cent of the retained nicotine of the inhaled smoke. The amount recovered in the urine is about doubled if the urine is rendered more acid by administering ammonium chloride, and it is decreased to a fourth by giving alkali, presumably by absorption of free nicotine from the urinary bladder (Haag and Larson, 1942). It is also excreted by the lungs and sweat, a small amount by the milk, 0.12 to 0.5 mg. per liter of milk, when smoking one to twenty cigarettes per day; there was no demonstrable effect on lactation or nurselings (Perlman and Dannenberg, 1942). *The unexcreted nicotine is destroyed,* chiefly in the liver. Rabbit's kidney and lung, as well as liver, contain an enzyme system capable of detoxicating nicotine (E. Werle, 1938). There is no significant increase of nicotinic acid or its derivatives in the urine (Larson and Haag, 1942). Dixon and Lee, 1912, claimed that the destruction is increased by habituation. Biedl *et al.*, 1932, report that the blood pressure is more sensitive to nicotine in dogs whose liver has been removed. With frog's liver, however, Clark, 1912, found no destruction.

Acute Nicotine Poisoning.—Fatal nicotine poisoning occurs from accidental ingestion of nicotine insecticides: 288 cases were reported in the registration area of the United States in the five years of 1930 to 1934 (J. B. Beeman and Hunter, 1937; F. E. Franke and Thomas, 1936). Serious poisoning occurs industrially from inhaled tobacco dust (Burstein, 1927), in nicotine extraction (Genkin *et al.*, 1935) and sometimes through the medicinal use of tobacco, especially by the laity.

The application of tobacco to wounds or bruises is not without danger. E. G. Garvin, 1913, reported the death of a girl of six and one-half years, forty-five minutes after the administration of less than 1.5 Gm. of tobacco by enema, against pinworms.

Toxicity.—Nicotine is one of the most fatal and rapid of poisons; the vapor arising from a glass rod moistened with it and brought near the beak of a small bird causes it to drop dead at once, and two drops placed on the gums of a dog may give a similar result. The fatal dose for a man is about 40 mg. of nicotine, with death in five to thirty minutes. The fatal dose of tobacco is about 2 grams; one cigar contains a quantity of nicotine which would prove fatal to two persons, if directly injected into the circulation.

Symptoms.—In lighter cases, such as occur in *smoking*, the peripheral and nauseant actions predominate. There is first an increased flow of saliva, partly reflexly through the mechanical irritation of smoke, but mainly by direct stimulation of the ganglia through the nicotine. Nausea, vomiting and diarrhea soon appear. There is a sensation of oncoming sweat, which does not actually break out. A feeling of exhaustion appears early, partly as the result of nausea, partly as the first indication of central collapse action. Palpitation is also noted. *Severe cases* show immediate faintness, prostration and muscular weakness; severe nausea, vomiting and diarrhea, followed quickly by collapse with or without convulsions. Death occurs usually within a few minutes after ingestion, but may be delayed for several hours. *Autopsy* often shows hemorrhagic gastritis or acute cardiac dilatation (Beeman and Hunter, 1937). Anemia of the meninges and peculiar changes of the cortical cells have been described in animals.

In man, 1 to 4 mg. of pure nicotine by mouth produced prompt burning in the mouth, a scratching sensation in the pharynx, increased salivation, a sensation of heat spreading from the region of the stomach over the whole body; excitement with headache appeared, then vertigo, confusion, disturbed vision and hearing, photophobia, dryness in the mouth, cold extremities, nausea, vomiting and diarrhea. Respiration quickened, but difficult. Pulse at first increased, then irregular. After forty-five minutes there was syncope, with clonic spasms. Recovery occurred, but general depression persisted for three days. With *intravenous injection* of 1.5 to 6 mg. of nicotine, Maddock and Collier, 1933, observed increase of respiration, cutaneous vasoconstriction, rise of systolic pressure by 12 to 16 mm., and increase of heart rate by 8 to 36 beats, without any seriously toxic phenomena.

Subacute industrial nicotine poisoning as observed in nicotine extraction occurs usually as acute outbreaks with predominance of parasympathetic stimulation: bradycardia (the most frequent symptom), arrhythmia, hyperchlorhydria, smooth muscle spasticity, salivation, sweating. Sympathetic stimulation was indicated by angiospasm and tremors. The pupillary reactions were disturbed (Genkin *et al.*, 1935).

Proof of Nicotine Poisoning.—The odor furnishes valuable evidence. The extracted nicotine may be tested on animals. The muscular tremors and the positions which a frog assumes after nicotine (Van Praag, 1854) are characteristic, especially the folding of the hindlegs on the back. A control animal should be observed. Nicotine is very *resistant to putrefaction* and has been isolated from the decomposed bodies of animals three months after death.

Treatment of Acute Nicotine Poisoning.—If the stomach has not been thoroughly evacuated by vomiting, it should be washed. Charcoal or permanganate should be administered. *Artificial respiration is the most important measure.* It should be instituted as soon as collapse appears, and prolonged until the peripheral muscular action of nicotine has worn off. Epinephrine may be injected if the heart has failed (Franke and Thomas, 1936).

Injections of formaldehyde and *methenamine derivatives*, especially iodomethylate of tetramethylene tetramine, effectively antagonize many of the nicotine actions, including the toxic effects on the heart, blood pressure and respiration, and on the isolated intestines (J. Gautrelet and Halpern, 1934; Corteggiani, 1935). Their clinical usefulness requires confirmation.

Related Alkaloids.—Several plants contain alkaloids closely related to nicotine and having similar actions:

Nicotiana sylvestris contains *nornicotine*, lacking the methyl group of nicotine. It has similar actions, but is less potent (P. S. Larson *et al.*, 1945). *Duboisia hopwoodii*, chewed by the natives of Australia, contains as its chief alkaloid *piturine*, which is *d-nornicotine*. Its actions are qualitatively identical with those of nicotine (C. E. Hicks *et al.*, 1935).

Anabasine, an isomer of nicotine, occurring in a weed of the pigweed family, perennial in northern Africa, Russia and Armenia, is identical with the synthetic *neonicotine*. Like nicotine, it first stimulates and then depresses autonomic ganglia, its potency being one-fifth to one-third that of nicotine. It also exerts the other actions of nicotine; for instance, on the respiration (H. B Haag, 1933; Anitschkow, 1935). As *insecticide*, it is cheaper than nicotine and more effective against aphides, but less effective against other insects.

Cytisine, an alkaloid of the ornamental Laburnum tree, resembles nicotine in its actions (Dale and Laidlaw, 1912), stimulating and then paralyzing autonomic ganglia, the sympathetic being more susceptible to it than to nicotine (Zachowski, 1938).

Caulophyllum contains methyl-cytisine, with similar actions; also volatile oil, a saponin (Lloyd's Leontin), and caulophyllosaponin (Power and Salway, 1913).

Pyridine, C_5H_5N, one of the nuclei of nicotine, is a strong local irritant with low toxicity; a 10 per cent solution has been used by atomizer in asthma and fetid bronchitis. It produces first dyspneic then shallow respiration. Brunton and Tunnicliffe (J. Physiol., *17:* 292) refer the effects mainly to sensory paralysis. Large doses arrest the heart. Smaller amounts stimulate the bone marrow to increased production of blood platelets (R. L. Lee and Minot, 1917). Its toxicity for man and animals was studied by L. J. Pollock *et al.*, 1943. *The inhalation of crude pyridine vapor* by cats, an hour daily for three to four months, resulted in pulmonary emphysema and chronic bronchitis and slight fatty infiltration of the liver and kidneys (H. Ludwig, 1936). *Derivatives of pyridine* were studied by de Caro, 1927, for relation of structure to muscle-nerve action.

Pyrrole, $(HC_2)_4NH$, the other nucleus of nicotine, has a low local and systemic toxicity. Its action and those of its alkyl ketones on frogs were studied by Rabbeno, 1929 and 1930. They cause tonic contraction of excised gastrocnemius muscle, passing into rigor and not affected by atropine or physostigmine. In mammals, pyrrole and its derivatives, pyrrolidine and pyrrolidone, give a *melanotic color* to the urine, and pyrrolidone produces temporary darkening of the fur of rabbits, disappearing again as excretion progresses (Sarcadi, 1922). *Intraperitoneal injection* of pyrrole into dogs results in epileptic seizures, with succession of aura and tonic and clonic convulsions, at first with lucid intervals between attacks. Death occurs by status epilepticus. These effects occur only if the pyrrole is absorbed by the portal system and are ascribed to liver injury. The brain shows pathologic changes (Rezek, 1937).

TOBACCO AS A HABIT-DRUG

Tobacco is smoked, chewed, snuffed, or rubbed on the gums ("dipped") for its tranquillizing and stabilizing effect on the psychic and emotional functions. The effects are due practically entirely to the nicotine. Tobacco smoke contains other toxic constituents, but their quantity is too small to be practically important. This has been proved both by chemical considerations and by animal experiments (Lee, 1908; K. B. Lehmann; van Leeuwen, 1918). In the habitual use of tobacco, a limited tolerance is acquired against the acute nauseant and emetic effects of nicotine, but it is confined to the quantity to which the individual is accustomed and does not extend to most of the other actions, nor to the total toxicity. When the tolerance has been acquired, the continued use of tobacco within the individual limit of tolerance does not cause unpleasant symptoms; but if the limit is exceeded, acute or chronic phenomena arise. They take many forms: especially local irritation of the respiratory tract; digestive and nutritional disturbances; functional cardiac arrhythmias; depression of various parts of the central nervous system; neuralgias; more rarely impairment of vision. Exceptionally, these may occur after a long period, some twenty years, of moderate use. When the habitual use has become firmly established, withdrawal or even limitation of the usual allowance, causes craving, discomfort and restlessness, as with other drug habits, but not as severe as with morphine. They are probably purely psychical, the absence of an accustomed emotional crutch, and pass their acme in about three days.

Historical.—Tobacco (Tábacum), the dried leaves of Nicotiana Tabacum, an herby plant belonging to the potato family, was probably indigenous to tropical America. It was smoked by the natives at the time of Columbus and was introduced into Spain and Portugal in 1559, and from there to France and Italy; into England in 1585, directly from America. Its use was at first combated by Church and State as an enslaving addiction. The opposition ceased when Richelieu in France and Charles I in England discovered its possibilities as a source of taxation (H. Beer, 1931). Tobacco was first cultivated by white men in Virginia in 1612; fifteen years later, 500,000 pounds of cultivated tobacco were shipped annually to England.

The *consumption of tobacco* increases considerably in periods of national restlessness and exhaustion. Before World War I, the annual world production was estimated as one and a half million tons; by 1920 it had increased to two and a half millions, and by 1929 perhaps three and three-fourths millions (Conte Corti). The consumption of cigarettes in the United States increased from eight and a half millions in 1910 to 190 trillions in 1941.

Tolerance and Habituation.—The quantitative effects of nicotine vary considerably in different persons. Similar variations are observable in animals. Children and adolescents appear more susceptible than adults, but there are no critical data for comparable conditions. The rapidity and completeness of the habituation also vary with individuals, depending partly on individual susceptibility, partly on the manner in which the drug is used, whether the smoke is inhaled, the saliva expectorated, and the like.

Wahl, 1920, found that nonhabituated men are nauseated by 1 or 2 mg. of nicotine, by mouth; tobacco users required more than 8 mg.

Habituation in Animals.—Edmunds, 1909, and others could not produce tolerance. Behrend and Thienes, 1933, also found that adult rats did not become tolerant, but young rats developed definite tolerance to minimal convulsive doses and to the conditioned salivation reflex, but not to minimal fatal doses. Hatcher, 1904, showed that the serum of habituated animals does not protect others against intoxication. Dixon and Lee, 1912, claimed that the liver of habituated animals destroys nicotine somewhat more rapidly. Edmunds, 1916, failed to confirm this.

Psychic Effects.—Habitual users of tobacco experience a certain pleasure, which appears to resolve itself into a reposeful, calming and stabilizing effect on their nervous equilibrium, provided that the quantity of the tobacco is not excessive; otherwise it may increase nervous excitability. *The stabilizing action* has been demonstrated objectively by the threshold to painful electric stimuli. Smoking leaves the normal threshold unaffected, but both excessive and defective irritability are brought toward normal, the effect being similar to that of rest (Mendenhall, 1925). In the same sense, smoking tends to nullify the sensory depression by analgesics and hypnotics (Hale and Grabfield, 1923).

Monkeys also "smoke tobacco with pleasure," and "have a strong taste for tea, coffee and spirituous liquors" (Charles Darwin, "Descent of Man," Chap. I).

The nicotine is not the only element in the enjoyment and tranquilization: the esthetic satisfaction of the aroma of the tobacco, the haze of the smoke and the reflexes from the mucous membrane of the mouth and nose also play a part. But a group of subjects, after becoming accustomed to hypodermic injection of 1.2 to 6 mg. of nicotine, preferred this to the smoking of a cigarette. They also obtained similar psychic effects from 4 mg. by mouth or 0.1 mg. by vein (L. M. Johnston, 1944). Habitual smokers obtain less satisfaction from cigarettes of low nicotine content (0.34 mg.) than from the same cigarettes enriched with nicotine to 1.96 mg. (J. K. Finnegan *et al.*, 1945).

Haggard and Greenburg, 1934, suggested that nicotine tranquilizes by restoring the *blood sugar level* in fasting; but this can not be significant, as the effect is the same after meals, when it does not raise the sugar level (D. L. Thomson, 1934).

The resultant of these actions on *efficiency* depends greatly on individual conditions, on temperament, fatigue, difficulty of the tasks, suggestion, etc., so that direct tests of efficiency have given discordant results. For instance, the speed and accuracy of arithmetic addition have been reported as increased (Berry, 1917), and as unaltered (Wahl, 1920). The sensation of fatigue and discomfort (including hunger) can be temporarily obscured, and a temporary extra spurt of effort secured; but whether the total performance is increased is an open question. Deprivation of tobacco induces in habitual users a condition of nervousness, analogous to the craving of the more serious drug habits, that interferes with work, especially with mental effort and concentration. Attempts have been made to evaluate the effects of tobacco by comparing the efficiency of groups of smokers and nonsmokers. Such studies generally show some superiority of the nonsmokers; for instance, in the endurance of telegraph workers (Baumberger and Martin, 1921); scholarship (E. L. Clark, 1900; Meylan, 1910); growth in youth (Seaver, 1897); resistance to tuberculosis (Flick, 1908). It has not been possible, however, to decide whether the apparent inferiority is the effect or the cause of the tobacco habit: those who are handicapped by inferiority naturally feel the greatest need for, and succumb most readily to, the euphoria of smoking.

Effect on *Muscular Work.*—Baumberger *et al.*, 1921, found that habitual smoking (outside of working hours) did not appear to affect the work output of glassblowers, who require strenuous physical dexterity. Chewing during the work appeared to impair the output (perhaps by a slight curare action?). With the ergograph, Palmen, 1911, found that cigarette smoke at first increased the *muscular work*, but that fatigue set in sooner and the total activity was decreased.

Local Effects.—The nicotine and other basic constituents of the smoke act as fairly strong irritants, as shown by the biting sensation on the tongue, noted especially when the smoke is concentrated on one point, as in pipe smoking, and by the watering of the *eyes* when they are touched by the smoke. The constant irritation of the mucous membrane of the mouth, throat and pharynx leads to *catarrh* and hoarseness. The tar of cigarette smoke is chiefly responsible for these effects (W. D. McNally, 1932). Cigarette smoke also depresses the effectiveness of the tracheal *cilia*, averaging 40 per cent. This is not proportional to the nicotine content and is especially marked with mentholated cigarettes (W. L. Mendenhall and Shreeve, 1937, 1940). Appleton and Lehmer, 1928, reported that cigarette smoking diminishes the *mouth bacteria*, but the decrease is temporary and not impressive.

Long-continued irritation by carcinogenic constituents of the tar (Roffo, 1939) appears to favor development of *epithelioma* of the lip and tongue, if the quantity consumed is large or the smoker specially disposed.

Chewing of tobacco also appears to be an etiologic factor in oral cancer, starting with leukoplakic changes of the cheek where the cud is held (Friedell and Rosenthal, 1941). Tobacco tar produces papillomas when painted daily for three months on the skin of rabbits. This is exceptional with tar of denicotinized tobacco (C. M. Flory, 1941). Nicotine as such is not concerned in tumor production in rabbits (A. H. Roffo, 1941).

Acute Circulatory Effects of Smoking Tobacco.—*In unhabituated individuals*, or when the customary amount is exceeded, there is a brief and moderate rise of blood pressure, succeeded by considerable fall when the nausea-collapse sets in. The pulse rate quickens as much as 20 per minute. The cardiac output is considerably increased (Grollman, 1930). *Experienced smokers*, when they remain within their customary limits, show no demonstrable change in blood pressure (or slight rise, Lee, 1908), or cardiac output, and slight or no increase of pulse rate (Grollman, 1930). Lowering and inversion of the T wave of the electrocardiogram occur after smoking in about a third of the subjects (Graybill *et al.*, 1938). It is commonly believed that excessive smoking causes "shortness of breath," but the concept is indefinite and difficult to establish.

Definite and prompt *cutaneous vasoconstriction* can be demonstrated, in experienced as well as inexperienced smokers, by lowering of the skin temperature (Maddock and Coller, 1933), and by microscopic observation of the nailfold (I. S. Wright and Moffet, 1934).

It occurs even with a single cigarette, is more pronounced with inhalation of the smoke and lasts half an hour after the smoking. The vascular response to smoking is generally parallel to the response to cold (E. A. Hines and Roth, 1938). It is most pronounced in healthy young adults (Cates and Giovanaszzi, 1939). It is confined largely to the skin, so that the blood flow through the arm is not decreased (Abramson). It is due chiefly to the deeper inspirations and occurs also with denicotinized or cornsilk cigarettes, or with puffing an unlighted cigarette (Mulinos and Schulman, 1940; F. E. Franke and Hertzman, 1940; W. F. Evans and Stewart, 1943). However, G. M. Roth *et al.*, 1944, claim that all the circulatory effects of smoking two cigarettes, by habitual smokers, are duplicated by intravenous injection of 2 mg. of nicotine and not by smoking cornsilk cigarettes.

J. Parkinson, 1917, studied the immediate circulatory response to the smoke of four or five cigarettes in normal subjects and those with "*soldier's heart.*" All the subjects who "inhaled" the smoke showed effects, which were generally greater in the patients with circulatory instability. The response consisted in increased pulse rate, averaging nine beats in the patients, and slight rise of blood pressure, 5 to 10 mm., systolic, 5 mm. diastolic. Respiration was unaffected, but exertion easily rendered the subjects "breathless." W. G. Thompson and Sheldon, 1917, investigated the acute effects of smoking in *patients with high blood pressure.* The response differed greatly: the maximum effects ranged from a rise in systolic pressure of 25 mm. and in pulse pressure of 22 mm. to a fall in systolic pressure of 30 mm. and in pulse pressure of 34 mm. Rise, fall and no effect were about equally numerous, and varied even in the same patient. There was no difference between cigars and cigarettes. Nicolai and Staehelin, 1910, found that in tobacco users the heart rate averaged somewhat higher, especially in work; no definite changes could be made out in the systolic and diastolic blood pressure or electrocardiograms.

In *animals* the effect of tobacco smoke on the circulation is identical with that of nicotine, showing that this is indeed the active agent.

In *intact mammals*, there is a brief fall, then a high rise of blood pressure. The heart is slowed, then quickened. Cardiac disturbances appear, especially auricular fibrillation, and these are antagonized by formaldehyde compounds, as is nicotine (Hendrikson, 1930; Tournade and Malmejac, 1930; J. F. Johnson and Winder, 1942.) The electrocardiographic changes are the same as with nicotine (Mattioli, 1932). *Perfusion of excised heart* (rabbit's) with Ringer's solution through which tobacco smoke had been passed produced the typical nicotine effects on perfusions through excised rabbit's heart, *i. e.*, temporary vagus standstill. Prolonged perfusion, however, leads to permanent arrest, due not to the nicotine, but to collidine and other bases that occur in the smoke of tobacco or other leaves, for instance, oak (Clerc and Pezzi, 1914). In *heart-lung preparations* (dog) tobacco smoke produced complete nicotine paralysis of the vagus. The rhythm of the denervated heart was not changed. The *coronary vessels* were dilated both by smoke and by nicotine. Direct effects on the myocardium occurred only with amounts far above those of ordinary smoking (Mansfield and Hecht, 1933).

Delayed functional cardiac disturbances are common. The first warning symptoms are occasional palpitation, quickened heart rate and functional arrhythmia. These become persistent if the nicotine is continued, but disappear on withdrawal. In advanced cases, the abstinence must be continued for months. The arrhythmia is due to extrasystoles, pointing to increased irritability of the cardiac structures. The extrasystoles are usually auricular. Auricular fibrillation and "flutter," and sino-auricular block have been encountered (Neuhof, 1916). The block disappeared within three days after stopping the tobacco. In graver cases, the cardiac irregularity may lead to sudden fainting (*syncope*). *Respiratory distress* accompanies the marked cardiac phenomena.

Functional extrasystoles occur also after coffee, digitalis, quinidine, salicylates and in acute infections and neurasthenia. They are less frequent when the heart rate is above 120, and may therefore be suppressed by exercise and fever (M. Campbell, 1929).

The cardiac disturbances may cause precardial pain and hyperesthesia, which may radiate to the left nipple and ulnar surface of the left arm. Nicotine has little if any causative relation to *angina pectoris*, for all statistical studies confirm that the proportion of heavy, light and moderate smokers is not materially different for patients who develop angina, and for a comparable group of the general population. But a developed angina may be exaggerated by smoking (just as ordinary physical exercise does not produce angina, but in angina the exercise provokes the attack). Patients with developed angina, therefore, tend to smoke less because they are afraid of nicotine (P. D. White and Sharber, 1934).

Coronary ligation in animals renders the heart hypersusceptible to nicotine electrocardiogram disturbance. The exaggerated response diminishes with time (Bellet Kershbaum *et al.*, 1941).

The question as to *arteriosclerosis* is not clear. Statistics indicate that patients with *thrombo-angiitis obliterans* are nearly always heavy smokers (B. Weicker, 1940). The incidence of arteriosclerosis obliterans in diabetes mellitus is nearly twice as great in smokers as in nonsmokers. The statistics show no significant difference between light and heavy smokers (Weinroth and Herzstein, 1946). When the vessels are diseased, as in endarteritis obliterans and in coronary disease, the acute vasoconstrictor action of nicotine would tend to interfere with the collateral supply (Maddock, Malcolm and Coller, 1936).

In rabbits, chronic nicotine poisoning produces anatomic arterial and cardiac changes, similar to those of epinephrine (Adler, 1914). Lissauer, 1914, also described histologic changes in the cardiac and other ganglion cells. It may be doubted whether these results should be transferred to man.

Experimental Endarteritis.—M. Friedlander, Silbert and Laskey, 1936, report the production of arterial changes by injection of tobacco into male rats, while female rats failed to develop them. Other investigators have been generally unsuccessful in producing vascular damage in rats or rabbits, even when convulsant doses of nicotine were injected twice daily for two to six months (Thienes, Behrendt *et al.*, 1937).

Acute Effects of Smoking on the Gastro-Intestinal Tract.—In those who are not accustomed to tobacco, or who exceed their accustomed quantity, it produces the nausea, emesis and diarrhea discussed under nicotine. With experienced users, the smoking of one to three cigarettes, or hypodermic injection of 0.4 mg. of nicotine, generally causes some increase of saliva (reflexly), and depression or inhibition of the hunger contractions (Carlson and Lewis, 1914), also reflexly; but significant gastric retention or increase of gastric acidity is exceptional. The motility of the colon is generally increased. There is little if any effect on the secretion of gastric juice and bile. If the tolerated dose is exceeded, undesirable effects set in, and patients with gastric ulcer and colon disturbances should be cautioned against excess (Schnedorf and Ivy, 1939). *Intestinal motility* is increased by cigar or cigarette smoke, both in those accustomed and in those who are not. The effect begins in a few minutes and lasts for half an hour to an hour after the smoking is stopped (Simici and Popesco, 1936). H. Rosenblum, 1938, reports that a single cigarette may increase the volume and acidity of gastric juice, especially with gastric ulcer patients.

Chronic Digestive and Nutritional Disturbances.—Various forms of "nervous dyspepsia" develop fairly early with continued excessive smoking. They include loss of appetite, hyperchlorhydria, alternating constipation and diarrhea, loss of weight and anemia. They are due partly to the local irritation of nicotine and tar, partly to degenerative cellular changes and partly to the nervous irritability.

Ingestion of tobacco tar by rats in nontoxic dose for periods up to two years produced gastric lesions in half of the animals. They involved especially the glandular zone, beginning with hemorrhagic ulceration, progressing to rodent ulcer, and after a year to carcinoma (Roffo, 1941).

A direct action upon *hematopoiesis* may have a part in the anemia, the continued administration of nicotine to animals leading to diminution of red corpuscles, and increase of leukocytes. It is also claimed that it diminishes the oxygenating power of hemoglobin.

Salivary Glands.—The amylolytic activity of the saliva may be completely lost, with histologic changes in the glands. They may recover in time, after withdrawal (Bosco, 1930).

Metabolism.—Changes of basal metabolic rate on smoking are inconstant, small, and in both directions (Goddard and Voss, 1942). There are no significant effects on the respiratory quotient, nor on the blood sugar (see below) or blood lactic acid (A. B. Dill *et al.*, 1934). With habitual smoking, the nitrogen excretion may be rather more diminished than the assimilation, so that there may be a gain in body nitrogen. Transitory albuminuria may occur. The *organ weights* of rats do not show significant changes on nicotine feeding, if they are compared with controls of equally restricted food income; nor do the viscera show histological changes (R. H. Wilson *et al.*, 1938).

Blood Sugar Level.—Smoking has little effect on the normal level, but raises the fasting level (0.08 to 0.1 per cent) to normal (0.12 to 0.14 per cent), and the fasting respiratory quotient from 78–82 to 85–90, presumably by increasing the epinephrine output. It returns to the fasting level in about half an hour (H. W. Haggard and Greenburg, 1934; Burstein and Goldenberg, 1928). The rise of the blood sugar is more marked in *diabetic patients*, amounting to 0.4 to 0.5 per cent (Caponnetto, 1928).

Nervous Disturbances.—Excessive use of tobacco may induce headache, insomnia, anxiety, irritability of temper, tremors, heightened reflexes, neuralgias, vertigo, sometime mental slowness and lethargy.

Other effects which have been attributed to nicotine but with insufficient cause are: impotence, epilepsy and insanity (G. W. Jacoby, 1898; Naecke, 1909).

Nicotine blindness is rare. It seems to be favored by alcoholism. This, and the associated thiamine deficiency, may be the real cause. The sight gradually becomes dim, with central scotoma, impaired accommodation and often miosis. It is always bilateral. The anatomic changes consist in retrobulbar optic neuritis, with subsequent atrophy. Until degeneration has set in, a complete cure can usually be effected by abstaining from nicotine; later, this will only arrest the further progress (de Schweinitz, 1896). The amblyopia has been attributed to vasoconstriction. Vasodilators (sodium nitrite, acetylcholine) are reported to hasten the recovery of vision (Pfimlin, 1930; W. F. Duggan, 1935, 1937).

Other Toxic Amblyopias.—Many poisons may produce blindness, temporary or permanent, in susceptible individuals, especially on continued administration. This has been recorded for stramonium, cannabis, chloroform, opiates, carbon disulfide, arsenic, lead, iodoform, aspidium, quinine, salicyl, methyl alcohol, and the like. For most of these the changes are analogous to those of nicotine. With methyl alcohol, quinine and salicyl, the retinal ganglion cells are also involved. The metals and aspidium may produce primary optic atrophy without preceding neuritis (de Schweinitz, 1896 and 1902).

Female Sexual Functions.—There is no evidence that these are injured by smoking. During lactation, insignificant traces of nicotine pass into the milk.

Feeding diets with 0.025 per cent of nicotine to female rats alters the *estrus cycle*, probably as a result of the gastro-intestinal disturbance (R. H. Wilson and DeEds, 1937). Behrendt and Thienes, 1932, obtained no disturbance of the estrus cycle, or of skeletal growth. *Toxic doses* (0.1 mg. per Kg.) administered to rats daily for a month tend to prevent pregnancy, or the young die early. This has been attributed to catarrhal inflammation of the uterus and tubes. The ovaries appear normal (Sodano, 1934). *Injection of subconvulsive doses* into rats, twice daily for six to twelve months, decreases fertility, and the progeny are also less fertile than those from unpoisoned parents (Thienes, Lombard *et al.*, 1946).

Longevity.—R. Pearl, 1938, finds that statistics show a significant deleterious correlation with the amount of smoking: Starting with the age of thirty years, 81 per cent of nonsmokers survive to the age of fifty; 78 per cent of moderate smokers, and 63 per cent of heavy smokers. But those who are reckless with tobacco are likely to be careless of health in other respects.

Treatment of Nicotine Addiction.—The catalogue of injurious actions to be charged against the abuse of this drug is large; but it must be noted that these are absent with moderate use, and can be abolished if the use of the drug is promptly limited on their first appearance. Actual withdrawal is not always necessary. Limitation in quantity, sufficient expectoration and the avoidance of deep inhalation of the smoke may suffice. Quick total withdrawal does not lead to serious abstinence symptoms, as with morphine (except possibly in some neurotic subjects), although it may disturb the function of the bowels for a few days. The principal point in the treatment is to keep the patients' thought off the topic of tobacco, and to supply the accustomed stimulus to the mouth in some other manner, as by chewing ginger or gentian. The use of tobacco should be avoided or restricted in pathologic conditions in which there are special contraindications to it—in heart and vascular disease, dyspepsia, inflammation of the respiratory tract, and so forth.

Other Active Constituents of Tobacco Smoke.—Nicotine alone is responsible for the systemic effects of tobacco smoke; the effects on animals and organs, on the heart, blood pressure, respiration, striped muscle and others agree qualitatively and quantitatively. Other active substances are formed in the combustion, but their quantity is too small to be significant. Nor is there any foundation for the popular notion that commercial cigarettes contain opium or other narcotics (Thurston, 1915).

Other toxic combustion products vary considerably according to conditions. Lee found in the smoke of 100 Gm. of tobacco, besides 1.165 Gm. of nicotine, the following: pyridine bases, 0.146 Gm., chiefly pyridine and collidine; hydrocyanic acid, 0.08 Gm.; ammonia, 0.36 Gm.; CO, 410 cc. *Carbon monoxide* is the most abundant of the toxic constituents of tobacco smoke, aside from nicotine; but Haggard and Greenberg, 1934, state that a person walking on a street with heavy automobile traffic would show a higher percentage of CO hemoglobin than after heavy smoking. Even when many persons smoke in a confined atmosphere, the CO of the air would not rise to more than $\frac{1}{100}$ per cent, and at most 5 per cent of the hemoglobin would be bound to carbon monoxide, according to the U. S. Bureau of Mines. The *hydrocyanic acid* in the smoke of a cigar amounts to only 0.002 to 0.5 mg., and would have no significance (Lehmann and Gundemann, 1912). The quantity of the *pyridine bases* is so small that the amount formed from a dozen cigars would not be materially toxic (Lehmann, Arch. J. Hyg., *68:* 319. The paper describes the separation of nicotine from its decomposition products). The *volatile oils*, which constitute the aroma of the tobacco, are practically inactive. *Menthol cigarettes* are ordinary cigarettes made from tobacco sprayed with a menthol solution. *Arsenic* is sometimes present in harmful quantities when Paris green has been used on the plant as an insecticide. *Free ammonia*, about a third as much as nicotine, is present at the burning end, which is therefore alkaline, but it is bound in passing through the tobacco, and the smoke which reaches the mouth is acid (Bailey and Petre, 1937). Cigarette smoke also contains *aldehyde* and *furfurol*, especially with American tobacco, but the amount is probably not sufficient to be materially irritant, for irritation also occurs when these are low (Bogen).

Acrolein may be formed from the combustion of the glycerol generally added to cigarette tobacco as a hygroscopic agent. Mulinos and Osborne, 1934, reported animal experiments, and F. B. Flinn clinical observations, to show that this is responsible for the acute local irritation, and that the latter was much less for cigarettes moistened with diethylene glycol. With more exact quantitative comparisons, however, H. B. Haag, 1937, and Holck and Carlson, 1937, found that the presence of glycerol in cigarettes did not render their smoke more irritant. *Cigarette paper* does not form toxic combustion products (Wenusch and Schoeller, 1938).

The **nicotine content of tobaccos** ranges between 1 and 8 per cent of the dried leaf. In Havana and Maryland, 1.5 to 3; Virginia and Kentucky, 6 to 8; South American, 2 to 6; German, 1.5 to 3. A number of other alkaloids have been announced to exist in small amount in tobacco (Pictet and Rotschy, 1901), and there is a volatile oil developed in drying and "sweating." The dried leaves were formerly official, but are now obsolete in medicine; if used, an infusion may be made. The dose was given as 0.5 Gm. *Commercial tobaccos packaged for consumption* contain the nicotine median and range shown in the following table (E. M. Bailey, Noland and Mathis, 1928). This also gives the figures for the so-called (and miscalled) "denicotinized" tobaccos:

	Ordinary Brands (Percentage)	*"Denicotinized" Brands (Percentage)*
Pipe tobaccos....	1.95 (1.45–2.84)	0.98 (0.97–2.26)
Cigars..........	1.38 (0.91–1.80)	0.91 (0.67–1.54)
Chewing tobaccos	1.90 (1.06–3.11)	0.95 (0.95–2.10)

Snuff contains 0.29 to 1.17 per cent of nicotine; the daily consumption by confirmed users furnishes 20 to 60 mg. of nicotine (D. Goede, 1944).

The nicotine percentage of American brands of *cigarettes* is given by Bogen, 1929, as

	Percentage
Domestic............................	average 2.5
Blends............................	1.5 –2.5
Oriental............................	1.25–1.5
West Indies	1
"Denicotinized".....................	0.9 –1.4*

* The last figure from C. F. Bailey and Petre, 1937.

Denicotinization.—The methods of removing nicotine from tobaccos spoil its aroma (Storm van Leeuwen, 1918), and the commercial brands do not carry the process far enough to make a significant difference in the effects. Clinically, the stimulation of gastric secretion in hyperchlorhydria is not suppressed (Bernay and Faure, 1937). A small wad of loose cotton in the holder filters out about half of the nicotine, and is quite as efficient as any of the commercial devices, which aim to fix the nicotine by tannic acid or ferric chloride (H. Beer, 1931).

Nicotine Content of Tobacco Smoke.—Not all the nicotine passes into the smoke; a part is burned, depending on the dryness of the tobacco, and another part is condensed in the stub or pipe stem, depending on the length of these. Not all that passes into the smoke is aspirated, a part going into the air between aspirations, depending on the rapidity of smoking; and not all that is inspired is absorbed, a part being expired, depending largely on the depth of the inhalation.

Nicotine exists in tobacco mainly in the form of salts of organic acids (Garner, 1908), especially as acid malate and citrate (Kissling). By the heat of smoking, these are largely dissociated, part of the nicotine being burned and part passing into the smoke as free nicotine (Lehmann, 1909).

Moisture.—The drier the tobacco and the greater the heat, the less nicotine will escape destruction. Moist tobacco, especially cigars, therefore, produce severer effects. This is more important than the nicotine content of the original tobacco (Lee, 1908). The smoke of a moist cigar contains 50 to 75 per cent more nicotine than with the same tobacco in a dry cigar (Heinz), but generally 84 per cent or more of the nicotine of a cigar passes into the smoke. With cigarettes, practically all the nicotine may pass into the smoke, without oxidation or decomposition (Nagy, 1932), presumably because their looser texture facilitates aspiration.

Condensor Effect of the Stub.—As a cigar or cigarette is smoked, the stub becomes much richer in nicotine (three or four times, Lehmann), as well as in tar, for these are condensed there in large degree by the cooling and the filtration of the condensed droplets. The temperature of the smoke falls to that of the room when it has passed through half the length of a cigarette; that of a short stub may rise to 60° C., 140° F. Consequently, the smoke becomes progressively richer in nicotine as the stub shortens. If not more than two-thirds of a cigarette is smoked, about two-thirds of the nicotine and tar is retained by the stub (Malinos and Cockrill, 1938). Winterstein and Aronson found 24.5 mg. of nicotine in the smoke from the first third of a cigar, 29 mg. from the middle third and 46 mg. from the last third. C. O. Jensen and Haley, 1935, recovered 6 per cent of the nicotine of cigarettes from the smoke if four-sevenths of the length was smoked; 11.5 per cent if five-sevenths was smoked, and 17.5 per cent if six-sevenths was smoked.

The *speed of smoking* increases the amount of smoke inhaled, as compared with that which escapes directly in the air from the burning end. For instance, Bogen, 1929, found that when a cigarette was smoked to two-thirds of its length in ten minutes, 0.2 mg. of nicotine was inhaled and 9 mg. escaped; if smoked in five minutes, 2 mg. were inhaled and 4 mg. escaped; if smoked in two minutes, 6.5 mg. were inhaled and 1.5 mg. escaped. *Inhaling smokers* absorb and excrete about ten times as much nicotine as do those who do not inhale (Haag and Larson, 1942).

The preceding data are based on chemical methods which do not actually identify the nicotine. This may be done quantitatively by the blood pressure rise produced by solution of the smoke. By this means, and with intermittent smoking, cigar smoke contains 160 to 425 mg. of nicotine per 100 Gm. of cigar consumed. "Light" and "heavy" cigars do not show constant differences. So-called "nicotine-free" cigars yield as much nicotine in the smoke as ordinary tobacco (Storm van Leeuwen, 1918).

Absorption of Nicotine from Tobacco Smoke.—With ordinary smoking of cigarettes, a fifth to a third of the aspirated nicotine is fanned out with the expired air. The remainder, 60 to 80 per cent, is absorbed chiefly from the dorsum of the tongue. Of the smoke inhaled, the absorption amounts to 93 to 95 per cent (Bodnár *et al.*, 1935; I H. Pierce, 1937).

Under average conditions, the amount of nicotine which enters the mouth in smoking a cigarette (leaving a stub) ranges from 1.8 to 8.5 mg. *The amount absorbed*, with ordinary smoking, ranges from 1.4 to 3.3 mg.; and with inhalation, 1.7 to 8 mg. (Asherton, 1919; Bodnár *et al.*, 1935; I. H. Pierce, 1937). *Deep inhalation* therefore secures stronger nicotine action, and may render cigarettes more harmful than other forms of smoking.

◆

LOBELIA AND LOBELINE

The herb Lobelia inflata was used by the American Indians as a substitute for tobacco. It was introduced into medicine by Samuel Thompson about the beginning of the nineteenth century as the main basis of his peculiar system of treatment. The chief constituent is the alkaloid *lobeline* with actions closely resembling those of nicotine (Edmunds, 1904). A brand of this alkaloid, "*alpha lobeline*," has been recommended for emergency respiratory stimulation, but safe doses are not reliable and effective doses are not safe. Clinically, the stimulation is transient (at most half an hour), and is often complicated by nausea and vomiting, sometimes with severe collapse and Cheyne-Stokes respiration (Norris and Weiss, 1927; W. R. Marshall, 1928). Large doses are convulsant. There are also two other alkaloids (B base and lobelidine) with apparently identical but somewhat weaker actions.

Oral administration of lobelia has also been employed in respiratory affections, especially in chronic emphysema, spasmodic croup and spasmodic bronchitis. It is a nauseant expectorant, but deranges digestion. As emetic it is effective, but not sufficiently safe.

Respiration and Circulation.—In animals, *intramuscular injection* of lobeline, 0.5 to 5 mg. per Kg., results in marked increase of respiration, slowing of the heart and rise of blood pressure (Van Leeuwen, 1917). These effects are analogous to those of nicotine, and are caused chiefly by reflexes from the carotid body. Large doses involve the centers directly (Heymanns *et al.*, 1932; Comroe, 1938; C. F. Schmidt and Comroe, 1940). Cisternal injection also causes powerful stimulation of the respiration (Janossy, 1925). *Intravenous injection* (clinically, 1.5 to 3 mg.) produces immediate stimulation of the respiration, but also strangulation, coughing and intestinal contraction (Frankati, 1929). Large doses produce convulsions and paralyze the respiratory center and the cardiac muscle (Muto and Iwakawa, 1910).

Efficiency in Respiratory Depression.—In *animals*, large doses of lobeline (2 to 5 mg. per Kg.) overcome the respiratory depression of morphine, though somewhat less effectively that of the aliphatic narcotics (Wieland and Mayer, 1922). The response, however, is not certain (Meissner, 1923). The stimulation passes off within half an hour, and the narcotic depression returns, complicated by the depressant effects of lobeline (R. G. Smith, 1928). *Clinically*, successful results have been reported against depressant poisons (morphine, hypnotics) and in pneumonia, laryngeal stenosis, asphyxia of the newborn, and the like (Eckstein, Rominger and Wieland, 1921, and others). The maximum hypodermic dose of the crystallized ("alpha") lobeline is 10 mg. for adults, 3 mg. for children, which is considerably smaller than the doses found necessary in animals, justifying doubt as to the interpretation. The dangers have been mentioned. Intravenous injection has been used, with one-third of the hypodermic dosage, but Wieland and Mayer warn against this.

The bronchial muscle responds to lobeline with slight initial constriction in living cats (Curtis and Wright, 1926). It has no direct effect on excised bronchi, but prevents contraction by pilocarpine, acetylcholine and arecoline (Björkman, 1926).

Excised Intestines of Rabbits.—Small doses of alpha lobeline produce transitory increase of tonus and amplitude, followed by depression and, with large doses, by paralysis (Antal and Gömöri, 1927).

Lobeline against Tobacco Habit.—J. L. Dorsey, 1936, recommended oral administration of lobeline sulfate (8 mg. in capsule), whenever the desire to smoke is experienced. The intense nausea would generally discourage smoking, but it often proceeds to gastric distress, vomiting and circulatory disturbances, too drastic to render the treatment advisable (I. S. Wright and Littauer, 1937).

Poisoning.—The symptoms are often alarming but rarely dangerous, because emesis nearly always occurs. Many of the specimens of the dried drug are almost inactive. Poisoning is treated by gastric lavage and stimulants.

CONIUM

Conium or "Water-Hemlock," an Umbelliferous herb, contains a number of alkaloids, of which *coniine* is the most important. This is dextro-x-propyl piperidine, and was the first alkaloid synthesized. Children are sometimes poisoned by eating the root. The juice is believed to have been the poison administered to Socrates. It was introduced into medicine by Stoerck, 1770, but is now practically obsolete. It was used as sedative and antispasmodic in chorea, mania, convulsions, whooping cough and asthma; and locally in hemorrhoids and other anal lesions. Its peripheral actions are similar to those of nicotine, but it produces more pronounced paralysis of the central nervous system and of the skeletal muscle nerve endings. Poisoning is treated by tannic acid, evacuation and stimulants. Its actions on the *excised intestines* are also similar to those of nicotine (Ikeda, 1916). It produces initial stimulation and subsequent depression of the *autonomic ganglia*, abolishing the response to cardiac vagus stimulation and the pressor response to nicotine (Linegar *et al.*, 1943). These effects are also produced by piperidine. Dimethyl piperidines depress without stimulation, and do not contract skeletal muscle, as do piperidine and conessine (Koppanyi and Vivino, 1946).

Lupines have some importance as poisons of grazing stock. They contain bitter alkaloids, one of which appears to be related to coniine (C. D. Marsh *et al.*, 1916).

◆

LATHYRISM

The eating of the peas of Lathyrus produces in man paralysis of the legs which may be permanent if the consumption is continued (Stockman, 1917). Small local outbreaks have occurred frequently in southern Europe (Stockman, 1929), and in east India, where these peas constitute a third to half the diet during two or three months (T. C. M. Young, 1927). The pea contains small quantities of two active alkaloids with identical central effects: motor paralysis, apparently cerebral; increase, then decrease, of spinal reflexes. Both weaken the heart. One also produces a curaroid effect on skeletal muscle endings (Dilling, 1920). Acton and Chopra, 1925, attribute lathyrism to amine bases.

Similar effects are produced by other legume seeds, including lentils and ordinary peas, when they are eaten in large quantities or when purified extracts are injected hypodermically. The poisonous principle is apparently identical, an acid. It produces degeneration of nerve cells and fibers in the brain and spinal cord. Small doses are stimulant; larger, narcotic, similar to opium, coca and tobacco (Stockman, 1931).

Sweet peas (Lath. odoratus) produce lathyrism when liberal quantities are added to the diet of rats. The toxic factor is extractable by boiling water and is not destroyed by prolonged cooking (B. Y. Geiger *et al.*, 1933).

Favism is a clinical syndrome caused by the ingestion of the seeds or "broad bean," *Vicia fava*, occurring chiefly in Sardinia, Sicily and Calabria. It consists in sudden hemolytic attack, the red count falling to 1,000,000 to 2,000,000, with marked leukocytosis, followed by hemoglobinuria and jaundice. The attack lasts two to six days and is rarely fatal, except in children. Autopsies show intense reaction of the reticulo-endothelial system, hyperplasia of the bone marrow and acute swelling of the spleen. The picture resembles that of quinine hemolysis. Passive transfer tests indicate allergy with sensitization by milk (A. A. Luisada, 1941).

◆

GELSEMIUM

This, the root of Yellow Jasmine, acts similarly to nicotine and coniine. Its central depressant action is more marked (Cushny, 1892). It contains a crystalline alkaloid, *gelsemine*, with weak strychnine action; and several amorphous alkaloids, *gelseminine* and *gelsemoidine* (C. W. Moore, 1910; Sayre, 1910 and 1912; Sayre and Chillingworth, 1914), which are chiefly responsible for the effects of the drug. "Gelseminine" Merck has been shown to consist of gelsemine. Stevenson and Sayre, 1915, describe a further alkaloid, "sempervirine."

The actions of *gelsemine* and *dihydrogelsemine* are quantitatively similar. They relax the rabbit intestine and contract rabbit uterus (F. G. Henderson and Chen, 1943). Gelsemine produces a sharp vasodilator fall of blood pressure on intravenous, but not on intramuscular, injection. It abolishes the response to electric stimulation of the cardiac vagus and the vasodepressive response to acetylcholine. It does not abolish the pressor response to nicotine (Linegar *et al.*, 1943). It produces reversible depression of the excised *heart* of frogs. This is antagonized by barium or epinephrine, not by atropine (Moisset de Espomes, 1938). *Gelseminine* depresses the tonus and contractions of excised intestine (Ikeda, 1916). On intravenous injection of *gelsemicine* there is a latent period of three to thirty-five minutes, followed by depression of the motor neurons of the brain and spinal cord, resulting in respiratory arrest. The vagus is not affected, but sympathetic stimulation is suggested by mydriasis, intestinal relaxation and uterine stimulation (K. K. Chen and Chou, 1939).

Therapeutic Uses.—Gelsemium (1 to 10 drops of the fluidextract) is employed in neuralgic conditions, especially trigeminal neuralgia, nervous headaches, cerebral hyperemia and hysteria. There is no pharmacologic explanation of these uses. Its local application to the eye dilates the pupil, but produces considerable irritation (Putzeys and Romie, 1887). It is no longer used as a mydriatic.

Toxic Effects.—Small doses sometimes cause toxic symptoms, which may be delayed for hours. The warning signs are ptosis, double vision, dilated pupils, weakness and depression. Fatal doses produce slowing and arrest of the respiration. A drachm of the fluidextract is said sometimes to cause death, and 30 minims are dangerous. Poisoning is *treated* by evacuation, atropine and stimulants. The *standardization* is discussed by Pittenger, 1923.

◆

SPARTEINE

This alkaloid, isolated from Scoparius (Broom top), has been used to slow the pulse in cardiac disturbances, but its effects are uncertain, it weakens the heart, and can not take the place of digitalis.

Sparteine is a pyridine derivative, like nicotine and coniine, and has similar actions (Fick, 1873). Its central effects are slight and its toxicity relatively low (Griffé, 1886, took 0.4 Gm. without bad effects, except slight confusion). It has no direct action on the vasomotor center, but the depression of respiration tends to produce asphyxial stimulation (Pilcher and Sollmann, 1915). Peripherally, it has a fairly strong curare action, arresting respiration by paralyzing the phrenic endings (Cushny and Matthews, 1895). Larger doses also paralyze the respiratory center (Muto and Ishizaka, 1903). Like coniine and piperidine, it depresses autonomic ganglia, abolishing the response to cardiac vagus stimulation and the pressor response to nicotine; it intensifies the pressor response to epinephrine (Linegar *et al.*, 1943). It has a weak local anesthetic effect (Guinard and Geley, 1894). No habituation could be induced in guinea pigs (Dorlencourt, 1913).

Uses.—Sparteine was recommended by Sée, 1885, in cardiac disease, valvular and functional, nervous palpitation, Graves' disease, asthma, and the like. Clarke, 1887, claimed that it produces marked slowing and strengthening of the pulse, the effect appearing in thirty minutes and lasting for five to six hours. Probably most clinicians consider it useless (Leo, 1887). It is devoid of the cardiac tonic action of digitalis, and without this the slowing would be of little value. The influence of drugs on functional cardiac neuroses is difficult to judge.

Circulation.—The experimental data on mammals are variable and confusing. *Small doses* produce peripheral vagus paralysis (Fick and all subsequent workers). This may sometimes result in preliminary quickening of the pulse (Gluzinski, 1889) and removal of vagus arrhythmias (Masius, 1887) and of acetylcholine slowing (Mercier and Hamet, 1931). The vascular effects of acetylcholine are also inverted and potassium actions are reinforced (Hazard, 1939). *Full doses* generally cause slowing and irregularity of the heart. The slowing increases the amplitude of the excursions, but the tendency of the heart is diastolic, in contrast to digitalis (Cushny and Matthews). With intravenous injection, the slowing becomes so extreme that it may be fatal; but this extreme action is of short duration, does not occur on oral administration and is probably due to direct irritation of the endocardium. The *slowing and arrhythmia* with ordinary doses appear to be due to direct depression of the cardiac muscle: They are not prevented by atropine; and electrocardiograms of *excised mammalian hearts* show that sparteine invariably checks the function in all directions (Sakal, 1919). The *frog heart* is stimulated by dilute and depressed by more concentrated solutions, but the effects are slight if the salts of the perfusing solution are properly balanced (Barridge and Seth, 1928).

The *blood pressure* falls progressively, owing to the cardiac depression. The intraventricular pressure is lowered in dogs, and the kidney volume decreases (Duvillier *et al.*, 1922). Perfused ear vessels and coronaries of rabbits are constricted (Romm and Krister, 1931). Cow, 1911, reports that excised arteries are dilated. Rise of blood pressure is sometimes seen (Cerna, 1894), probably due to asphyxia. Sparteine does not antagonize the hypotensive effect of acetycholine (Mercier and Hamet, 1931).

Sensitization to Epinephrine.—Sparteine prolongs the hypertensive effect of epinephrine and tends to restore it when it has been abolished by yohimbine. The mechanism is not clear (R. Hazard, 1932, 1933). Similar "disinversion" is produced by pituitrin (Frohlich and Pick, 1913; Hamet, 1934) and by ephedrine (Hazard and Wurmser, 1935).

Vasoconstrictor Constituent of Scoparius.—Burquet and Vischniac, 1931, reported the production of vasoconstriction of extracts of scoparius, devoid of alkaloids or glucosides.

The **diuretic effect** has been affirmed and denied, clinically and experimentally (MacNider). Its existence is doubtful, but Mercier *et al.*, 1932, reported diuresis and increase of chloride concentration as well as twenty-four-hour output, in dogs. Fronmueller, 1878, contended that the reputed diuretic effect of the parent plant (Scoparius) is due mainly to *scoparine*, a neutral principle.

Respiration.—Moderate doses of sparteine stimulate the respiration and antagonize narcotic depression by a carotid sinus reflex (Zunz and Tremonti, 1931).

Skeletal Muscle.—Small doses of sparteine potentiate the response to indirect stimulation and to acetylcholine. Larger doses have a curarizing action (G. Coppée and Bacq, 1941).

Excised Intestine.—Sparteine depresses the tone and contractions (Ikeda, 1916).

Hemolysis.—Dodel, 1928, reported that sparteine sulfate is a hemolytic agent, and that sodium salicylate protects the corpuscles against this action.

Sparteine Sulfate is hygroscopic and freely sol. in water or alc. Dose, 10 mg., $\frac{1}{6}$ grain, gradually increased to 0.13 Gm., 2 grains, every six to eight hours. Overdoses produce nausea and vomiting.

◆

GUANIDINE AND METHYLGUANIDINES

Guanidine (imido-urea), $NH:C:(NH_2)_2$, and methyl- and dimethyl-guanidine occur in urine (Kutscher and Lohmann, 1908; Major, 1924). They are closely related to creatine and arginine, and are formed in the putrefaction of proteins. They produce more striking pharmacologic effects than the other nitrogenous metabolites. These effects include fibrillary twitching of striped muscles; with large doses also a curare action; convulsive phenomena and sustained high blood pressure. This suggested that retention of the guanidines might be the cause of clinical tetany (Klinger, 1921), chorea (Fuchs, 1914), eclampsia, and of hypertension (Major and Stephenson, 1925). Since convulsions and high blood pressure can be produced in many other ways, the causative relationship could only be established by the demonstration of effective concentrations of guanidine in the blood. This appears unlikely. The retention of a part of the normal output of guanidine, through impaired kidney function (Major), probably has no greater significance than the similar retention of creatine and uric acid.

Guanidine Derivatives.—A considerable number of these have been studied as to toxicity (Garino, 1916), and especially as to the effect on blood sugar level (Bischoff and Long, 1931). The latter is discussed under *Synthalin.*

Guanidine Substances in Blood and Urine.—These fluids normally contain substances with color reactions strongly suggestive of methyl-guanidine, although their identity has not been definitely established (Andes and Meyers, 1937). In normal males, the daily urinary excretion amounts to 3 to 10 mg. Their concentration in the oxalated blood ranges normally between 0.20 and 0.28 mg. per 100 cc., two-thirds of this being in the cells. It rises to 2.5 mg. per cent in uremia. It is high in *hypertension,* if there is N retention (Andes, Linegar and Myers, 1937). In hypertension produced experimentally in dogs by constriction of the renal arteries, the rise of guanidine bases in the blood parallels the nitrogen retention, without relation to the rise of blood pressure (C. G. Child, 1938). In *normal pregnancy,* it is normal up to and including delivery. It increases to double in three to seven days after parturition and gradually returns to normal by the end of the third week. The postpartum increase is almost wholly in the cells. In severe *pregnancy toxemia,* it may rise (to 0.73 mg. per cent), often accompanied by nitrogen retention (Andes, Linegar and Myers, 1937). Normal values were found in *parathyroid tetany.* Severe damage of the liver by *arsphenamine* did not increase their concentration in the blood, unless there was also severe renal damage (Andes, Hawk and Emerson, 1938).

Fate.—Injected guanidine and methylguanidine are excreted in part unchanged by the urine, but a part disappears. They do not increase the excretion of creatinine, but Wishart, 1920, claims that guanidine injection increases the creatine content of the muscles.

Striped Muscle.—Guanidine greatly increases the sensitiveness of striated muscle to *acetylcholine* (E. Frank *et al.,* 1923). The effects resemble those of nicotine. In excised frog muscle, concentrations above 0.2 per cent produce a *curare-like paralysis;* concentrations between 0.025 and 0.06 per cent cause characteristic *twitchings* (Grant, 1920). These are mainly fascicular; but in frogs, at the height of the poisoning, they are interspersed with contractions of the entire muscles, in regular sequence; and this is the main phenomenon in toads (Frank and Stern, 1921). Gugens and Baumann, 1876, showed that the contractions are peripheral, for they persist after destruction of the central nervous system. Evidence that the action involves the *neuromuscular junction* was furnished by Feng, 1938: A toad sartorius muscle-nerve preparation treated with guanidine responds to a single shock, when applied to the nerve, by a brief tetanus followed by rhythmic twitching; but if the same shock is applied to the muscle, there is but a single twitch. (Guanidine does not produce twitchings if applied directly to a nerve trunk.) The twitchings are abolished by curare and by atropine (Frank and Stern) and do not occur if the nerve endings have been allowed to degenerate (Fuehner, 1920). No twitchings occur if the application is confined to the nerve-free ends of the sartorius muscle, probably because the sarcolemma is less permeable at these regions. The same phenomena are shown by barium and by physostigmine; there is even a potentiated synergism between guanidine and barium (Fuehner, 1920). The guanidine twitchings are suppressed by weakening the muscle (Langley, 1915), and by calcium or magnesium (Fuehner, 1907 and 1911). Local anesthetics (cocaine or procaine) remove the guanidine and nicotine stimulation, but appear ineffective against barium (Frank and Stern, 1921).

Other substances that produce fibrillary twitchings in skeletal muscle comprise: nicotine; parasympathetic stimulants, *i. e.,* physostigmine and acetylcholine; muscular stimulants, *i. e.,* barium, aconitine, veratrine; decalcifying ions, *i. e.,* oxalate, citrate and fluoride; also thiocyanate and some of the metals.

Guanidine, like barium, causes rhythmic contractions of the *melanophores,* synchronous for all these cells in a fish scale, indicating that the action is on a neurofibrillar network, rather than on the end cells, as the latter would not be synchronized by a direct action. This is probably analogous to the muscular twitching (Veil *et al.,* 1932). The *melanophores of frogs* are contracted by methylguanidine, producing pallor of the skin. This is prevented by the previous injection of calcium lactate (Ochoa, 1928).

In **myasthenia gravis,** the administration of guanidine may produce marked and well sustained improvement of muscular function (Dodd, Riven and Minot, 1941), but it fails in many cases. Successful results are attributed to sensitization of the muscle toward acetylcholine. Excessive doses produce nervousness, gastro-intestinal, circulatory and other symptoms, decrease of plasma volume and blood sugar changes. These indicate reduction of dosage, but can be relieved by atropine, and less effectively by calcium (A. S. Minot, 1939), without interfering with the muscular action. A test dose of 10 mg. of guanidine hydrochloride per kilogram of body weight per day should be administered in capsules, and subsequent dosage adjusted to the individual response. It has no effect on other myopathies (A. S. Minot *et al.,* 1939).

Toxic doses fed to animals for several weeks produce changes in muscle metabolism and structure similar to those of muscular dystrophy: loss of creatine and phosphate, severe disturbance of carbohydrate metabolism and electrolytes (R. P. MacFate, 1942).

Guanidine Convulsions.—In mammals, general clonic convulsions are more conspicuous than localized twitchings. With hypodermic injection, there may be a latent interval of an hour; similarly with methyl- and dimethlguanidine.

Cisternal injection in dogs results in marked and prolonged rise of blood pressure and muscular twitchings, greater than with equal doses by vein. They are controlled by cisternal injection of calcium (Resnik and Mason, 1936).

Calcium and Phosphate Equilibrium.—Injection of convulsive doses of guanidine into rabbits greatly increases the phosphate of the serum, and the calcium of the serum is generally somewhat decreased (Watanabe, 1918). The blood calcium is lowered in methylguanidine poisoning, as in parathyroid excision (Bayer, 1922). Repeated injections of sublethal doses of guanidine do not cause calcium deposition in rachitic rats, or decalcification of formed bone (Burns, 1929).

Blood Pressure.—Intravenous injection of guanidine (0.1 to 0.4 Gm. per Kg.) or of methylguanidine produces an immediate large rise of the blood pressure, which is sustained for one-half to four hours (Major and Weber, 1929). In man, 0.05 to 0.08 Gm. per Kg., by vein, raises the systolic pressure by 30 to 50 mm. for about an hour.

The rise is apparently caused by vasoconstriction, through a peripheral action, for it occurs on perfusion (Rothberger, 1902), and the decrease of limb volume is not altered by section of the nerves or of the spinal cord. It is prevented by ergotoxine (H. Goldblatt and Karsner, 1933). The pressure rise occurs before the muscular twitchings. It may be lowered temporarily by nitrites, and more permanently by the injection of calcium and potassium (Major and Stephenson, 1924, 1925). The *heart rate* is slowed during the rise of blood pressure. With intravenous injection of methylguanidine up to 25 mg. per Kg., the inhibitory response to electric *vagus stimulation* is often increased; with 50 to 60 mg., it is temporarily decreased; and with 100 mg., there is generally slowing without vagus block and other cardiac irregularities, and sometimes profound diminution of vagus response (Potter and Stoland, 1932). With *frog heart*, weak concentrations of guanidine and methylguanidine increase the height of the systole; higher concentrations produce diastolic arrest (G. Rosenow, 1921).

Guanidine Shock.—Dogs poisoned with guanidine gradually develop circulatory failure to shock level, with loss of plasma volume. This may be prevented by atropine and less effectively by calcium (A. S. Minot, 1939). The mechanism is not clear.

The **respiration** is greatly slowed, to four or five per minute, and is arrested by larger doses. The animals may be saved by artificial respiration (Klinger, 1921; Major; Major and Stephenson). Guinea pigs are rendered dyspneic by 0.01 Gm. per Kg., and killed by 0.03 Gm. per Kg. The dyspnea gave rise to the theory that methylguanidine was the active agent in *anaphylaxis* (Heyde and Vogt, 1913), but Loewit, 1913, showed the absence of bronchial constriction; indeed, Potter and Stoland, 1932, reported that it produces bronchial dilatation (in dogs); and D. Burns states that guanidine confers *protection* against anaphylaxis if it is injected immediately before or after the provocative dose. Guanidine or methylguanidine, 0.05 per cent, markedly depresses oxygen uptake in various *isolated tissues* (Banu and Gavrilescu, 1934).

The *salivary response to chorda tympani nerve stimulation* is decreased by methylguanidine and completely inhibited by large doses (Potter and Stoland, 1932). *Excised intestines* are stimulated.

Creatinine occurs in urine, but it is controversial whether it exists as such in normal blood, or as a precursor from which it is formed in the kidneys (review, V. C. Myers and Muntwyler, 1940). Creatinine and creatine increase the amplitude of the cardiac contractions in mammals and frog and give some evidence of vasodilatation; but these effects require higher concentrations than exist in life (B. G. Shapiro, 1938).

SYNTHALIN

Guanidine and especially some of its derivatives tend to lower the *blood sugar level;* and this may be pushed to the production of hypoglycemic convulsions, which may be relieved by glucose injection, similar to insulin, although not as effectively (E. Frank, Nothmann and Wagner, 1926). The action has a quite different mechanism, involving damage to the liver function and structure (Boedeker and Junkersdorf, 1931) with exhaustion of the hepatic glycogen (Staub, 1928), which may be preceded by temporary hyperglycemia (Simola, 1927). The nature of the alteration in the carbohydrate metabolism is not understood (Lublin, 1927; Staub, 1928; Kauffmann and Valisco, 1931). Acute nephritis has been observed (Blatherwick *et al.*, 1927; Kawetal, 1929).

One of the more effective derivatives, decamethylene diguanidine, was tried by E. Frank *et al.*, 1926, in diabetes, under the name of "*synthalin*," and most of the clinical and experimental data refer to this product. (In 1928 they introduced the dodecamethylene diguanidine as synthalin B, as being less toxic; but the differences are not essential.) They reported relief of the diabetic symptoms, after oral doses of 50 mg. twice daily for several days, the action being slower but more prolonged than with insulin (as would necessarily follow from the mechanism of its action). It was found unsatisfactory, however (Umber, 1927). The restoration of the blood sugar level is generally imperfect; in dogs, also, it is effective only if the pancreatectomy has been incomplete (Ralli and Tiber, 1929). On the other hand, it causes serious side actions, gastro-intestinal disturbance and nervous depression (in contrast to the relief by insulin), nephritis and hepatitis when continued for a few weeks (Karr, Belk and Petty, 1929). Other guanidine derivatives have been investigated by Bischoff *et al.*, 1929 and 1931, but none is promising, since the liver damage and toxicity closely parallel the hypoglycemic action. Other pharmacologic properties of synthalin were studied by Junkmann, 1927; their toxicity by Simola, 1927. It is a strong protoplasmic poison and antiseptic (Staub, 1928).

◆

CURARE

This South American arrow poison paralyzes the skeletal muscles through selective depression of their receptive mechanism. It has no effect on sensory nerves and is not an anesthetic. It produces a number of side effects, resembling nicotine in depressing autonomic ganglia (vagus); and strychnine in stimulating the spinal cord. It may produce glycosuria. Intravenously, it causes temporary fall of blood pressure, which returns rapidly to normal with moderate doses. Death occurs by paralysis of the respiratory muscles; animals may be saved by artificial respiration, the drug being rather rapidly excreted by the urine. Curare is mutually antagonistic with physostigmine. It is much less toxic by the stomach, on account of slow absorption and rapid destruction and excretion. It diminishes the response to tonic impulses before it affects brief contractions, as those of voluntary action and of respiration. Carefully graduated doses of standardized preparation are used therapeutically to mitigate the convulsions of the "shock treatment" of mental diseases; to secure muscular relaxation in surgical anesthesia, especially by cyclopropane and pentothal; to relieve proprioceptive spasticity in tetanus, in encephalitis and poliomyelitis;

and as a diagnostic agent in myasthenia gravis, by the exaggerated response. The margin of safety is rather narrow, but standardized preparations appear safe. The erythrina alkaloids and quinine methyl derivatives have a similar or identical action and are perhaps safer.

Origin.—Curare, Woorara or Urari comprise several varieties of extracts, prepared by the Indians of northern and western South America as arrow poisons from several plants. They were brought to Europe from Guiana by Sir W. Raleigh, 1595. They vary greatly in composition (certain varieties were supposed, probably erroneously, to contain snake venom), and they deteriorate on keeping, especially if moist, so that commercial curare is a very unreliable drug. The potent alkaloidal ingredients are derived from several Strychnos species and from several genera of the Menispermaceae (R. C. Gill, 1938). The *varieties* are designated by the kind of containers in which they reach commerce. The source of *tube curare* (in bamboo tubes) is said to be *Chondodendron tomentosum* (Menispermaceae). (Another species, M. Scholtz, 1911, was formerly used under the name of *Pareira Brava* as a bitter tonic.) It contains d-tubo-curarine and curine. A purified and biologically standardized solution marketed as "*Intocostrin*" is at present the most reliable curare preparation for clinical use (A. R. McIntyre and King, 1943). *Calabash (gourd) curare* is obtained principally from *Strychnos* toxifera and contains curarine. *Pot* or *jar (Topf) curare* comes from Strychnos Castelnaei and Cocculus toxiferus, and contains protocurarine and protocurine. Gill, 1946, asserts that the Indians put up all varieties of curare in all kinds of containers, and that these classificiations are wholly misleading. All the varieties consist of brown masses, intensely bitter, not wholly soluble in water, more soluble in dilute acid. The *active constituents* are alkaloids. Curarine and protocurarine have the most typical effects, and the latter is probably stronger. Tubocurarine has a much weaker muscle-nerve action, a stronger strychnine effect and increases the heart rate. Curine is devoid of the muscle-nerve action, but first stimulates and then depresses the heart. It can be converted into curarine (Boehm). *Curarine* is related chemically and in actions to strychnine. Its preparation from calabash curare was described by Boehm, 1887, and by L. Lewin, 1923.

Other Arrow Poisons.—A variety of these are widely used among primitive people. They are often bizarre mixtures, but always with a potent ingredient belonging either to the curare, strychnine or digitalis group (Santesson, 1934). One of the South American arrow poisons, used by Colombian Indians is prepared from the latex of a tree, Ogcodeia, with digitalis actions (Uribe and Mezey, 1946).

Paralysis of "muscle-nerve" endings is ordinarily the only symptom of curare poisoning. When the curare is introduced under the skin, it causes total loss of proprioceptive tonus, then of the voluntary and finally of the respiratory movements. The phenomena appear analogous to myasthenia gravis.

Sequence.—In man, on intravenous injection of the ordinary clinical dose, the effects begin within two minutes, as haziness of vision, followed by ptosis, relaxation of the face muscles, sensation of tightness in the throat, huskiness of voice; then inability to raise the head, next the arm and leg; finally shallowness of respiration. The peak is reached in two and a half or three minutes. The sequence is similar in animals: first the short muscles of the toes, ears and eyes; then the limbs, head and neck; finally the respiratory muscles, first the thoracic, then the diaphragmatic, and lastly the abdominal (Chiò, 1912). The muscles which are least affected by curare are those which contain the largest amount of utilizable oxygen, and survive longest after the death of the animal. This supply of oxygen accounts, perhaps, for the lesser susceptibility to the depressing action of curare. The heart is not affected except with much larger doses.

Development of Paralysis.—The first sign of curare action consists in incapacity for sustained effort on repeated stimulation of the nerve; *i. e.*, whereas a single contraction is normal, fatigue sets in more readily than usual (Boehm, 1894). Then the height of contraction is somewhat lowered. Then the current must be strengthened to obtain any response; and finally even the strongest stimulation of the nerve is ineffectual. However, if the sciatic nerve of a cat is stimulated with a tetanizing current, the muscle does not recover from the curare as rapidly as it would without this stimulation (Luco and Rosenblueth, 1939).

The site of action was investigated by Fontana and established by the work of Cl. Bernard, 1857. It is evident that some structure is paralyzed. The paralysis might have its seat in any part of the central nervous system or it might be peripheral. Stimulation of the sciatic does not produce a contraction if the dose has been sufficient. The point of attack must, therefore, be peripheral to the sciatic nerve. This leaves the nerve trunk itself, the nerve endings and the muscle fibers. Stimulation of the muscle directly is effective, so that it is excluded. To decide between the nerve trunk and nerve endings, Bernard placed a mass ligature around the body of a frog, with the exception of the sciatic nerves, and tightened the ligature so as to exclude the lower extremities from the circulation. He then injected the curare. In this manner the peripheral portions of the sciatic nerves and the endings did not come into contact with the curare, and the nerve trunk alone was exposed to the poison. He found that stimulation of the trunk caused normal contraction, consequently that curare had no action on it, thus leaving only the endings. He also proved the point in a simpler manner by ligating one leg exclusive of the nerve, and by placing the muscle of one and the nerve of another muscle-nerve preparation into the solution. Garten, 1912, has shown by careful methods that even prolonged exposure to strong curare solutions does not affect the nerve trunk. Bernard's experiments show that curare acts on a mechanism between the nerve trunk and the contractile mechanism. This was conceived as the "motor end-plate." Further observations showed that its action is not on the nerve endings that degenerate after section of the nerve, but on the receptive mechanism. This is probably localized mainly at the end plate (Langley). The curare appears to be *fixed at the surface* of the cells, the excess being easily washed out. The fixation is completed within a minute, but the action in excised frog muscle progresses for an hour after the preparation has been removed from the solution (R. Boehm, 1910).

Direct stimulation of the muscle (in cats) requires a somewhat stronger current under curare, but not if the nerve has degenerated. Epinephrine also restores the threshold of muscular stimulation. Fatigue increases the threshold (Gruber, 1914). Henriquez and Lindhard, 1920, reported that the contraction of curarized muscle on direct stimulation does not give rise to an action current. This has been confirmed and denied (H. Schafer, 1936). Its significance is not clear.

Potential of Motor End Plate.—Buchthal and Lindhard, 1935, report that curarization is accompanied by disappearance of the marked potential difference which normally exists (either positive or negative) between the end plate and the muscle fiber.

G. Coppée, 1943, concludes that curarizing agents act chiefly on the motor end plates, depressing their response to nerve impulses (but not the liberation of acetylcholine). He suggests that they unite with a radical of an organic complex so as to release its *potassium*, which lowers the excitability of the end plate.

Invertebrates do not show blockage of nerve-muscle transmission by curare, but a central paralytic action (Piotrowski, 1893; B. Katz, 1936).

Dissociation of Chronaxia.—Lapicque reported that curare (and fatigue) increases the chronaxia of the aneural part of the sartorius muscle (other curarizing agents, such as sparteine, do not), and attributed the curare action to the dissociation of the chronaxia of the muscle and nerve (stated to be normally alike, notwithstanding the difference in their rheobase), this dissociation interfering with the transfer of the excitation from the nerve to the muscle. Rushton, 1933, however, found that curarization can be accomplished without raising the chronaxia of the muscle, if precautions are taken to avoid stimulating the intramuscular nerve. This removes the factual foundation of the Lapicque theory. H. Davis and Forbes, 1936, conclude that while there is usually approximate isochronism in the chronaxia of a muscle and its motor nerve, this does not seem necessary for neuromuscular transmission and that dissociation of chronaxia is not necessary for curarization.

Acetylcholine Antagonism.—Curare and all curarizing substances inhibit the tonus effect of acetylcholine on skeletal muscle; physostigmine and neostigmine antagonize curare. Crude curare preparations inhibit serum *choline esterase* (M.M. Harris and Harris, 1941); pure d-tubo-curarine does not, so that it is not concerned in the curare effect (McIntyre and King, 1943). Intra-arterial injection of d-tubo-curarine into denervated mammalian skeletal muscle may produce strong contraction, similarly to acetylcholine (McIntyre, King and Dunn, 1945).

Removal of curare block may be obtained by washing in physiological solution, or by maintaining the circulation; by summation of stimuli (Bremer); by physostigmine or by veratrine (review, G. Coppée, 1941).

Myasthenia gravis **closely resembles curare poisoning in all respects, and myasthenia patients are up to twenty times more sensitive to curare than are normal individuals.** Intravenous injection of a twentieth of the ordinary dose of standardized curare strikingly increases the myasthenic symptoms, so that it serves as a diagnostic test. The test should be terminated in two or three minutes by intravenous injection of 1.5 mg. of neostigmine methylsulfate and 0.65 mg. of atropine sulfate (A. E. Bennett and Cash, 1943).

Relief of Spastic Contractures by Curare.—Langley, 1905 and 1914, showed that the nicotine tonus of skeletal muscle is relaxed by doses of curare, which do not weaken the response to nerve stimulation. Subparalytic doses are similarly effective against Parkinsonian rigidity, against the persistent contracture of traumatic tetanus and against the stiffness of parathyroid tetany (R. West, 1935; Burman, 1939).

The use of curare against convulsive and spastic conditions has been made feasible by the introduction of standardized extracts. It had previously been suggested especially for strychnine, traumatic tetanus and hydrophobia, but involved too much danger of fatal respiratory paralysis.

Mitigation of Convulsions in "Shock Therapy."—Partial curarization, to generalized flaccid motor paralysis, protects adequately against traumatic complications of metrazol or insulin therapy of mental disorders. With intravenous injection of intocostrin, one-half unit per pound of body weight, the effect occurs immediately, with intramuscular injection in fifteen minutes. More is given if necessary, until the patient is unable to raise the head. The ordinary dose of metrazol may then be injected, producing convulsions of the normal type, but much less powerful. The curare effects slowly recede and disappear in fifteen to twenty minutes. The therapeutic results appear as good as those without curarization. No serious accidents have been reported. Any depression of respiration generally lasts less than five minutes without treatment, but all effects can be removed by intravenous injection of 0.5 mg. of neostigmine (1 cc. of 1:2000). Artificial respiration has not been necessary (A. E. Bennett, 1940). Some cardiac embarrassment is reported in about 10 per cent of patients (G. L. Jones and Pleasants, 1943).

Surgical Operations.—Intocostrin, 70 units intravenously, is used to secure muscular relaxation in cyclopropane and pentothal anesthesia (S. C. Cullen, 1944). H. R. Griffith, 1945, employs 100 units; with this dosage, transitory arrest of respiration occurs in about a tenth of the patients. It is treated by artifical ventilation with oxygen for ten or fifteen minutes. Neostigmine should be available, but was never needed.

Ether somewhat potentiates the intocostrin action (W. Schallek, 1946).

In *spastic states of children*, ½ to 1½ units per pound of body weight are administered intramuscularly at four day intervals.

In *acute poliomyelitis*, curare sometimes gives subjective improvement, but the objective response is not encouraging (M. J. Fox, 1946).

Central Nervous System.—In addition to the peripheral nerve-muscle block, curare has central convulsant effects. These predominate in rats and mice (0.5 to 0.75 units of intocostrin per Kg.), while muscular relaxation prevails in rabbits and cats. The convulsions are of the picrotoxin type, and are antagonized by amytal. They occur also on direct application to the central nervous system (R. E. Cohnberg, 1946; also in dogs, McGuigan, 1916).

Curare and the drugs with curare action suppress the

electrical activity of the frog brain (E. P. Pick, 1945). When curare is applied directly to the spinal cord of frogs, it causes typical *strychnine convulsions*. With ordinary methods of administration these are masked by paralysis of the nerve endings. Certain samples, however, cause strychnine convulsions before the typical curare action appears.

In man, intravenous injection of d-tubo-curarine, with artificial respiration, produces no change of consciousness, sensation, appreciation of pain, electro-encephalogram, or any other manifestation of stimulant, depressant or analgetic action of the higher nervous centers, even with doses more than twice as great as those that cause complete respiratory paralysis (S. M. Smith, Brown *et al.*, 1947).

Paralysis of Respiration as Cause of Death.—In cold-blooded animals in which the respiratory exchange takes place largely through the skin, and respiratory movements are unnecessary, the poison is gradually eliminated if the animal is kept in a moist atmosphere. Complete recovery occurs after eight to ten days, except when the dose is excessive, in which case other factors come into play. Warm-blooded animals die of paralysis of the respiratory muscles. If artificial respiration is kept up and the dose has been only enough to produce paralysis, they may also *recover*. The recovery of the respiratory muscle begins immediately, while the sciatic endings require several hours. The effect of the curare increases progressively with the dose: it is as if an increasing resistance were gradually introduced between the nerve and the muscle. The seat of the *respiratory paralysis* is peripheral, for stimulation of the phrenic nerve does not result in contraction of the diaphragm. The respiratory paralysis, if it is not too profound, is promptly removed by *physostigmine;* stimulation of the sciatic also becomes effective again. *Bronchial muscle* is not affected by curare (Trendelenburg).

Autonomic Ganglia.—The vagus, vasomotor, salivary, pupillary, etc., ganglia are depressed, but usually not as strongly as with nicotine. The antagonism to nicotine stimulation indicates that the paralysis involves the ganglion cells. The order in which the ganglia are affected is also the same as with nicotine (Langley, 1918), and has been discussed in the general section on autonomic poisons.

Effects on the Circulation.—If artificial respiration is maintained, the first effect of curare on the circulation consists in a fall of blood pressure, due to peripheral vasomotor depression. The action is apparently on the ganglion cells (Langley, 1918). This is soon accompanied by quickened heart beat, from depression of the vagus ganglia. The depression does not readily pass into paralysis, so that stimulation of the vagus or sciatic is still effective; indeed, the vasomotor reflexes may be increased, through the central action of the curare. Martin and Stiles, 1914, found that the threshold of the vasomotor center is not raised, even by large doses. The reflex depressor fibers are rendered more sensitive (Langley, 1912), or rather, the depressor response is more nearly proportional to the strength of the stimulus, than in normal animals (Martin and Stiles, 1914). These effects on the circulation pass off within fifteen minutes and the circulation returns to normal, while the muscular paralysis persists. They therefore do not seriously interfere with the employment of the drug. *Perfusion of frog's vessels* shows vasoconstriction, which is not modified by absence of calcium (Pearce, 1913).

Vagus.—The peripheral effects correspond to those of nicotine. Electric stimulation of the vagus does not arrest the heart, but it may be slowed, or beat faster (Dale and Laidlaw, 1911). The *vagus conduction* is slow, in the frog heart, analogous to the skeletal muscles (M. Lapicque and Veil, 1916). Perfusion of the *medulla oblongata*, in the turtle, may stimulate the cardioinhibitory center somewhat, but more commonly tends to diminish the sensitivity of the center to other stimulants (Bush, 1920). The *lymph hearts* of frogs are arrested (Bernard).

Sensory nerves are not affected by curare. The reports of early travelers who describe poisoning by curare arrows mention that sensation is not impaired when motion is impossible.

Peristalsis is often increased, partly by asphyxia, but also with artificial respiration. Bidder, 1865, found no direct effect on intestinal or other smooth muscle, even with the largest doses. Ikeda, 1916, with excised intestine found stimulation of the muscle and slight increase of tone.

Urinary Bladder.—Edmunds and Roth, 1920, found that curare, like atropine, failed to abolish the motor response to parasympathetic and sympathetic stimulation in cats.

Pancreatic Secretion.—Curare, in doses which do not paralyze skeletal muscle, suppresses the secretory response of the pancreas to vagus stimulation, but not to secretin (Gayet and Guillaumic, 1934).

Creatine output, which has been considered as an index of the tonic functions of muscle and is supposed to be controlled by the sympathetic system, is not affected by curare, nor does curare prevent the increase by epinephrine, caffeine, etc. (O. Reisser, 1916).

Glycosuria is a frequent but not constant phenomenon (Morishima, 1899). It is not wholly due to asphyxia, for it can not be completely prevented by artificial respiration (Macleod, 1909). The earlier literature is reviewed by S. Weber, 1904. *Insulin hyperglycemia* antagonizes the toxicity of curare, but not the curare effect of cobra venom (Nechkovitch, 1927).

The **epinephrine output** is markedly depressed by curare in the dosage required to paralyze skeletal muscle (Stewart and Rogoff, 1919).

Inactivity by Gastro-Intestinal Canal.—The effects of curare are usually not obtained on oral administration. Experiments (mainly by Bernard) have shown that: (1) It is not destroyed by the gastric juice, pancreatic juice, or saliva. (2) It passes slowly through the walls of the stomach when the epithelium has been killed, and not at all if the epithelium is still living. (3) It is to some extent fixed or destroyed by the liver, for it is much less active when injected into the portal than into the jugular vein. The discrepancy, however, between the gastric and hypodermic dose persists, even when the liver is largely excluded by Eck's fistula; so that the liver destruction can not be very important in mammals (Polimanti, 1914). It is also destroyed *in vitro* by ox bile and by bacteria. In *frogs* the liver is the main agent in the disintoxication: in normal animals fifty times as much curare is required by mouth as hypodermically; the difference disappears completely if the liver is excised; digestion of curare with liver substance destroys its activity. (4) It is rapidly excreted unchanged in the urine. In *mammals* the inactivity of curare by the mouth is due partly to its destruction by the bile and bacteria, but mainly to the capacity for absorption being less than the capacity for its destruction or excretion. If the renal vessels are tied, poisoning occurs readily even when it is taken by the stomach. If very large doses are taken on an empty stomach, sufficient may be absorbed to cause symptoms.

Intocostrin is a purified extract from Chondrodendron tomentosum (marketed in ampuls of 6 and 10 cc.), standardized on rabbits so that each cubic centimeter corresponds to 20 units of a standard drug. The ordinary intravenous dosage in shock treatment and anesthesia is 0.5 unit per pound of body weight; in myasthenia gravis, 0.1 unit per pound. The anoxic fatal dose for dogs is 0.065 cc. per pound; with artificial respiration it is about twenty times higher, 1.3 cc. per pound. The effect is greater if a sublethal dose is again injected on the succeeding day. Treatment by artificial respiration is more effective than prostigmine (F. Cole, 1946).

Curare-like effects from other drugs are fairly common as side actions, but they are often so overshadowed by other actions that they can be elicited only on excised muscle. The *erythrina alkaloids, quinine methochloride* and ethochloride are suitable, however, for the clinical control of metrazol convulsions.

Over thirty synthetic curare substitutes were studied by H. F. Chase and Lehman, 1942, and Chase, Lehman and Richards, 1944. Quinine ethochloride had the most favorable therapeutic index. A. M. Harvey and Masland, 1941, reporting on the clinical side actions, found that crude curare, beta erythroidine and quinine methochloride all produced moderate fall of blood pressure. The erythroidine and quinine compound occasionally resulted in disorientation and mental confusion. Quinine methochloride sometimes caused severe toxic reactions, with vomiting and abdominal cramps.

Quinine methochloride is effective by oral as well as parenteral administration (A. E. Bennett, 1941). It blocks the transmission of nerve impulses to skeletal muscle, and also the response to acetylcholine (A. M. Harvey, 1940). A. J. Lehman, Chase and Yonkman, 1942, report that *quinine ethochloride* ranks high in absolute toxicity, but has the greatest margin of safety. Its curare action is intense but brief, and therefore easily controlled.

Erythrina Alkaloids.—Several alkaloids, erythroidine, coralloidine, and the like, have been isolated in pure form from various species of Erythrina, "Coral tree," small leguminous trees or shrubs growing in Mexico, Central America, Brazil and tropical Asia. Their curare action was demonstrated by Ramirez and Rivero, 1935 (cited by Santesson, 1938). In frogs, 2 to 10 mg. of the alkaloids per kilogram produce a curare paralysis of short duration, but with larger doses it may last four days. In cats and rabbits the muscles also recover quickly from intravenous injections, unless the dosage is so large as to paralyze the diaphragm; in this event, recovery occurs under artificial respiration in less than an hour. Hypodermic administration is also effective. The alkaloids differ in dose and duration of action. They are not excreted in the urine and appear to be destroyed. The action is antagonized by physostigmine. The erythroidines produce strong parasympathetic stimulation, perhaps analogous to that of nicotine (Lehman and Chase, 1942). The isolation and actions are described by Kunna, Kniazuk and Greslin, 1944. *Erythroidine hydrochloride* is being tried clinically in dystonic and spastic conditions and to mitigate the convulsion treatment of schizophrenia. *Beta erythroidine hydrochloride* is injected intravenously, 100 mg. as 3 per cent solution, every ten seconds until the eyelids droop (generally about 400 mg. in all). This is followed immediately by the metrazol injection. The curare effect reaches its peak in one minute and lasts about fifteen minutes, but there is some variability of response. Excessive respiratory depression may be antagonized with 0.5 mg. of neostigmine (J. M. Williams, 1941). Erythroidine may produce intraventricular heart block, sometimes fatal; Chase and Lehman consider its use too dangerous. Its oral administration is reported to have a hypnotic rather than a curare action (M. S. Burman, 1939, 1940).

Curarizing substances belong chiefly to the following groups: (1) *Alkyl quaternary ammonium derivatives:* methyl and ethyl ammoniums, choline, muscarine, probably curarine. (2) *Pyridine derivatives:* piperidine, nicotine, coniine, arecoline, F 933, sparteine. (3) *Tropine derivatives:* atropine, hyoscyamine, scopolamine, cocaine. (4) Strychnine, methylstrychnine and brucine. (5) Cobra venom. (6) Excess of calcium ions. All desensitize striped muscle to acetylcholine; some diminish the sensitiveness toward potassium; but this is increased by atropine and especially by sparteine (review, G. Coppée, 1941). Pilocarpine curarizes frogs, but not cats (Coppée, 1943). Curarizing effects are also obtainable with guanidine (Brown and Fraser, 1869); delphocurarine, Heyl (Kahn, 1909); quinoline, thalline; morphine and related alkaloids; cocaine; camphor in frogs, but not in warm-blooded animals; certain putrefactive ptomaines; products of muscle metabolism; botulism toxin. S. Fraenkel, 1904, attributes the curare action of the *ammonium bases* and related drugs to the stereochemic orientation of the valences. For excised frog sartorius preparations, *strychnine methyliodide* is a more potent curarizing agent than curarine, but it is less effective *in vivo*, because it is promptly excreted (Cowan and Ing, 1934).

Botulism Toxin.—According to Edmunds and Keiper, 1924, all the phenomena of poisoning by the toxin of the anaerobic bacterium Clostridium botulinum are explained by stimulation, then depression, of the receptive mechanism of the parasympathetic and skeletal muscle. The phenomena set in after a latent period of about twelve hours. In striped muscle, a single stimulus through the nerve produces good contraction, but repeated stimulation leads to rapid exhaustion and paralysis. The response to direct stimulation of the muscle is not altered. Death occurs by asphyxia and may be indefinitely postponed by artificial respiration. The recovery of the muscular excitability, however, is so slow that this treatment is not feasible clinically. Physostigmine fails to counteract the paralysis; but pilocarpine antagonizes the parasympathetic effects on the eye and heart. Congo red injection has been successful in animals, but has not been tested clinically. Its dose would be 10 cc. of 1 per cent solution in 5 per cent dextrose, intravenously. The toxin is destroyed by boiling ten to fifteen minutes so that well boiled food is safe. No outbreak from factory canned foods has been reported since 1925. Man and guinea pigs are highly susceptible, dogs and rabbits are relatively tolerant. The curare action can be produced in frogs if these are warmed.

Botulinus toxin has been isolated as a protein of high molecular weight, crystallizing as needles (C. Lamanna et al., 1946).

EPINEPHRINE

Epinephrine (also called *adrenaline, suprarenine* and numerous similar names) is the active principle of the medulla of the suprarenal gland. It is a relatively simple amine derivative of catechol, and can be prepared synthetically. It behaves as a feeble base and may be classed with the alkaloids. Its solutions are unstable unless a preservative is added. Its typical action consists in a highly specific stimulation of the receptive mechanism of the entire sympathetic system, and the effects upon any given organ—whether augmentory, inhibitory or indifferent—correspond with the effects of stimulation of its sympathetic innervation. They were described in the general section on autonomic drugs. Very dilute concentrations may have opposite effects. Epinephrine, ephedrine and their homologs also inhibit the transmission of nerve impulses in sympathetic ganglia (Marrazzi, 1940). The most important practical manifestation of the sympathetic stimulation consists in a high rise of blood pressure, from peripheral stimulation of the vasoconstrictor mechanism of the systemic vessels, and of the accelerator mechanism of the heart. Epinephrine is used locally for arresting hemorrhage and enhancing the anesthetic effects of cocaine; hypodermically, in bronchial asthma; intravenously, tiding the patient over acute circulatory collapse. Epinephrine leaves the blood stream rapidly and is then destroyed, especially in the liver, so that the effects of intravenous injection are of short duration. It is poorly absorbed from mucous membranes, and its absorption from subcutaneous injections is delayed by its vasoconstrictor effect, so that the response is relatively slight, except as regards especially sensitive conditions, such as asthma, or in hypersensitive individuals. Overdoses, intravenously, kill by acute dilatation of the heart. Other phenyl alkylamines, for instance ephedrine and benzedrine, have similar actions, but differ in important respects.

Influence of Dosage on the General Effects.—The results of increasing intravenous doses may be tabulated (Langley, 1901) as: (*a*) rise of blood pressure; (*b*) inhibition of bladder, mydriasis; (*c*) contraction of uterus, vas deferens and seminal vesicles; salivation and lacrimation; inhibition of stomach and gallbladder; increased bile secretion; inhibition or stimulation of internal anal sphincter; (*d*) contraction of erectores pilorum; (*e*) uncertain effect on tunica dartos and on sweat. *The sensitiveness of different functions to epinephrine* in the normal cat is in the following sequence, in the order of greatest to least: liver, glycemia, blood vessels, denervated heart, nictitating membrane, stomach, iris, pilomotor, salivary (S. Chang, 1937).

The *relative potency of adrenergetic drugs* may be measured by their inhibition of synaptic transmission through sympathetic ganglia. By this criterion epinephrine ranks highest, amphetamine and ephedrine relatively low (A. S. Marrazzi, 1946).

Historical.—Epinephrine is identical with the "*chromaffin substance*" (giving a green color with ferric chloride, and pink with alkalis, iodine or chlorine, and taking up chromium salts; Henle, 1865), which was discovered by Vulpian, 1856, in the medulla of the adrenal bodies, and in association with sympathetic cells elsewhere. The suprarenal medulla is a direct outgrowth of the sympathetic system and consists at first of neuroblasts. The cortex is of mesoblastic origin and does not contain epinephrine, but does contain the cortical hormone, corticosterone and choline (Lohmann, 1907). The pressor action of the medullary substance was discovered by Oliver and Schaefer, 1895, and by Czybulski and Symonovicz, 1895. This was followed by many attempts to separate the active principle. The researches of v. Fuerth, 1898, and particularly those of Abel, paved the way to its isolation in crystalline form, which was first accomplished by Takamine, 1901, Aldrich, 1901, and Abel, 1903. Its structural constitution was determined by Jowett, 1904, and its synthesis accomplished by Stolz, 1904, Dakin, 1905, and Flächer, 1908. Extracts of the *retroperitoneal chromaffin tissue* contain epinephrine or a closely related substance, having the typical action on intestinal and uterine muscle (Fulk and Macleod, 1916). Abel and Macht, 1912, found considerable epinephrine (along with the digitaloid bufagin) in the "parotid glands" of the tropical toad, Bufa agua. It does not occur in the ordinary toad.

Chemical Structure.—Epinephrine is dioxyphenyl (pyrocatechol) ethanol-methyl-amine, $C_6H_3(OH)_2$—CHOH—CH_2—$NHCH_3$. Its structure is related to that of tyrosine, and it may perhaps be derived from this or similar amines in the body.

Action of Isomers.—The natural epinephrine is levorotatory. The synthetic base is racemic. The l-component is identical with the natural base. The dextrorotatory base produces qualitatively the same actions, but has only about a twentieth the potency; the racemic mixture, therefore, has about half the activity of the natural base (Cushny, 1908 and 1909). Froehlich, 1909, claimed that the d-base has a much more persistent action.

Related Sympathetic Substances.—Barger and Dale, 1910, showed that peripheral "sympathomimetic action" is not peculiar to epinephrine, but is shared more or less by a large number of primary and secondary amines, the simplest being the primary fatty amines, such as amylamine. The catechol nucleus is a rather unessential constituent, and the action of catechol itself is not related to that of epinephrine. The intensity and specificity of action increase as the amines approach the composition of epinephrine itself. It is noteworthy that the various sympathetic effects and the augmentory and inhibitory stimulations vary independently in these various amines; nor is there any parallelism between instability and activity. Later work is reported by Raymond-Hamet.

1932, Tiffeneau, 1933, Tainter, 1933, and Hjort, 1934. The latter found only two derivatives truly and consistently sympathomimetic. Changes in the phenolic OH have most marked effects. Ephedrine which lacks these groups is much more stable, acts more directly on smooth muscle and is not sensitized by cocaine. The side chains are relatively unimportant.

Effects on Circulation.—The intravenous injection of epinephrine into a normal animal, with intact vagi, produces striking phenomena due to the interaction of vasoconstriction, vagus stimulation and stimulation of the cardiac accelerator mechanism. The blood pressure rises sharply; as it approaches its maximum, the heart beats are greatly slowed. The sensitiveness of the carotid sinus to blood pressure changes is increased (review, C. W. Darrow, 1943). The pressure is not sustained, but returns quickly to normal. The heart beats also return to their former rate, but more slowly than does the pressure. The blood pressure may rise to a high level, especially if the vagi have been divided or paralyzed. In dogs, it may exceed 300 mm. of mercury. The extent of the rise increases with the dose, but not in simple proportion. The main element in the rise is ordinarily the intense vasoconstriction, for the volume of the organs diminishes as the blood pressure rises. The cardiac stimulation, however, is also an important factor, and sometimes is the more important.

Relation of Dosage to Rise of Blood Pressure.—With intravenous injection in atropinized dogs, this is somewhat as follows (from the data of Hunt, 1901, and others): 0.00008 mg. per kilogram = rise of 5 mm.; 0.00025 = 7 mm.; 0.0005 = 15 mm.; 0.0007 = 20 mm.; 0.0017 = 25 mm.; 0.004 = 45 mm.; 0.006 = 66 mm.; 0.03 = 150 mm. The degree of rise diminishes as the initial blood pressure rises, so that the response obeys the Weber-Fechner law (D. M. Lyon, 1923).

Double Peak of Blood Pressure.—A typical blood pressure curve after large doses of epinephrine (1½ to 1 cc. of 1:10,000, by vein) shows (1) a first rise, due essentially to the peripheral vasoconstriction action; (2) a first fall, interpreted as a beginning relaxation of this peripheral constriction; (3) a slight second rise, attributed to stimulation of the vasomotor center, superimposed on the residual peripheral vasoconstriction, for this peak does not occur after decapitation or high section of the cord (McGuigan and Hyatt, 1918); (4) the final fall, probably due to impurities (Weidlen, 1912), presumably mainly choline (Hunt).

The venous pressure is not altered by small doses; it rises with large doses which embarrass the heart (Capps, 1911 and 1913). The rise is due to back pressure from the arterial constriction and not to the contraction of the veins (Burton-Opitz, 1922); which epinephrine also produces. The rise of vein pressure has also been observed in normal men, after the hypodermic injection of 0.4 to 1 mg. of epinephrine (G. Rosenow, 1920).

Velocity of Blood Flow.—Microscopic observation of the mesenteric vessels in living cats shows this to be increased in the arteries for twenty to thirty minutes after intravenous injection of 0.02 mg. of epinephrine. In the capillaries it was increased for five to seventy-five seconds and then decreased for seventy to 225 seconds (Kisch, 1928). The strong constriction in perfusion experiments slows or arrests the flow.

Cause of the Brief Action of Epinephrine.—When epinephrine is injected intravenously, the effects disappear within a few minutes after the injection ceases. This goes parallel with the disappearance of epinephrine from the blood, and is due to the rapid destruction of the substance. Epinephrine is readily oxidized and thus rendered inactive. The oxidation occurs presumably in many tissues, including the blood, but with different velocity. The blood vessels and especially the liver probably have the largest share. The vessels continue to respond practically uniformly and indefinitely to whatever epinephrine may be present in the blood. Its effects may therefore be repeated by repeating the intravenous injection, and they may be rendered continuous by continuous infusion. A uniform infusion maintains a uniform moderate rise of blood pressure for a considerable time.

Differences According to Methods of Administration.—Epinephrine produces practically no systemic effect when administered by mouth, and is uncertain by rectum (Hoskins, 1921), so that it evidently does not pass readily through the epithelium. It is much less effective by hypodermic or intramuscular injection, or from the serous cavities, than it is by intravenous injection. These differences are due to the rate of absorption, and this in turn to the vasoconstriction. With subcutaneous injection, the vasoconstriction may be so complete that the epinephrine must enter mainly through the lymphatics (D. M. Lyon, 1923). The richness of the local vascular supply is an important factor (Fornet, 1922). The interference is less with intramuscular and peritoneal injections (Lappom, 1915) and with intradural injections (Auer and Meltzer, 1918). Injection under pressure in the nasal submucosa may be almost equivalent to intravenous injection (Pilcher, 1914). The placenta appears to be impermeable to epinephrine injected into the mother (Shimidzu, 1920). The unabsorbed epinephrine at the site of the injection is apparently not destroyed, for the local blanching may persist for one to eight hours (root of rabbit's ear, Meltzer and Auer, 1921; scarified skin, Sollmann and Pilcher, 1917). When this epinephrine becomes gradually absorbed it exerts its systemic actions, and the product of degree times the duration of action is not much less than with intravenous injection (Fornet, 1922; Lyon, 1923). The rate of absorption after hypodermic injection may be increased by *massage* (Luckhardt and Koppanyi, 1926). The absorption is slower if the epinephrine is dissolved in oil. This may be utilized when a prolonged action is desired, as in chronic bronchial asthma (Keeney *et al.*, 1939).

The *blood pressure response in man* is usually practically unchanged on oral administration, but marked reactions may occur (Menninger, 1925). Hypodermically, 0.5 to 1.5 mg. give uncertain results, usually a rise of 10 to 12 mm., rarely higher (to 45 mm.). The same doses intramuscularly give a more constant and higher rise, usually 8 to 25 mm., but sometimes much higher, over 90 mm., so as to produce alarming symptoms (Halsey, 1909). In patients with *arterial hypertension,* 1 mg. hypodermically usually lowers the systolic pressure slightly for half an hour, and the diastolic pressure somewhat longer (A. H. Elliott and Nuzum, 1935). Auer and Gates, 1915, found that *intratracheal injection* of epinephrine produces a prompt rise of blood pressure, presumably by aspiration and absorption from the alveoli. If the vagi have been divided, fatal pulmonary edema often follows. This may be prevented by atropine. S. Weiss and Magasay, 1927, recommended intratracheal administration to relieve asthmatic attacks. Even severe paroxysms can be relieved by carrying epinephrine through the skin by *electrophoresis* (H. A. Abramson, 1939). H. Heller, 1933, reports that *cisternal injection* of epinephrine does not affect the blood pressure. *Lumbar injection* of epinephrine may cause muscular spasm and tremor. Injection under the dura or into the substance of the *cerebrum* produces an apparently natural sleep, lasting two to five hours, with regular respiration and reflexes, and fall of temperature (Bass, 1914). Bass does not believe that these effects can be explained by vasoconstriction. *Oil suspension of epinephrine* on intramuscular injection has about the same toxicity as aqueous solution. The onset of symptoms (blood sugar rise, pupillary dilatation and others) is generally delayed with oil, but the duration is not lengthened (B. K. Richards, 1943).

The disappearance of epinephrine from the blood stream after intravenous injection closely parallels the return of the blood pressure (D. E. Jackson, 1909; Trendelenburg, 1910). About 75 per cent disappears from the blood within fifteen seconds after the injection (Weinstein and Manning, 1937).

Persistence of Action if the Concentration of Epinephrine is Maintained.—In excised kidneys, the perfusion flow may be arrested for a long time, sometimes for hours, by a single injection of epinephrine. The stimulation does not give way to "fatigue" or to depression, no matter how much epinephrine is used. In living animals, *repeated injections* of the same dose, in the same animal, give quantitatively the same pressor effect (Bayac, 1905), for at least twenty successive injections (Kretschmer, 1907). Sufficient time must elapse between injections for the circulation to return to normal; otherwise, there will be superposition. *The uniformity of response is not unlimited:* Froehlich and Pick, 1912, found that if large doses are given in rapid succession, the rise becomes less pronounced and finally disappears, although the blood pressure may remain normal. This is perhaps due to an altered distribution of the blood, for Froehlich, 1910, found that a single dose of d-epinephrine, which has a much more prolonged action, may abolish the response to ordinary l-epinephrine. *Epinephrine is not an antigen:* No antibody is produced, even if the (hypodermic) injections are continued over three months (Elliott and Durham, 1906); nor is there any habituation (Pollak, 1910).

Continuous intravenous injection maintains the pressure rise uniform as long as the rate of injection is uniform (Kretschmer, 1907). The blood pressure level rises as the rate of injection is increased, from the minimal effective dose until a maximum is attained. In rabbits, this occurs when the rate of injection corresponds to about 0.01 mg. per kilogram per minute. Up to this point, the destruction must keep step with the injection, else the rise would be progressive. Further injection produces no further rise, but, when the injection is arrested, the return to normal is inverse to the rate at which the epinephrine has been introduced, since it takes a longer time to destroy the excessive epinephrine. L. R. Dragstedt *et al.*, 1934, continued the injection up to fifteen days in unanesthetized dogs. The blood pressure rise was sustained, but gastrointestinal inhibition developed and proved fatal. Samson, 1932, who had also continued the injection into dogs up to thirteen days, found consistently intracellular fatty changes in the liver and in the Henle loops of the renal tubules and altered staining reactions in the anterior hypophysis and in the adrenal cortex. Continuous injection of excessive doses results in shock (N. E. Freeman *et al.*, 1941).

Response of Blood Pressure and Intestines in Unanesthetized Dogs.—Continuous injection raises the blood pressure with smaller doses than are required to inhibit the intestines (C. A. Dragstedt, 1928), but in unanesthetized dogs the intestines may be more sensitive (Dragstedt and Hoffmann, 1928).

Continuous Injection in Normal Human Subjects.—A. E. Koehler *et al.*, 1937, found that 1:50,000 solution of epinephrine injected intravenously at the rate of 2 mg. per hour maintains a uniform rise of systolic blood pressure averaging 51 mm. Hg. The diastolic pressure usually drops below that of the control period. The oxygen of the venous blood is higher, indicating more rapid blood flow, and the skin temperature rises when the injection has lasted an hour, the basal metabolic rate has risen 29 per cent on the average, the blood sugar 141 mg. per cent, and the blood lactic acid 22.3 mg. per cent. When the injection is stopped, the systolic and diastolic pressure drops in a few minutes below the initial control period, but the skin temperature continues to rise, and also the venous oxygen saturation. *Patients with essential hypertension* reacted similarly to basal metabolic rate and blood sugar, but the blood pressure rise averaged higher, with greater and more lasting drop after stopping the injection. *Continuous intravenous injection of epinephrine* can be maintained for days in patients, injecting 1:750,000 solution of epinephrine in saline, at the rate of 20 to 200 drops per minute (M. Friedemann, 1919).

Fate of Epinephrine.—The brief action of epinephrine with intravenous injection is due primarily to its rapid diffusion out of the blood stream, then to its rather slow oxidation in the tissues generally and to a slight extent in the blood.

Excretion plays an insignificant share, for only traces are found in the urine even after large injections (von Fuerth), and the pressor effects disappear even when access to the excretory organs is prevented by clamping the aorta (Jackson, 1909). After oral administration, if precautions are taken to prevent oxidation in the alimentary tract, up to 70 per cent of the epinephrine is excreted by the urine as conjugated derivatives (D. Richter, 1940).

The *oxidation of epinephrine* presents some confusing phenomena (review, K. H. Beyer, 1946). It occurs readily if the saline solution is exposed to air; but quite slowly in the blood and tissues, where it is protected by ascorbic acid and proteins or amino acids (Bacq, 1937), and perhaps other substances (R. G. Smith, 1937), so that it requires enzymatic activation by either amino-oxidase or phenolase, perhaps after demethylation to nor-adrenaline. Some organs inactivate epinephrine by specific enzymes (Rico and Baptista, 1935).

Oxidation may occur in the ortho OH group; or by forming esters in these groups; or by oxidative de-amination of the side chain. It is not known which predominates.

The *phenolase oxidation* (*in vitro*) results first in the red crystallizable *adrenochrome* (D. E. Green and Richter, 1937). This is inactive pharmacologically. It is fairly unstable and can act as a reversible redox system. Its formation is hastened by cytochrome and somewhat by methemoglobin, but it is doubtful whether epinephrine plays a significant part in cell oxidation under physiological conditions.

Tyrosinase oxidation of adrenochrome produces a colorless substance, *adrenoxine*, known only by its properties. It is highly mydriatic, dilates blood vessels, and inhibits the heart and the intestines. It is not modified by atropine, ergotamine or F 933, but is sensitized by cocaine (Heirman and Goddart, 1939). It is also formed when epinephrine is incubated with smooth muscle (Heirman, 1938). Further oxidation *in vitro* results in active *melanins*. These products are also formed when watery or saline solutions of epinephrine undergo spontaneous oxidation (review, Jeanne Lévy, 1939). The oxidation of epinephrine by epinephrine oxidase takes an entirely different course which does not produce adrenachrome and adrenoxine. *Spontaneous oxidation of epinephrine* is especially prompt in dilute and alkaline watery and saline solutions (B. Moore, 1895) with the succession of changes in color and actions that was described for the phenolase oxidation.

Destruction of epinephrine in living tissues proceeds slowly, for instance with subcutaneous injection, or when it is perfused through rabbit's *ear* (A. D. Steinberg, 1935), or through the liver or other abdominal viscera. Gioffredi, 1907, reported the rate of epinephrine destruction especially high in perfused liver. Later investigators, however, found a practically normal rate of pressure fall in animals in which the liver, kidneys, spleen and all the abdominal organs had been removed (Markowitz and Mann, 1929; Weinstein and Manning, 1937). Kretschmer, 1907, found that the destruction *in vivo* is hastened (*i. e.*, the action is shortened) by lessening the alkalinity of the blood by the injection of acids; and *vice versa.*

Blood in vitro has a curiously slow destructive effect, so that the activity is preserved for many hours (Oliver and Schaefer, 1895); indeed, small quantities of serum retard the destruction materially (Schwerschnikoff, 1913), probably by the reducing action of amino acids, glutathione and ascorbic acid (A. D. Welch, 1934). The inactivation in blood or serum is never complete, but proceeds to an equilibrium. It may be completed by adding liver or other tissues (W. A. Bain *et al.*, 1937). Cerebrospinal fluid destroys epinephrine much more rapidly than does serum (Meltzer, 1911).

The *accelerating effect of tissues* is due to phenolase (Blaschko *et al.*, 1937; D. Richter, 1937), and goes through the stages and actions sketched above, which occur also in the spontaneous oxidation of epinephrine solutions. *Sympatholytic drugs* are supposed to accelerate the oxidation (Heirman, 1938; Bacq, 1938; Lissak, 1938; Goffart, 1939).

Formaldehyde and acetaldehyde (not glyceric aldehyde or methyl glyoxal) promptly inactivate epinephrine through its amido group. This action is catalytic and requires the presence of oxygen; it is not prevented by ascorbic acid (J. Cramer, 1911; G. Bayer and Wense, 1938; Malafaya-Baptista and Toscano-Rico, 1935).

Action on Blood Vessels.—The powerful vasoconstriction is the main factor in the rise of blood pressure, for the organ volume and the outflow of blood from veins are diminished. The site of action is almost entirely peripheral, for the rise occurs if the central nervous system has been destroyed; the perfusion flow through excised organs is slowed or arrested (Bier, 1897); and rings of excised artery contract if placed in epinephrine solutions (A. B. Meyer, 1907). The vasomotor center is not usually affected directly; it may respond indirectly, generally by constriction, to the increased pressure; occasionally by dilatation, when the increased blood supply relieves a preexisting asphyxial stimulation (Pilcher and Sollmann, 1915). The sympathetic constriction involves the smooth muscle in arteries, veins and capillaries. Its intensity varies with the relative abundance of the muscular tissue; it is therefore more intense in the arterioles. Important differences exist also in the susceptibility of the vascular area, presumably according to the development of their sympathetic receptive mechanism. The maximum constriction occurs in the splanchnic vessels, especially the kidneys, and in the vessels supplying voluntary muscles and mucous membranes. The constrictor action is weak in the coronary, cerebral and pulmonary vessels; and in the intact animal these vessels are passively dilated by the displacement of blood from the more powerfully constricted areas. Certain vessels are *dilated directly* (Cow), for instance the coronary in man. In others, dilatation occurs only with very dilute solutions, or under special conditions, late in the course of prolonged perfusions, or when the vascular tone is already high. The reactions are also influenced by the presence of other vasomotor drugs. The constriction of susceptible vessels persists as long as effective concentrations of epinephrine are present. Even *very large doses* of epinephrine (7000 times the effective quantity) do not paralyze the vasomotor mechanism. As to *other aromatic amines*, the pressor action in decerebrated animals is greatest with catechol compounds, less with phenol compounds, and least with phenyl compounds (Crismon and Tainter, 1939).

Comparison of Epinephrine Derivatives.—M. L. Tainter (review, 1941) grades these as follows, in descending order of efficiency: *Cardiovascular action on intravenous injection:* Epinephrine > cobefrine > neosynephrine > ephedrine > propadrine. *Adjuvant to local anesthesia:* Epinephrine, 1:50,000, equals cobefrine, 1:10,000, or neosynephrine, 1:2,500. *Decongestion of mucosae:* Prefers ephedrine, 1 to 3 per cent, or neosynephrine, $\frac{1}{4}$ per cent.

Arterial rings are suspended in oxygenated Ringer's solution (A. B. Meyer); better results are obtained if a careful technic is followed (Rothlin, 1921). Epinephrine constricts most arteries, but relaxes some, for instance the pulmonary vessels (Rothlin). The response is usually much greater with a second exposure of the washed artery. This holds true also for other vascular drugs (Rothlin). Epinephrine favors the occurrence of *rhythmic contractions* in the arterial rings. These may also be evoked by other conditions that raise the tone of the arterial muscle, by muscular stimulants (Wachholder, 1921); by oxygen (Helene Friedmann, 1920); and by distention (Bayliss). They are abolished by muscular depressants and by carbon dioxide.

Direct Effect on Veins.—Gunn and Chavasse, 1913, showed that excised veins also react by constriction, although this does not apply to all veins (Crawford and Twombly, 1913). Segments of the superior vena cava, near the heart, enter into rhythmic pulsations. Domenjoz and Fleisch, 1939, studied the responses of perfused veins to drugs with reference to the relation of action to chemical structure. (Active contraction of the veins has also been demonstrated *in situ* by stimulation of the efferent nerves; by reflexes and by asphyxia; Hooker, 1918.)

Perfusion of organs is usually demonstrated on the hind legs of the frog (Laewen-Trendelenburg), but the ear of the rabbit or any mammalian organ may be used to illustrate differences in the reactions of various areas. Morton and Tainter, 1940, compared a series of sympathomimetic amines on perfused cat leg. Epinephrine and other constricting drugs slow or arrest the outflow; nitrites and other dilating drugs quicken the flow. The method is delicate, but is somewhat complicated by the formation of edema. Continued perfusion with Ringer's solution increases the sensitiveness, perhaps by washing out excess acid from the muscles (Alday-Redomet, 1920). Frog legs three days old and distinctly putrid continued to respond to epinephrine. *Prolonged perfusion with epinephrine* may alter the response of the frog legs so that they tend to react by dilatation to increased concentration of epinephrine, and to histamine and pituitary; but preserve their constrictor response to barium, strophanthin and nicotine. Epinephrine thus becomes antagonistic to barium (Bauer and Froehlich, 1918).

Microscopic Examination.—In the frog's foot, epinephrine may be seen to constrict especially the arterioles, and to antagonize local vasodilators, such as sodium barbital (W. Jacobi, 1920). Krogh, 1919, and his pupils and others (Carrier, 1922, and so on) have shown that the capillaries are also involved, and Krogh observed that the action is on the smooth muscle fibers that are sparsely scattered over the capillaries and serve as sluices. They are generally constricted, but may be unaffected or dilated according to the organ and species.

Dilator Action of Epinephrine.—This is the predominant response of certain mammalian vessels (D. Cow, 1911), but may occur in others under special conditions, especially with very dilute concentrations; late in the course of perfusions; and particularly when the vascular tone is already high (Brodie and Dixon, 1904; Ogawa, 1912). In unanesthetized animals, the injection of epinephrine at the estimated rate of normal secretion tends to *raise* the blood pressure (C. A. Dragstedt, 1928). Increase of temperature diminished the contractor response, and at 41° to 45° C. reversed into dilatation. *Frog's vessels* do not show dilatation with dilute solutions, or with increase of temperature, but only in the absence of calcium or after *degeneration of the nerves* (Pearce, 1913). In the *ear of the living rabbit*, the constriction is followed by dilatation, especially on the succeeding day (Meltzer and Auer, 1921). The vessels of the *denervated ear* were said to dilate with doses that are constrictor for the normal ear (Engeloch, 1915), but Meltzer and Auer, 1921, could not distinguish any special difference after denervation.

Cannon and Lyman, 1913, reported that small doses either raise or lower the blood pressure, according to its previous level, and adduce evidence that the lowering is due to a direct dilator action on constricted arterial muscle. The fall occurs after ergotoxine. The dilator reaction is confined mainly to the vessels of the legs, for the fall of pressure which occurs with normal cats (0.002 mg.) occurs also if the splanchnic vessels are ligated, but is replaced by a rise if the splanchnic vessels are intact and the important peripheral trunks ligated (Hartmann, 1915). The dilator reaction fails if the vessels are already relaxed, as by hemorrhage or depressor stimulation. However, Swetschnikoff, 1914, on isolated rabbit's ear, observed the same constriction, whether the pressure was high or low. The vasodilator effects observed in living animals are due partly if not solely to *direct action* on the vascular muscles, for they may occur after complete degeneration of their nerves (Dale and Richards, 1918). In cats the dilator reaction is developed to the full degree only eleven weeks after birth (Hartmann and Kilborn, 1918).

Therapeutic application of the local vasoconstriction is made for the control of capillary hemorrhage, for the relief of congested mucous membranes and to diminish the absorption of local anesthetics.

Epinephrine as a Local Hemostatic.—Solutions of 1:50,000 to 1:1000 arrest capillary hemorrhage in any situation to which they can be applied locally, especially in nasal and laryngeal operations. The dilutions must be freshly prepared, since they lose their activity in a few hours. The action persists as long as the epinephrine is present; but when this has disappeared there is often secondary hemorrhage, if the clot fails to adhere to the dilating vessel. Ephedrine is less liable to such accidents, since its constriction passes off much more slowly. Epinephrine is of little use against venous, and still less against arterial, hemorrhage (Hanzlik, 1918). With high concentrations, the intense and persistent ischemia may cause tissue injury, with delayed healing and even necrosis (Hrubetz, 1933).

On inflamed mucous membranes, epinephrine gives relief by contracting the dilated vessels. It is used in catarrhal conditions, *e. g.*, in *conjunctivitis* and especially in *hay fever*, and to widen the nasal air channel and the entrance of the *sinuses*.

Oily solutions or ointments, containing $\frac{1}{10}$ per cent of the free alkaloid, prolong the action. Epinephrine is nonirritant, but its action is brief, and it is claimed that its continued use has caused chronic turgescence of the mucous membrane (J. N. Hall, 1910). Vasoconstrictors are useful in surgical procedures and in acute sinusitis, but they are reported to lengthen the course of acute rhinitis and to increase the incidence of sinus and ear complications. Allergic vasomotor rhinitis is said to be made more severe by them (B. M. Kully, 1945). Concentrations stronger than 1:4000 should not be used on the conjunctiva, as 1:1000 causes an unpleasant sensation of muscular spasm (Fantus). Against *hemorrhoids* it may be used in suppositories: 1 mg. ($\frac{1}{16}$ grain) of the alkaloid in 1 Gm. of Theobroma oil.

Skin Reaction to Epinephrine.—The intracutaneous injection of epinephrine (a drop of 1:100,000) produces intense blanching and "gooseflesh," persisting for several hours (Sollmann and Pilcher, 1916). The blanching occurs though the circulation of the skin has been obstructed, so that the action must involve the capillaries (Cotton *et al.*, 1916). It was claimed that modifications of this reaction occur in "hyperthyroidism" (Goetsch), but they are not characteristic and are seen in 20 per cent of normal individuals (van Wagenen, 1922).

Differences in the Response of Vascular Areas.—The reaction of different vessels to epinephrine varies quantitatively and somewhat qualitatively, depending on the sympathetic susceptibility. In cats and rabbits, doses large enough to raise the blood pressure cause constriction of the skin vessels and dilatation, chiefly passive, of the arterioles, of the muscles and intestines.

Direct dilatation is revealed by perfusion of excised arteries. The arterioles of the skeletal muscles are dilated by small and constricted by large doses. Those of the skin, bone and spleen are not dilated by any dose. The reactions of other important areas are complex (Rothlin, 1921). When injected directly into the human *brachial artery*, 0.0001 to 0.3 mg. of epinephrine produces constriction of the vessels of the hand and arm with pallor and coldness, similar to Raynaud's disease. It is not effectively antagonized by mecholyl. Amphetamine produces systemic but no local effects (Myerson *et al.*, 1938).

The effects on coronary circulation have been studied extensively. The results appear confusing, partly because the direct action varies in different animals; partly because it is not very strong, and is therefore easily complicated by indirect effects and by differences in experimental methods. Clinically, it probably causes coronary constriction in most cases, and reduces the flow.

Excised coronary arteries respond to dilatation in most mammals, but by constriction in man and monkeys (Barbour, 1912; Barbour and Prince, 1915; Park and Janeway, 1912; and others). *Perfusion of the arrested heart* may cause either dilatation (Elliott, 1905) or weak constriction (Wiggers, 1909). Katz and Lindner, 1939, report dilatation in arrested dog heart, sometimes preceded by slight constriction.

In the beating heart, the coronary flow is increased in most species of animals (excised hearts, Wiggers; Markwalder and Starling, 1913; not in monkeys, Barbour and Prince, 1915) because of the pumping action of the contracting cardiac muscle. In the intact animal, this occurs even if the blood pressure is kept level by hemorrhage (F. Meyer, 1913); and the increase would be still greater if the blood pressure, and therefore the coronary pressure, were allowed to rise (Bond, 1911). In *anesthetized dogs*, epinephrine injection increases the coronary flow, much more than would correspond to the rise of aortic pressure, indicating a weak dilator action on the coronary arteries. This tends to supply the increased metabolic requirements of the augmented heart action; but may not always be adequate to prevent angina (H. D. Green, Wégria and Boyer, 1942). A vasoconstrictor effect on the coronary vessels can be discerned in the excised heart only with doses which are too small to affect the cardiac muscle (Brodie and Cullis, 1911). In the *monkey*, however, and therefore presumably in man, the conditions are different. All doses slow the coronary flow of the excised monkey heart, whether this is beating or resting (Barbour and Prince, 1915). The coronary effects of epinephrine were also studied by Anrep and Stacey, 1927; Ducret, 1930; F. M. Smith *et al.*, 1926.

After experimental occlusion of a coronary branch in dogs, epinephrine and synephrine do not effectively increase the *collateral circulation* (Wiggers and Green, 1936).

The pulmonary vessels show weak vasoconstriction (A. S. Dale and Narayana, 1935). Tribe, 1912, attributed the negative results reported by some investigators to the dilator effect of the chloretone in certain commercial solutions. Barbour, 1912, found that the reaction of arterial rings varied according to their situation; the intravisceral portion of the artery did not react; the extravisceral portion was constricted.

Pulmonary Circulation in Living Animals.—Epinephrine generally causes a large rise of pressure in the pulmonary artery (Wood, Jr., 1911). The response is complex, depending on the species, as well as on dosage and other conditions. With *dogs* and *cats* the cardiac stimulation tends to predominate, so that the pressure rises in both the pulmonary and systemic vessels (Schaefer and Lim, 1919). The volume of the blood in the lungs increases (Anderes, 1915) and the pulmonary circulation is quickened, with moderate doses. Large doses delay the circulation time (Langlois and Desbouis, 1912), either by injury of the heart or by constriction of the pulmonary vessels. When *cardiac dilatation* occurs, the diminished efficiency of the heart causes a further rise of the pulmonary pressure with falling arterial pressure (Hallion and Nepper, 1911). This favors the production of *pulmonary edema.*

Portal vessels are markedly constricted on perfusion, in mammals and frogs (Berezin, 1914), as also in intact animals (Burton-Opitz, 1913). The response is much greater than that to electric stimulation of the nerves (Macleod and Pearce, 1914). Edmunds, 1915, confirmed the constrictor effect on excised portal vein.

Cerebral Vessels.—In *man*, small doses of epinephrine first diminish and then increase the brain volume (Raphael and Stanton, 1919). The dilatation is probably passive. In *animals*, Wiggers, 1914, found constriction; Berezin, 1916, observed constriction, but requiring higher concentration than for peripheral vessels; Dixon and Halliburton claim dilatation. Cow observed slight relaxation of arterial rings. There is undoubtedly passive dilatation in the intact animal (Biedl and Reiner, 1905). The vessels of the pia and retina are constricted (Hirschfelder, 1915). By direct microscopic examination in unanesthetized living animals, Cachera and Fauvert, 1936, observed dilatation of the arterioles by 10 to 45 per cent, and of the veins by 15 to 20 per cent, on intravenous injection of epinephrine. The brain volume increased.

The **renal vessels** appear to be highly sensitive to epinephrine, so that doses too small to affect the general blood pressure diminish the volume of the kidneys and slow their vein flow (Hoskins and Gunning, 1917). Somewhat larger doses may cause dilatation (Ogawa, 1912), which is passive, for if the blood pressure is kept level all concentrations produce constriction (Ozaki, 1927). Ordinary doses diminish the kidney volume. Perfused kidneys are constricted; but if the sensitiveness of the vessels has been dulled by prolonged exposure, they may respond with dilatation (Sollmann, 1905). Direct microscopic inspection of the frog kidney shows swelling of the glomerular vessels when small doses are injected; and shrinkage with larger doses (Richards and Schmidt, 1924). The swelling of the glomerular tufts occurs also if the blood flow is kept constant (A. N. Richards, Barnwell and Bradley, 1927), indicating constriction of the efferent vessels, and thus increased filtration pressure. It has been contended that glomerular filtration in various conditions is regulated almost entirely by the efferent arteries, but the evidence is not clear, and it appears more probable that the afferent arteries may also play a part (H. Lamport, 1941)

Urine Flow.—Small doses of epinephrine, which increase the kidney volume, increase the urine flow (Bardier and Frenkel, 1899; Ogawa, 1912). The diuresis is aided by hyperglycemia (Biberfeld, 1897). The intravenous injection of ordinary doses ($\frac{1}{20}$ mg. per rabbit) diminishes the urine flow and the renal vein flow in direct proportion to the rise of blood pressure (Cushny and Lambic, 1921). Hypodermic injection of large doses (2 mg. per rabbit) produces a strong diuresis that lasts for several hours (Biberfeld, 1907). It is independent of the glycosuria (Konschegg, 1912). In *anesthetized dogs*, intramuscular and slow intravenous injection result in polyuria; rapid intravenous injection causes oliguria with protein in the urine (Toth, 1937).

Cerebrospinal Fluid.—The secretion is not affected, the pressure varying merely with the blood pressure changes (Dixon and Halliburton, 1916; Weinberg, 1933).

Lymph Secretion.—The thoracic lymph flow increases parallel to the rise of arterial pressure; the effect, therefore, is apparently circulatory (Yanagawa, 1916).

Synergisms and Antagonisms.—The actions of epinephrine and the related bases, ephedrine, tyramine, and the like, are altered by conditions, including other drugs, and often show potentiated synergism and antagonism, sensitization and desensitization, and reversal of the normal responses. The modification of the blood pressure reactions is especially characteristic: Previous injection of ergotamine or ergotoxine and of certain dioxane derivatives prevents the response to epinephrine, so that this causes a fall, while cocaine sensitizes to the pressor action. With ephedrine, the corresponding dosage of ergotamine has little effect, and cocaine diminishes and may even reverse the pressor response of ephedrine and tyramine (Tainter, 1929).

Other sympathomimetic amines exhibit various modifications of these synergisms and antagonisms (Raymond-Hamet, 1930, 1931; Schaumann, 1930).

Epinephrine and ephedrine show considerable potentiation on mammalian blood pressure, frog vessel perfusion, and on the uterus. On the other hand, ephedrine may contract a uterus which has been inhibited by epinephrine (O. Schaumann, 1928).

Ergotamine or Ergotoxine Antagonism.—The cause of the actual lowering of blood pressure by epinephrine, after the injection of ergot, the "vasomotor reversal" (Dale, 1905; Sollmann and Brown, 1905), has not been established. It lasts only for a few minutes (E. Polak, 1926). Ergotamine is relatively ineffective against the *ephedrine* rise, and does not cause reversal (De Eds and Butt, 1927), unless the dose of ephedrine is small (Curtis, 1928). The antagonism to epinephrine is also less marked in the *other organs;* for instance, as regards bronchial dilatation (Swanson, 1929). *Anesthetics* markedly influence the vasomotor reversal by ergotamine: This occurs under ether or urethane anesthesia; but in barbiturate anesthesia, ergotamine reinforces the epinephrine rise, in cats and dogs (Herwick *et al.*, 1938). *Quinine and quinidine*

(3 mg. per Kg.) produce vasomotor reversal to epinephrine and to splanchnic stimulation, in dogs and cats; and reversal of the epinephrine stimulation in rabbits' uterus, but they are additive to the relaxing effects of the epinephrine on virgin cat uterus. Most of the other actions of epinephrine are not affected by quinine or quinidine (E. E. Nelson, 1928). *Yohimbine* acts somewhat like ergotoxine, producing blood pressure reversal in dogs toward epinephrine, but only weakening the pressor response to ephedrine (Raymond-Hamet, 1927, 1931). *Corynanthine*, an isomer of yohimbine, occurring in Pseudocinchona africana, has double the sympatheticolytic potency of yohimbine. As local anesthetic it is but an eighth as potent. It is also antipyretic (C. C. Scholz, 1935). *Gambirine* occurring in a Rubiaceous plant is likewise sympatheticolytic (Rothlin and Hamet, 1935).

Cocaine Sensitization and Desensitization.—Cocaine, in doses which have no effect by themselves, greatly increases the response to some of the augmentory reactions of epinephrine, and inhibits others (Froehlich and Loewi, 1910; von Fischel, 1915). The modifications for ephedrine and tyramine are quite different (De Eds, 1927).

The cocaine synergism is probably explained by inhibition of epinephrine oxidation. Cocaine, procaine, stovaine, butyn and percaine all potentiate epinephrine, and all inhibit amine oxidase of rat and guinea pig liver, cytochrome oxidase and catechol oxidase (Philpot, 1940) and phenol sulfur esterase (C. Torda, 1943). The influence of cocaine on some of the principal organs is as follows: *Heart and blood-vessels:* increase of the augmentory response to epinephrine, decrease to tyramine and ephedrine; *uterus* of nonpregnant cat: diminished inhibition by epinephrine and tyramine; *intestines:* diminished inhibition by tyramine, varying effects on epinephrine; *denervated iris:* increased dilator response to epinephrine, not to tyramine or ephedrine; *bronchial dilatation:* increased for epinephrine, decreased for ephedrine and especially for pseudo-ephedrine. *Cocaine alone* dilates the blood vessels of perfused limbs; stimulates the virgin cat uterus and cat intestine; and has no effect on isolated auricle (Burn and Tainter, 1931). *Strychnine* is reported to sensitize to epinephrine similarly to cocaine (Martinetti and Marri, 1939).

The dye *thionin* has no effect on the blood pressure of normal animals, but causes a rise if the animal has had epinephrine within twenty-four hours previously (Gautrelet, 1921).

Parasympathetic drugs generally give simple algebraic summation with epinephrine. *Atropine* antagonizes the epinephrine constriction in frogs, although it has no direct effect alone, nor does it antagonize barium (Hildebrandt, 1920). *Acetylcholine*, like epinephrine, constricts the frog vessels when perfused alone; but the two together produce dilatation (Kolm and Pick, 1920).

Nonspecific Drugs.—Nitrites, caffeine, histamine and sometimes pituitary, antagonize the epinephrine rise. The effect of *nitrite* is almost quantitatively additive. In perfused frog vessels, epinephrine is balanced by one hundred to two hundred times its weight of nitroglycerin (Gramenitzki, 1930). *Caffeine* antagonizes epinephrine in doses which are ineffective on the normal vessels (Sollmann and Pilcher, 1911). Mutual antagonism with *histamine* and *pituitary* was described by Lhosia, 1920. Others found simple summation of the pressor effects with pituitary (Hoskins, 1915). Pituitary injection does not increase, but rather diminishes, the epinephrine hyperglycemia (Stenstroem, 1914). *Sodium bisulfite*, 0.1 to 0.2 per cent, materially increases the toxicity of intramuscular injections of epinephrine, neosynephrine and procaine, presumably by checking their detoxication. It has no effect on ephedrine (R. K. Richards, 1943). *Barbiturates* are reported to augment the vasoconstriction (Busquet and Vischniac, 1938). *Apocodeine* antagonizes the epinpehrine constriction (Brodie and Dixon, 1904). *Spleen extract*, intravenously, increases the pressor response to epinephrine (Collip, 1920). Lendle and Pühlmann, 1939, studied the effect of the *concentration* of various substances on the epinephrine-sensitivity of perfused rabbit ear. They found the response reduced by vasodilating concentrations of narcotics, antipyrine, quinine and caffeine, while capillary poisons, arsenic and borates, reduced the epinephrine response in concentrations which do not cause much change when used alone; adenyl, nitrites and possibly barbiturates required more than dilating concentrations to decrease epinephrine response.

Ion-Ratio.—The constrictor response of the perfused ear of rabbits to epinephrine is increased by reduction of the *calcium* concentration and decreased by either excess or absence of calcium. Changes in *potassium* concentration have little effect (Masago, 1928).

Synergism with Thyroid.—Thyroxin, which by itself evokes no reaction of the blood vessels, sensitizes them to the constrictor action of epinpehrine and to the dilator response of stimulation of the depressor nerve. The epinephrine synergism may also be produced by stimulating the thyroid secretion through the superior laryngeal nerve, or through the cervical sympathetic; but it is local, for it occurs in perfused organs. The pupillodilator reaction is not sensitized (Asher and Flack, 1911; Santesson, 1918). The quantitative reactions of the skin, of metabolism, and the like, to epinephrine have been proposed as tests of "hyperthyroidism," but no constant relations have been established.

Central vasomotor stimulation, pressor or depressor, electric or by nicotine, is diminished or abolished by epinephrine (Oliver and Schaefer), independently of the level of blood pressure (Hoskins, 1915). *Decrease of blood volume* by *hemorrhage, shock or deep ether anesthesia* diminishes the response to epinephrine, and this may be restored by transfusion (Rous and Wilson, 1919).

Cardiac Effects.—In intact animals these are complicated by the vasomotor phenomena. The pulse rate is sometimes slowed, in response to the rise of blood pressure; but the heart tends to escape from the inhibition and to be greatly quickened by direct stimulation of the accelerator receptive mechanism. If the vagi have been previously divided, epinephrine produces pure acceleration with increase of the auricular, and still more of the ventricular, efficiency (Wiggers, 1916). At the same time, epinephrine has injurious effects on the heart muscle, which may produce ventricular fibrillation and cardiac dilatation if the dosage is excessive or the heart hypersensitive.

Electrocardiograms.—In human subjects, normal or with "irritable hearts," 0.5 mg. of epinephrine, intramuscularly, decreases somewhat the height of the T wave. The conduction time is not altered (Clough, 1919). In *complete heart block,* epinephrine quickens and strengthens the ventricles and auricles (van Egmond, 1913). Clinically, the acceleration occurs without changing the block; it is often interrupted by long pauses with syncope and may be followed by several days of extreme retardation (Lutembacker, 1921).

On perfusion through excised mammalian or cold-blooded hearts, the most conspicuous results of the ordinary experimental dosage consist in marked increase of the rate, excursions and irritability. Existing irregularities are removed, and the effects of muscular depressants are counteracted (aconite, MacNider; strychnine, Januschke, 1910; phenol, chloral and chloroform, Gunn, 1915; potassium, and so forth). A heart which has ceased to beat may often be revived by this drug. If the epinephrine is continued, the stimulation becomes less and may be complicated by depression. There is reason to believe that epinephrine always produces an injurious as well as a stimulant action on the heart, the injurious effect increasing with the concentration, while the stimulation is confined to an intermediate optimal range of concentration; so that the depressant effects predominate for very dilute and for high doses, as also for the prolonged action of intermediate doses (Sollmann and Barlow, 1926).

Excised mammalian heart responds markedly to the epinephrine stimulation. This is utilized in experimental technic to start hearts that have been arrested by injury or asphyxia (Hedbom; perfused apex strips, Leetham, 1913; muscular strips, Taussig and Meserve, 1925). The oxygen metabolism of the heart is increased in proportion to its activity and rate (Evans and Ogawa, 1914). With *excised papillary muscle of cat,* epinephrine causes considerable increase of systolic force; ephedrine may also do so, but the range between stimulant and depressant concentrations is narrow (S. Krop, 1944).

Normal Effects on the Perfused Frog Heart.—Dilutions of 1:10^{13} to 10^9 produce pure depression. Dilutions of 1:10^7 to 10^4 produce powerful stimulation, but this wears off quite rapidly, even when the concentration is kept constant; or rather, it is overcome by the progressive depression. With concentrations above 1:10^6 this gives place promptly to arrhythmia and cardiac arrest. Analogous phenomena are produced in isolated pieces of cardiac muscle; the auricular muscle is more responsive than the ventricular, both as to stimulation and depression. The stimulant concentrations diminish but usually do not remove the Luciani type of irregularity. The lower concentrations increase the irregularity (Sollmann and Barlow, 1926). The refractory phase is not affected (Junkmann, 1925). The *oxygen consumption* of the isolated auricle of frogs is increased by epinephrine (David, 1930).

Antagonisms.—The epinephrine stimulation of the frog heart is mutually antagonistic with the sympathetic depressant ergotoxine (Langecker, 1925; Amsler, 1920), and with the parasympathetic stimulant muscarine (Gottlieb) and acetylcholine (Barlow and Sollmann, 1926). The dioxane F 933 has little effect on the response of the frog and cat heart to epinephrine or sympathetci stimulation (W. T. Hill and Myers, 1939). The depressant action of epinephrine may be additive to the acetylcholine inhibition. A similar additive depression may occur with nicotine and ergotoxine (Amsler, 1920). The epinephrine acceleration is hindered by excess or absence of *calcium,* while potassium has relatively little influence (Libbrecht, 1920). The absence of calcium tends to render epinephrine depressant (Burridge, 1914). *Carbon dioxide* increases the response to epinephrine, although it is depressant when used alone (Patterson, 1916). *Serum* gives a potentiated stimulation with epinephrine (Moog, 1914).

The *tortoise heart* behaves essentially like the frog heart. With auricular segments, epinephrine strengthens the rhythmic contractions and abolishes the tonus waves (Gruber and Markel, 1918). The accelerative effect is greater on sinus segments than on ventricular segment , and it is greater on the apex than on the base of the ventricle. Concentrations higher than 1:10^7 depress the auricular tonus waves (Sollmann and Rossides, 1927). Epinephrine antagonizes the stimulant effect of nicotine and digitalis on the tonus waves, and it partially antagonizes barium (Gruber, 1921).

In birds, the cardiac effects of epinephrine, pituitrine and barium differ considerably from those in mammals (Paton and Watson, 1912). *Embryonal nerve-free chick heart* reacts to epinephrine essentially like the adult heart (Matsumori, 1929).

The *cardiac slowing* which occurs during the epinephrine rise of blood pressure is due practically entirely to reflex stimulation from the carotid sinus and aortic arch by the high pressure, for it does not occur if the nerves from the sinus and the depressor nerves are divided (Heymans and Renouchamps, 1922; W. T. Allen, 1931), or if the rise of pressure is prevented by a compensating device (Brooks *et al.,* 1918). It is mediated through the vagi, and does not occur if these are divided, or paralyzed by atropine. The degree of slowing varies much in different individuals, but it always tends to lessen the rise of pressure, and this mounts much higher if the vagi are cut.

Ventricular extrasystoles are commonly responsible for the cardiac irregularities which may occur apart from the rise of pressure and after denervation of the carotid sinus and after atropine (Terry and Peters, 1933; W. F. Allen, 1934). They are more common after morphine (Heinekamp, 1919) and after chloroform, and are due to direct cardiac injury. The carotid sinus reflex also depresses *the vasomotor and the respiratory center* (Heymans *et al.,* 1933).

Response to Stimulation of the Cardiac Nerves.—With perfused frog hearts, stimulant doses of epinephrine lower the threshold of cardiac vagus stimulation; the response to stimulation of the accelerator is diminished or abolished, since the heart can not go much beyond the augmentation produced by epinephrine (Barlow and Sollmann, 1926). With intact mammals, large doses of epinephrine abolish the vagus response (Kuroda and Kuno, 1915); perhaps because the accelerator response is too strong; or, more probably, because these large doses produce idioventricular rhythm (Winterberg).

Normal Epinephrine Output and Cardiac Activity.—Stewart and Rogoff, 1919, found that temporary exclusion of the adrenal blood from the circulation sometimes influenced the heart, especially when irregularities were present; and that in these cases, the disturbances disappeared when the adrenal blood was readmitted, or if corresponding doses of epinephrine were injected. Cannon, 1921, reported that the *denervated* heart is quickened by stimulation of the adrenals (also by stimulation of the cervical sympathetic and by massage of the thyroid).

Therapeutic Use of Cardiac Stimulation.—This is utilized especially in acute arrest of the previously healthy heart, as in anesthetic accidents or asphyxia, especially of the newborn. Epinephrine may resuscitate hearts that have apparently stopped, although the chance of revival diminishes rapidly, and permanent success is scarcely possible if the circulation has stopped longer than ten or fifteen minutes (Stewart, Guthrie and Pike; Timofecoski and Gofshtadt, 1926). If the collapse is merely threatened, the epinephrine ($\frac{1}{50}$ to $\frac{1}{10}$ mg.) may be injected into the jugular vein or carotid artery (toward the heart), and repeated at intervals. If the pulse can not be felt, $\frac{1}{2}$ to 1 mg. ($\frac{1}{2}$ to 1 cc. of 1:1000) is injected slowly, directly in the heart (right ventricle) by a long fine needle, thrust through the fourth intercostal space, close to the sternum. This heroic procedure would be justified only in otherwise hopeless cases; but it is sometimes successful when joined with artificial respiration and cardiac massage. Strophanthin, 1 mg., has sometimes been added, but may do permanent harm to the myocardium (Gunn and Martin, 1915; Volkmann, 1918).

Intracardiac injection of epinephrine alone has no value unless it is supplemented by cardiac massage. Epinephrine raises the threshold of ventricular fibrillation for a short time (Wégria and Nickerson, 1942), but excessive doses may evoke fatal fibrillation. This risk should be minimized, if feasible, by topical application of 10 per cent metycaine or 5 per cent procaine.

In an instance when the heart resumed thirty-five minutes after it had been arrested, the circulation and respiration remained good for three hours, but decerebrate convulsions set in and terminated in death (R. F. Barber and Madden, 1944).

Injection into the myocardium is more effective than into the cavities of the arrested heart (Sharpey-Schaefer and Bain, 1932); but drugs act from the right auricle even after occlusion of the coronary vessels, presumably by the Thebesian veins (Wiggers, 1930; de Chatel, 1935). Epinephrine accelerates recovery from *ventricular fibrillation* in cats (D. C. Smith and Mulder, 1936). *Reflex arrest of the heart* by pressure on the right carotid sinus is prevented by sympathomimetic drugs. Ephedrine is effective by mouth (Nathanson, 1937).

Against *persistent cardiac weakness*, epinephrine is useless, since its action is too fleeting; and it is dangerous, because the weakened and unstable heart muscle is especially susceptible to the direct injurious effects of the epinephrine and to the high blood pressure it produces.

Traumatic Shock.—Epinephrine may aid temporarily in tiding the patient over hemorrhagic shock, by diverting a large proportion of the blood stream to the coronary and cerebral vessels; but it would need to be promptly supplemented by transfusion (Rous and Wilson, 1918). The epinephrine would be given intravenously, very slowly, carefully watching the pulse; 0.1 mg. has produced alarming symptoms. In *shock proper*, epinephrine is essentially useless, partially because it does not remedy the chief difficulty, *i. e.*, the persistent loss of capillary tone, and partly because its action on the arterioles can not be maintained sufficiently long. This inefficiency is confirmed experimentally in anaphylactic and peptone shock (Simonds, 1916) and in standarized shock produced by controlled bleeding. The benefits of various vasopressor drugs are questionable at best, and do not justify the risk of myocardial damage (D. F. Opdyke, 1944). The pressor response to epinephrine is materially decreased by excessive and deficient pulmonary ventilation, hemorrhage, histamine, and various procedures tending to shock (G. W. Stavraky, 1942).

Epinephrine in Internal Hemorrhage.—Injection of epinephrine into the circulation may sometimes control hemorrhage from inaccessible situations (Hanzlik, 1918); but it is often unsuccessful and may be harmful, for the rise in blood pressure is likely to overcome the local constriction, especially in vessels that react poorly to epinephrine, such as the pulmonary and cerebral. Pulmonary hemorrhage is definitely increased (E. Frey, 1909).

In *intestinal hemorrhage*, the results of Wiggers, 1909, were somewhat more promising: after a momentary increase, the hemorrhage was reduced, and this effect outlasted the rise of pressure. However, Hoskins and Gunning, 1917, found that small doses generally dilate the intestinal vessels (increased volume and vein outflow). G. A. Hartman and McPhedran, 1917, also confirm this, but claim that still smaller doses constrict the vessels of the intestines, kidney and generally also those of the spleen.

The **coagulability of the blood** is not affected by direct addition of epinephrine, but when this is injected into an animal, coagulation time is shortened by small doses (0.002 mg. per Kg.) and retarded by large doses (0.05 mg.) (Cannon and Mendenhall, 1914). If the abdominal organs are removed from the circulation, these effects do not occur, so that the epinephrine acts presumably on the liver cells. Grabfield, 1916, found that the increased coagulability with small doses is due to increased prothrombin.

Hemolytic Action.—Epinephrine is strongly hemolytic for beef blood and to a less degree for other animals. It also produces methemoglobin. Serum weakens the action (Kariga and Tanaka, 1913).

Blood Volume and Cell Count.—Intravenous injection of fairly large doses of epinephrine generally causes a small decrease of plasma volume, estimated by dye methods, but this is variable (Gregersen and Pinkston, 1936), or may be absent (Yang and Chang, 1930). There is always an increase of the red and white cell count (Lamson and Keith, 1916) and of the total circulating erythrocytes (CO method, Hitzenberger and Tuchfeld, 1929). The blood platelets are also rapidly mobilized (Behamou and Nouchy, 1930), and the reticulocyte count rises (in young rabbits; Istamanowa and Chudoroschewa, 1910). Pituitary injection, physostigmine, strychnine and stimulation on the sciatic nerve produce similar effects (Edmunds and Lloyd, 1923), while histamine decreases the erythrocytes and increases plasma volume. The epinephrine polycythemia is attributed chiefly to mobilization of cells of the splenic pulp by contraction of the spleen (Edmunds and Stone, 1924; E. E. Nelson, 1924; Yang and Chang, 1930). This may be of some benefit in shock and hemorrhage, and especially in CO poisoning and methemoglobinemia.

Considerable increase occurs after removal of the spleen, so that about half of the cells are mobilized from other organs (P. F. Hahn, Bale and Bonner, 1943, "tagged" erythrocytes in pentobarbital anesthesia). Daily administration of epinephrine or posterior pituitary extract to splenectomized rabbits also produces polycythemia, attributed to increased erythropoiesis by vasoconstrictor ischemia of the bone marrow (J. E. Davis, 1942).

Leukocytes.—In dogs, the leukocytosis is followed by leukopenia, due to retention and destruction of the leukocytes in the liver (Fegler, 1927).

Normal Spleen.—Hoskins and Gunning, 1917, found that effective doses, in intact animals, cause a brief dilatation, followed by contraction. The threshold is more sensitive than that for the general arterial pressure. Rhythmic contractions of the spleen are sometimes started. In *malarial patients* with chronic enlargement of the spleen hypodermic injection of epinephrine, 0.25 to 1 cc. of 1:1000 rarely causes reappearance of a few parasites in the blood, never enough to provoke a febrile attack (Morishita and Furutama, 1927); the red cells are generally not increased, but there is always some leukocytosis, especially of the monocytes and large lymphocytes (Hughes and Shrivastava, 1930). Riolo, 1935, reported marked reduction of the spleen tumor from twenty to thirty daily injections intravenously, increasing from $\frac{1}{100}$ to $\frac{1}{10}$ mg.

The Toxic Effects of Epinephrine.—The *major accidents*, acute cardiac dilatation, pulmonary edema, ventricular fibrillation, terminating in death, usually follow intravenous injection and are especially liable to occur if the heart is already weakened or overexcitable, in cardiac disease, or as the result of chloroform, cyclopropane or other cardiac poisons. The induction period of chloroform anesthesia is especially dangerous. Such accidents should be treated with artificial respiration.

Gormsen, 1939, reviews twenty-eight *deaths from hypodermic injection of epinephrine*, reported in the literature, all due to overdosage by error in the concentration of the solution. The minimal fatal dose hypodermically is about 10 mg. The symptoms are immediate pain in the neck, anxiety, pallor, vomiting, dyspnea, rapid pulse, high blood pressure, collapse, death often in a few minutes. Necropsy shows edema and extensive hemorrhages in the lungs and small interstitial hemorrhages in the kidneys. In *cardiac insufficiency*, the hypodermic injection of 1 mg. generally produces distinct dilatation and extrasystoles (M. Loper *et al.*, 1918; D. Roth, 1914). Fatalities have occurred from 0.4 mg. hypodermically (Fridericia, 1915). In *poisoning by cardiac depressants* (*f. i.*, chloroform, phenol or caffeine) the intravenous injection of epinephrine temporarily restores the blood pressure, and this may give the heart a chance to recover. But if the blood pressure is raised much above the normal, the heart may go into ventricular fibrillation, and this may occur from doses of epinephrine which would be quite safe in healthy individuals (*chloroform*, Nobel and Rothberger, 1914; *phenol*, Sollmann). It is probably due to abrupt upset of the autonomic equilibrium, and it may be prevented by section of the carotid sinus and depressor nerves, or by preliminary injection of pilocarpine (Bardier and Stillmunker, 1927), or of epinephrine itself when this is administered previous to the chloroform. Ventricular fibrillation in response to benzene and epinephrine is a fairly satisfactory means of testing the susceptibility of the heart to fibrillation ("benzol-adrenalin" test; Wégria and Nickerson, 1943).

Epinephrine pulmonary edema is not due to back pressure as such, for it occurs only if hydremic plethora exists or if marked cardiac irregularity occurs. It is seen more often if the vagi have been divided or if asphyxia is present; conversely, artificial respiration tends to prevent the occurrence of the edema (Gates and Auer, 1917).

Fatal Effects in Animals.—Excessive doses of epinephrine produce vomiting, excitement, debility, bloody diarrhea, hematuria, ascending central paralysis, great fall of temperature, occasionally convulsions, complete prostration and *death* by respiratory (cat) or cardiac (dog) paralysis. Rabbits show multiple pulmonary hemorrhages, probably associated with edema. The *fatal dose* varies considerably (usually 0.1 to 0.6 mg. per kilogram intravenously, or 2.5 to 10 mg. per kilogram hypodermically), but is about five hundred times the therapeutic dose. A noticeable rise of blood pressure can be seen after $\frac{1}{1800}$ of the fatal dose. *Guanine* is said to lessen the toxicity and glycosuria. Atropine is also claimed to decrease the toxicity (Leo Schmidt, 1919). The toxic effects are the result of the peripheral actions; for as Cushny, 1909, pointed out, the ratio of activity of the different isomers is the same for the toxic as for the blood pressure effects. *Oral administration in rabbits* produces hyperglycemia and polyuria or oliguria, according to the dose. Large doses are followed by death in one and a half or two days, through damage to the stomach and intestines, the ischemia causing necrosis and perforation (S. Rosenkranz, 1938).

Minor Accidents; Hypersusceptibility.—The local application or hypodermic injection of epinephrine in ordinary doses does not normally produce marked symptoms. Not infrequently, however, excitable or susceptible patients respond in a few minutes by pallor, tremors, anxiety and nervousness, tachycardia and palpitation, precordial distress, increased rate of respiration, rise of blood pressure and temperature, wakefulness and sometimes hyperglycemia (Hewlett, 1918). The symptoms may be alarming. They usually pass away in a short time, but they may be fatal (Fischer, 1920). This hypersusceptibility occurs especially in patients of nervous temperament, most markedly in those with toxic goiters (also in experimental hyperthyroidism in rabbits; H. Rosenblum *et al.*, 1933); also in hypertension (O'Hare, 1920). It has been used (½ mg., intramuscularly) as a test for neurasthenia and "irritable heart" (D. M. Lyon, 1924). Serious results have followed epinephrine injection in angina pectoris (Cottrell and Wood, 1931).

Epinephrine Atheroma.—If rabbits receive frequent injections of large doses of epinephrine, atheromatous changes and calcareous patches are often observed in the aorta and other large vessels (d'Amato, 1905). These degenerations are not seen in dogs (Pearce and Stanton, 1906), or in monkeys, and presumably not in man. Dogs also give negative results with nicotine, lead or toxins (Adler, 1914). Identical lesions often occur spontaneously in rabbits which have never received epinephrine. The frequency of these spontaneous lesions varies in different series from 3 to 30 per cent, but they are so markedly more frequent after epinephrine treatment that this must at least exaggerate the tendency to the degeneration (I. Levin and Larkin, 1910). Success depends on frequent repetition of the epinephrine rather than on the size of the dose (Fleisher, 1909). The injury has been attributed to high blood pressure and to direct toxicity by epinephrine. The older experiments undertaken to decide between these views (summarized by I. Adler, 1908) did not take account of the spontaneous occurrence of the lesions. The toxic theory seems the more probable; although Dixon, 1913, stated that all pressor agencies, when repeatedly applied, produce degenerations of the middle coat. It is highly doubtful whether these atheromas of rabbits have any relation to human atheroma. Atheroma is also produced by feeding cholesterol, cottonseed oil, the aldehydes of fatty acids, hydrochloric acid, and by paracresol (Denny and Frothingham, 1914). The high blood pressure of *clinical hypertension* is definitely not due to epinephrine, for epinephrine would cause other marked disturbances, for instance of peristalsis, in doses much smaller than are required materially to raise the blood pressure.

Epinephrine Myocarditis.—Rabbits often show chronic myo-, endo- and pericarditis, after repeated epinephrine injections. This lesion, which is apparently independent of the atheroma, is much more frequent (60 per cent) if a single intravenous injection of epinephrine (0.2 mg.) is combined with sparteine (12 mg.), caffeine (25 mg.) or strophanthin (these drugs never cause the lesion if they are used without the epinephrine). The changes in the heart muscle start at once, progress for some seven days, persist about six weeks and then retrogress completely by sixteen weeks (Christian and Walker, 1911). Fleisher and Loeb, 1910, attribute the lesions to mechanical strain from excessive contraction of the muscle fibers, for the lesions are situated mainly at the base of the left ventricle, where the strain is greatest. The changes are analogous to those shown by striated muscle subjected to overexertion; and the lesions do not appear in the relatively stronger and more resistant hearts of dogs. H. A. Stewart, 1912, prefers a toxic theory. Hearts which show the microscopic changes are physiologically inferior to the normal; they are less able to cope with extra demands; and the animals appear more disposed to edemas (uranium) and to bacterial infections.

Respiration.—The epinephrine rise of blood pressure is generally accompanied by decrease of the rate and depth of respiration, sometimes to apnea. This was attributed to presso-receptor reflexes from the carotid sinus and aortic regions (Heymans *et al.*, 1933), but is probably due to reduced activity of the chemo-receptors (Gernandt *et al.*, 1945). It is followed by more lasting stimulation (C. F. Schmidt, 1929). *Central action currents* appear on intravenous injection (B. I. Hasama, 1935). In man, 1 mg. hypodermically increases the respiration volume by 8 to 94, mean 50 per cent; the rate is unchanged or also increased (Fuchs and Roth, 1912). Voegtlin and Wiggers, 1918, tried epinephrine against narcotic depression of the respiration, with doubtful results. Schmidt found it more encouraging, but it is inferior to ephedrine.

Bronchioles are dilated by epinephrine. It antagonizes all types of constrictor agents (choline esters, pilocarpine, histamine, barium anaphylaxis, and so forth), and is additive with dilator agents (atropine, nitrites).

The bronchodilatation was confirmed in intact animals by Januschke and Pollak, 1911, and others; on excised tracheal muscle by Trendelenburg, 1912; and on microscopic sections by Sollmann and Gilbert, 1937. It is more marked if the bronchial tone is high (Golla and Symes, 1913 and later). It is not prevented by ergotoxine or ergotamine, but is hindered by F 933 (Melville, 1937). Epinephrine and epinine are the most potent dilators of the group; arterenol is good; neosynephrine is fair, and ephedrine and benzedrine are poor (Cameron and Tainter, 1936)

Relief of Spasmodic Asthma, Anaphylactic Reactions, Serum Disease, Nitritoid Crises of Arsphenamine, Angioneurotic Edema, Urticaria, and the Like.—Epinephrine relieves these promptly (Kaplan, 1905), and is the most effective agent against them, although it is not always completely successful. The mechanism by which it checks edema formation is not understood. Clinically, 0.1 to 0.5 cc. of the 1:1000 solution is injected intramuscularly, repeated in half an hour if necessary and if there are no marked side effects (anxiety, tremor, tachycardia), It is more effective if given early, as preventive if possible. Atropine, 0.6 mg., may be added. Intramuscular injection of *oil suspension* (2 mg. of the powdered base in 1 cc. of peanut oil) gives more lasting action and is more economical in chronic bronchial asthma (Keeney *et al.*, 1939); but it may exceptionally produce prompt and severe toxic epinephrine reactions (Dorwart, 1940). Graeser and Rowe, 1936, advocate *inhalation* of a nebulized spray of 1:100 solution, especially for children, as equally effective for relieving asthma, but in severe cases it does not penetrate far enough into the bronchial tree (Graeser, 1939). This has also been used against angioneurotic edema (Klinefelder, 1937). *Ephedrine* can be administered by mouth, but it is less effective in asthma and is used chiefly in hay fever. Both agents may be applied locally against turgor of the turbinates or congestive closure of the nasal sinuses.

A patient taking ten deep *inhalations* of the nebulized 1 per cent epinephrine solution receives less than 0.08 mg. of epinephrine into the mouth, and only a hundredth of this reaches the bronchioles, much less than would be needed for systemic effects. The action is therefore purely local, but prolonged inhalation causes dangerous intoxication. Frequent repetition causes tracheal irritation, epithelial desquamation and inflammatory changes (Gagliani *et al.*, 1939).

Edemic Reactions.—Epinephrine diminishes the wheal reaction of the skin by codeine, which is allied to the edemic reactions of anaphylaxis. This response is apparently secured only by systemic and not by local administration (Pilcher, 1925), so that it can not be due to vasoconstriction. It is similarly effective against dionin chemosis and against paraphenylendiamine edema; ephedrine, tyramine and pituitary solution are much less effective (Tainter, 1928).

Eye.—Epinephrine has a mydriatic effect. This occurs readily in frogs; but only under specially favorable conditions in mammals. In the *normal human eye*, local instillation of 2 per cent epinephrine usually dilates it somewhat within an hour (S. C. Howell, 1934), but much less than with ephedrine. An unpleasant sensation of muscle spasm results from 1:1000 instillation, so that it should not be used (Fantus).

Epinephrine mydriasis in mammals may be produced by large intravenous doses. With local application, the mydriatic effect may be obtained if the oculomotor tone is low (weak illumination, W. H. Schultz, 1908), if the absorption is hastened (conjunctivitis, H. Straub, 1919), or if the excitability of the sympathetic is increased. This is supposed to occur in Basedow's disease and in pancreatic insufficiency. O. Loewi, 1908, accordingly proposed a mydriatic response to epinephrine as a diagnostic sign in these diseases, but later work showed that the increased mydriatic reaction occurs in all types of hyperglycemia (A. Loewy and Rosenberg, 1914). The sensitiveness also appears somewhat increased in chronic nephritis (Kato and Watanabe, 1920).

Denervation.—The mydriatic response to epinephrine is obtained a few days after excision of the superior cervical ganglion (Meltzer and Auer, 1904), or after removal of the ciliary ganglion (Joseph, 1915). This may be attributed to increased excitability of the sympathetic distribution, accompanying the degenerative changes which follow the excision (T. Schlossberg, 1932). An analogous increase of excitability in degenerating structures to epinephrine occurs in the ear vessels (Meltzer and Auer, 1903) and in other organs (Elliott, 1905); also in skeletal muscle on degeneration of the sciatic nerve (Edmunds and Roth, 1909). G. N. Stewart, Rogoff and Gibson, 1916, found the mydriatic responses of the denervated pupil a sensitive and reliable test for the discharge of epinephrine.

Localization of Mydriatic Action.—Lewandowsky, 1898, showed that the mydriatic effect occurs after degeneration of the sympathetic, so that the action must be on the receptive mechanism. The excised sphincter of the mammalian iris is also relaxed by epinephrine. This is counteracted by physostigmine, with mutual antagonism (Joseph, 1917). Pituitary counteracts the mydriasis in intact animals (Githens and Meltzer, 1917).

Other Evidences of Ocular Sympathetic Stimulation.—The mydriasis is accompanied by separation of the lids, protrusion of the eyeball and withdrawal of the nictitating membrane.

Mydriatic Reaction in Frogs.—Frogs are especially susceptible to the mydriatic action; and this may be produced by systemic application (1 cc., 1:100,000, into lymph sac) as well as in the enucleated eye (1:5000; Meltzer, 1909). The dilatation is prompt and persistent, submaximal, indifferent to light.

Epinephrine Miosis.—After repeated injections or local instillations, epinephrine may produce constriction of the pupils in mammals. This altered response is attributed to a change in the pupillo-dilator muscle (Kato and Watanabe, 1920).

Intra-Ocular Pressure.—The effects vary, but normal pressures are generally lowered somewhat by local application of 2 per cent solution of epinephrine (Howell, 1934), or by subconjunctival injection of 0.2 to 0.5 cc. of 1:1000 solution. In glaucoma with pressures above 40 mm. Hg., epinephrine injection causes no change (Vannas, 1927). The fall is probably due to intra-ocular vasoconstriction.

Intra-ocular injection of epinephrine into rabbits produces intense contraction of the retinal arteries, paleness of the disc and the ophthalmoscopic picture of optic atrophy. These effects persist for weeks or months and are not overcome by nitrite, atropine, pilocarpine or dionin. Albino rabbits developed cataract. These fundus changes did not occur in cats (Redslob, 1929). With intravenous injection, the rise of general arterial blood pressure tends to break down the capillary resistance, and so to raise the intra-ocular pressure. All doses contract the smooth muscle of the orbit, which raises the intra-ocular pressure. Mydriasis does not play a significant role (Duke-Elder *et al.*, 1932).

Lens opacities may be induced in mice and rats by epinephrine; a single peritoneal injection of 5 to 10 mg. per Kg. may suffice. The opacities are subcapsular and transitory and appear to be related to derangement of carbohydrate metabolism and circulatory impairment, resulting in increase of nonglucose-reducing substances in the blood. The liability is increased by inducing shock with histamine, potassium poisoning and adrenal cortex deficiency; it is decreased by ergotamine or phlorhizin (C. Suden, 1940).

Effect on Secretions.—Epinephrine may provoke secretion of the salivary and lacrimal glands (Langley, 1901); and of the skin glands of frogs (Ehrmann, 1905). The increased secretion of the submaxillary glands is accompanied by increased blood flow (Solem and Lommen, 1915). It occurs after degeneration of the chorda tympani nerve (Bonvallet and Minz, 1938). Small vasodilator doses (0.01 mg. for cats) increase the secretory response to *cholinergic drugs;* 0.05 mg. causes vasoconstriction and diminished secretory response (G. W. Stavraky, 1942). In most glands, however, secretion is diminished or arrested through the vasoconstriction. This is notably so with *pancreatic secretion* (Edmunds, 1909). This is apparently due to diminished blood supply, for the volume of the pancreas is decreased even by small doses and independently of the general blood pressure (Mann and McLachlin, 1917). Downs and Eddy, 1919, claim that *bile secretion* is increased by epinephrine. *Sweat* is increased in animals (Muto, 1916. He finds that the sweat glands are innervated by both the sympathetic and parasympathetic.). The sympathetic predominates in horse and sheep; whereas man, cattle and cats are more subject to the parasympathetic. Injection of epinephrine into a cat's paw produces sweating when the sciatic or posterior nerve roots have been divided. Injection at a distance or intravenously was ineffective (Dieden, 1916).

Gastric motility is depressed by epinephrine. The pyloric sphincter relaxes if the gastric tonus was normal or high; if it was low it is generally raised by epinephrine (J. E. Thomas, 1929). Similar depressive effects are produced by ephedrine and by both the vasopressor and the oxytocic fractions of pituitary (Schroder, 1933). *Excised stomach* is relaxed in most mammals, but contracted in some. The gastric sphincters are always contracted (Thomas, 1929).

Intestinal Motility.—Epinephrine relaxes the tonus and inhibits peristalsis in excised intestines, as also in fistula segments of unanesthetized animals. The sensitivity of excised intestines to epinephrine is less in rabbits than in cats and guinea pigs (Achutin, 1933). Atropine prevents and reverses the relaxing action in dogs (Raymond-Hamet, 1934). Similar effects are produced by ephedrine and tyramine, but these are antagonized by cocaine, which does not antagonize this action of epinephrine (Gruber, 1936). Epinephrine inhibition of excised intestine is antagonized reversibly by lack of oxygen (E. Starkenstein, 1941).

Very dilute solutions of epinephrine increase intestinal contractions in mammals (Hoskins, 1912) and in frogs (Roth).

The *ileocolic sphincter* differs from the ordinary intestine, being contracted by epinephrine or splanchnic stimulation (Elliot, 1904).

The gallbladder is relaxed by epinephrine (Lieb and McWhorter, 1915).

The **uterine responses** differ with conditions. *Clinically*, intramuscular injection of epinephrine, ½ cc. of 1:1000, produces prompt but brief relaxation of the parturient uterus, even if pitocin or ergotamine has been administered. This may be used to facilitate operative manipulation (Dodek, 1932; Bourne and Burn, 1927; Daro *et al.*, 1940).

Others, however, report divergent results for human uterus. W. E. Brown and Wilder, 1943, recording postpartum contractions by intra-uterine bag, report that intramuscular or intravenous epinephrine produces premature contraction followed by a compensating pause, but no inhibition or relaxation. J. Daels, 1941, finds on excised human gravid and nongravid uterus that epinephrine stimulates the exterior, propulsive muscular layer,

and inhibits the interior and cervical layer. This probably explains the contradictions; both actions would assist parturition.

The *effects in animals* correspond to stimulation of the hypogastric nerve: in pregnant cats it produces contraction; in nonpregnant cats, relaxation (Cushny, Kehrer, Dale); in nonpregnant guinea pigs, relaxation; in dogs, contraction followed by relaxation; in rabbits, increased tonus (Biagi, 1905). The fallopian tubes are also stimulated to contraction (Gunn, 1914). Through an artificial abdominal wall of celluloid, Ludwig and Lenz, 1923, observed that epinephrine arouses peristalsis in the uterus of the gravid rabbit or cat; but in the nongravid and puerperal animals it produces prompt arrest and fixation of the uterus in whatever tonus prevails at the moment. In the final stages of pregnancy the cat uterus is again inhibited by epinephrine and by hypogastric nerve stimulation (E. C. Del Pozo, 1946).

Modification by Sex Hormones.—The excised uterus of virgin or spayed guinea pigs, which is normally relaxed by epinephrine, is stimulated in about half of such animals if they have been treated with estrogen. If they received progesterone together with the estrogen, epinephrine is not stimulant until the uterus has been kept in warm Locke solution for two or three hours. Ergotoxin abolishes all augmentory epinephrine response (G. Balassa, 1941).

Reversal of Epinephrine Inhibition by Pituitary Extract.—The uteri of guinea pigs and nonpregnant cats are ordinarily relaxed by epinephrine. If, however, they are first treated with pituitary solution, the epinephrine produces contraction. This sensitizing action seems to be in the peripheral nervous mechanism and not in the muscle itself (Cow, 1919).

Excised Ureter.—Epinephrine (1:500,000) increases the rate and tonus, or starts the contractions. The effect is reversed by ergotoxine (Macht, 1916; Gruber, 1930). The response of the epinephrine isomers differs only quantitatively, the levo being much more stimulant than the dextro (Macht, 1918). The *urinary bladder* was discussed in the general section on Autonomic Poisons.

The smooth muscle of the **amnion** of birds, which is completely devoid of nerves, responds to epinephrine and other autonomic poisons (Baur, 1928).

The **pigment cells** in the frog's skin are contracted into spheres (Lieben, 1906). This also occurs in the melanophores of fishes, the effect being reversed by ergotoxine (Spaeth and Barbour, 1917).

Epinephrine in Annelids.—Chromophile material exists in the ganglia of a number of species, including the earthworms and leech. These have vascular systems, the contractions of which are accelerated by epinephrine (Gaskell, 1919).

The bioluminescence of fireflies (Photuris pennsylvanica) is modified by epinephrine into a steady bright glow, perhaps by direct action on the tracheal end cells (G. A. Emerson and Emerson, 1941).

Protozoa.—The pulsations of the vacuoles of paramecium are accelerated by epinephrine, pituitary and pineal extracts (Feather, 1919).

Skeletal Muscle.—Epinephrine, when applied to excised skeletal muscles, has practically no effect on their contraction, even in concentrations up to 1:15,000 (Kuno, 1915). The injection of epinephrine into living animals increases the efficiency (height of contraction and irritability) of their muscles, the increase persisting after the muscle is excised (Oliver and Schaefer, 1895). A sensation of muscle spasm is noticeable clinically if epinephrine solution, 1:1000, is dropped into the conjunctival sac (Fantus). Intravenous injection of epinephrine momentarily restores decerebrate rigidity that was relaxed by curare (Bremer and Titeca, 1928), but it has no action on normal tonus (Bremer, 1932). The improvement is particularly marked if the muscles (of cats) have been previously fatigued, or weakened by acids (Gruber and Kretschmer, 1918). The increased efficiency is partly an indirect effect, attributable to improved circulation through the muscle while this is still in the body (Gunning, 1917). *Creatine formation* is increased by epinephrine, even after curare (Riesser, 1916).

Nerve trunks are not affected.

Epinephrine Hyperglycemia. — Clinical doses of epinephrine (1 mg. hypodermically) do not alter the blood sugar level in normal human subjects, but they increase the sensitiveness to alimentary glycosuria (Landau, 1914); and in epinephrine-sensitive patients 0.5 mg. intramuscularly causes hyperglycemia (Peabody *et al.*, 1918) and decrease of the reserve alkali of the blood (Peters and Geyelin, 1917). Intravenous injection of epinephrine into rabbits, at the rate of 0.003 to 0.06 mg. per Kg. per hour, increases the level of sugar (F. Blum, 1901) and lactic acid in the blood, without altering the metabolic rate, and without producing the typical sympathomimetic actions. This quantity of epinephrine is considered within the physiological output and is about an eighth of that required to raise the blood pressure (Cori *et al.*, 1930). If the sugar level rises sufficiently, glycosuria results, generally proportional to the hyperglycemia (Gramenitzki, 1912).

The hyperglycemia ceases promptly by the destruction of epinephrine, when the injection is discontinued. A given quantity of epinephrine is more effective when injected slowly or by hypodermic injection than when given as a single intravenous injection (Barbour and Rapoport, 1921). With partial oxidation of epinephrine, the glycosuric action is lost first (McGuigan and Mostrom, 1913).

Mechanism of the Epinephrine Hyperglycemia.—The *initial* rise of blood sugar involves the conversion of hepatic glycogen into sugar, and is analogous to asphyxial glycosuria, diabetic puncture, or stimulation of the hepatic, splanchnic or sensory nerves; all acting probably on sympathetic nerves controlling the glycogenic functions.

The hyperglycemia is *not asphyxial*, for it is not prevented by artificial respiration; *nor is it renal*, for it occurs after excision of the kidneys (Zuelzer, 1901). It is not checked by barbiturates, and is probably due to a peripheral action (D. Campbell and Morgan, 1933). On the other hand, epinephrine increases the utilization of dextrose by the tissues (Himsworth and Scott, 1938).

Glycogenolysis as the source of the sugar is indicated by the fact that the degree of hyperglycemia and glycosuria depends upon the glycogen content of the animal; they are more intense in animals rich in glycogen; and conversely there is no glycosuria in animals whose glycogen has been completely removed by phlorhizin; and an existing phlorhizin glycosuria is not increased by epinephrine (Ringer, 1910). The evidence for the hepatic origin of the sugar is also convincing. The blood of the hepatic vein contains more sugar than that of the portal; sugar formation is increased on perfusion of the excised liver, and conversely there is no glycosuria when the functions of the liver have been injured by phosphorus (E. Frank and Isaac, 1911). The muscle glycogen is also mobilized by epinephrine, even after excision of the liver (E. Geiger, 1930). *If the injection of epinephrine is continued for some time*, the liver glycogen again increases, although the blood sugar and lactic acid continue high. The mechanism of this is obscure. Cori *et al.* reported that the muscle glycogen continues to fall and suggested that epinephrine stimulates the production of lactic acid from muscle glycogen and that this is then changed into liver glycogen, and this into sugar; but in fasting rabbits the muscle glycogen may also be increased by epinephrine (Markowitz, 1925), indicating formation of carbohydrate from some other source ("gluconeogenesis"; review, Macleod, 1934).

Habituation.—The hyperglycemic response in rabbits is not materially altered by prolonged daily repetition of hypodermic epinephrine injections (Affleck, 1929), except as the glycogen supply is depleted. Hyperglycemia persists somewhat longer than the glycosuria, so that continued injection of epinephrine appears to decrease the permeability of the kidneys for glucose (Pollak, 1909, 1911), perhaps by vasoconstriction. At this stage, diabetic puncture also produces only hyperglycemia, and not glycosuria. Phlorhizin, however, still causes glycosuria (Biberfeld, 1916).

Interfering Factors.—Epinephrine glycosuria is prevented by ergotoxine (Loewi), which diminishes the hyperglycemia and also the permeability of the kidney for sugar but not for chloride (Miculicich, 1912). It is also prevented by nicotine (Hirayama, 1911), by lymphogogues (peptone, hirudin; Miculicich), and by repeated hemorrhage (Wilenko, 1912). Urethane increases the activity (Underhill, 1911). Antipyretics suppress the glycosuria but not the hyperglycemia, so that their effect must be on renal permeability (Mansfield and Purjesz, 1915). *Amino acids* are reported to influence epinephrine hyperglycemia in different directions: tyrosine and tryptophane as increasing it; leucine and histidine as inhibiting; and phenylalanine, glutamic acid and amino acetic acid as indifferent (Chikano, 1929).

Relation of Adrenals to Other Glycosurias.—Removal of the adrenals prevents the usual glycosuric response to diabetic puncture, theobromine and splanchnic stimulation, probably as a result of shock (Stewart and Rogoff, 1918, 1920).

Related Amines.—The effects of forty amines on blood sugar are reported by R. C. Anderson and Chen, 1934.

Gaseous Metabolism.—The hypodermic injection of 0.5 mg. of epinephrine increases the basal metabolism of human subjects by 15 to 40 per cent. This has no relation to the thyroid activity (Marine and Lenhart, 1920). The respiratory quotient often rises (Tompkins *et al.*, 1919). The mechanism of the increased metabolism is not understood. It is out of proportion to the mobilization of glucose (Boothby and Sandiford, 1920). It does not appear to be due to excitement.

In unanesthetized, trained dogs, epinephrine (20 γ per Kg., intramuscularly) also increases respiratory metabolism, by 20 per cent for two hours (J. de Moerloose, 1942).

In dogs under morphine-barbiturate anesthesia, prolonged injection of small amounts of epinephrine, which have no effect on the heart rate and blood pressure, produces a transient decrease of gas metabolism. Rapid injection causes increase. The respiratory quotient rises in either case (Mertens and Rein, 1938).

Heat Regulation.—Injection of epinephrine produces fever (Freund and Marchand, 1913). Hirsch, 1913, found, presumably under different conditions, that the injection of epinephrine or pancreas lowers temperature by decreasing heat production. Cloetta and Waser, 1915, described rise of brain temperature and cooling of skin, with 0.2 mg. in rabbits, intravenously. Intracerebral injection acted similarly. The rise was not prevented by ergotoxine.

Nitrogen Metabolism.—Epinephrine, by vein or hypodermically, has little or no influence on the nitrogen excretion (Lusk, 1914). In dogs, large doses, hypodermically, increase the excretion of uric acid and especially of allantoin (Falta, 1914). Addis *et al.*, 1918, believe that the hypodermic injection of epinephrine into rabbits increases the *urea* excretion capacity. Maximal doses, however, diminish the output. The effect is smaller if the urea concentration of the blood is high.

Potassium Level of Blood Serum.—Intravenous injection of 0.05 to 0.2 mg. of epinephrine into dogs, cats or rabbits promptly increases the K level to 40 per cent above the normal, parallel to the hyperglycemia. The potassium is probably mobilized from the liver, for the rise is prevented by removal of the liver, and also by ergotamine or curare. In man, 0.1 mg. of epinephrine causes immediate and marked fall of the K level. The Na level is unchanged (A. Keys, 1938; D'Silva, 1934, 1936).

The **urinary phosphate excretion** is reported to be diminished by epinephrine (also by insulin).

Normal Distribution of Epinephrine.—The principal depot of epinephrine is in the medulla of the adrenal gland, in its "chromaffin" cells which are intermingled with nervous structures. It occurs also in special cells in other situations, always closely associated with sympathetic ganglia (Elliott, 1905). The neurohormone theory of sympathetic stimulation postulates that it or a near derivative is universally present, as "sympathin" about the terminations of the sympathetic nerves, although the quantity there is too small to be demonstrated chemically. It is not known whether this "sympathin" is formed locally or supplied by the suprarenal medulla; but the epinephrine in the circulation comes chiefly from the latter source. The level of epinephrine in the blood, however, is not enough even under the most favorable conditions to exert any effect on blood pressure, or even on the much more sensitive intestine, although it can be demonstrated in the blood of the adrenal vein by the blood pressure and by the pupil test (Stewart and Rogoff, 1916) or by the denervated heart (Cannon). It may therefore be doubted whether the adrenal output of epinephrine has much physiologic significance. It is even conceivable that adrenal epinephrine is mainly a waste product temporarily stored and perhaps destroyed in these glands; but it appears more probable that they constitute a depot which helps to maintain the normal epinephrine concentration of the sympathetic terminals. Adrenal epinephrine secretion is certainly not essential to life, for animals, including monkeys, live without noticeable disturbance when their output of epinephrine has been practically suppressed by excision of one adrenal, and section of the nerves of the other (Stewart and Rogoff, 1917, 1919). Cannon (review, 1940) believes that the adrenal medulla has some importance as an adjuvant to sympathetic impulses, in the extra demands of vigorous muscular work, asphyxia, low blood pressure, chilling and hypoglycemia. Epinephrine is not concerned in clinical hypertension, nor has the causation of any other pathologic condition been definitely connected with altered epinephrine content of the blood.

The *formation of epinephrine in the adrenal medulla* appears to be rapid, for if the store of epinephrine has been depleted to a third of the normal by the physostigmine, it is practically restored to the normal amount within twenty-four hours (C. W. Edmunds and Smith 1931).

The *total amount of epinephrine in the suprarenal glands* in man is normally about 4 to 5 mg. per gland (Elliott, 1914); in dogs, 2 mg.; in cats, 0.19 mg. (Marchetti, 1915); in sheep, to 7 mg. (Folin, Cannon and Denis, 1913). The percentage is about 0.1 per cent of the moist weight, in all animals. The content does not vary with the seasons (Seidell and Fenger, 1914). In glands obtained from autopsy material from various diseases, the epinephrine content is generally somewhat low, about 0.35 per cent of the dry weight in place of the normal 0.4 per cent (Lucksch, 1917). Epinephrine is present early in *fetal animals* (McCord, 1915). In the human fetus, it is absent at six months, but present at full term (J. H. Lewis, 1916).

Normal Adrenal Output and Concentration in Blood.—Epinephrine can be demonstrated in the blood of the adrenal veins; under special conditions and by especially sensitive methods also in the vena cava. The normal adrenal output in the cat and dog is about 0.00025 mg. per kilogram of body weight (Stewart and Rogoff, 1917, 1923). The normal concentration in the circulating blood is not known, but it has been deduced as 1:2 times 10^9, or 1 mg. in 2000 liters (Stewart, Mellon Lecture, 1926).

The *splanchnic control of the epinephrine output from the suprarenal medulla* seems to be complete in the sense that epinephrine disappears from the adrenal vein blood if the splanchnic nerves are divided, and stimulation of the peripheral stump of the divided splanchnic nerves increases the epinephrine output up to twenty times the normal, sufficiently to raise the blood pressure (Stewart and Rogoff, 1916).

Role of Epinephrine in Splanchnic Pressor Response.—A part of the blood pressure changes on splanchnic stimulation is due to the discharge of epinephrine (Perlman and Vincent, 1919). The phenomena are affected by the anesthetic (Parsons and Vincent, 1917) and are sometimes abolished by caffeine, curare and morphine (Perlman and Vincent).

Spinal Center.—In cats, epinephrine is liberated after section of the cord as low as the last cervical, but not after section of the mid-dorsal region (Stewart and Rogoff, 1917).

Drugs on the Adrenal Epinephrine Output.—This is increased by toxic doses of strychnine (up to one hundred times), and by morphine, acetylcholine, pilocarpine and physostigmine (the latter may deplete the normal epinephrine store of the glands to an eighth of the normal; Edmunds and Smith, 1931). Nicotine causes a temporary increase, followed in less than a minute by marked decrease.

The adrenal medulla is innervated by *cholinergic preganglionic sympathetic fibers*, as are also other sympathetic ganglia (Feldberg and Vartianinen, 1934). Physostigmine and neostigmine potentiate the action of coline esters both on sympathetic ganglia and adrenal medulla (W. B. Cannon and Rosenblueth, 1937).

The *acetylcholine* increase of epinephrine output is further increased by atropine (Houssay and Molinelli). Their actions are peripheral (H. Hermann *et al.*, 1937). *Atropine* has no effect in itself, but large doses diminish considerably the amount of epinephrine secreted in response to splanchnic stimulation, but not to nicotine or quaternary ammonium bases (J. T. Lewis and Luduena, 1934). *Potassium salts* increase (Hazard, 1933) by direct peripheral action, presumably through acetylcholine (H. Hermann *et al.*, 1938). *Physostigmine* potentiates acetylcholine, nicotine, hordenine and lobeline (J. Lévy and Olszycka, 1937). Curare decreases; strophanthin and anesthetics have no effect (Stewart and Rogoff, 1919–1921). Crowden, 1929, showed that the adrenal glands can be partly depleted by subjecting the animal to *external cold. Anesthesia* by chloroform, ether or urethane leads to discharge of epinephrine from the adrenal medulla (Bhatia and Burn, 1933). *Stimulation of sensory nerves* does not influence the epinephrine output (Stewart and Rogoff, 1924). Older methods gave deceptive results, partly because they did not really measure epinephrine and partly because they overlooked the important influence of the rate of blood flow through the adrenals. If the epinephrine output is constant, as is ordinarily true, then the concentration must vary with the rate of the blood flow through the adrenals. This is indeed so (Stewart and Rogoff, 1917).

Emotional States.—Imperfect methods of epinephrine estimation led to claims that emotion, fright, and such like states increase the epinephrine output (Cannon *et al.*) and diminish the epinephrine store (Elliott, 1912). Stewart and Rogoff, 1920, failed to confirm these claims by more exact methods; they found, moreover, that emotional reactions are quantitatively the same whether epinephrine reaches the blood or not.

Epinephrine Output and Blood Pressure.—The concentration in the blood never attains the level where it could affect the blood pressure except in pheochromocytomas (G. F. Cahill, 1948). Hoskins and McClure, 1912, pointed out that if epinephrine persisted normally in the circulation, it would result in inhibition of peristalsis, since the intestines are much more sensitive than the blood vessels. Trendelenburg, 1915, also found that the concentration in normal blood could not be over 1 in 1 or 2 billions, and is probably smaller—too small to affect the blood pressure or intestine. Further, Hoskins and McPeek, 1913, emphasized that the small quantity which could possibly reach the circulation would dilate instead of constricting the blood vessels. The fact that the adrenal glands do not normally contribute to the maintenance of vascular tonus is shown by temporarily *clamping the adrenal vessels.* The blood pressure does not fall while the clamp is applied (within forty hours; Austmann *et al.*, 1917), but only as death approaches; nor does it then rise when the clamp is removed (Hoskins and McClure, 1912).

Low Blood Pressure and Shock.—Stewart and Rogoff, 1914, showed definitely that the output of epinephrine and its concentration in the general circulation are not altered by low blood pressure. The concentration in the adrenal vein rises, but merely because the blood flow through the glands falls with the blood pressure, and the epinephrine is therefore less diluted. Etherization tends to lower the epinephrine store.

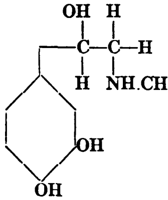
Constrictor Substance of Serum.—Normal serum has a constrictor effect on blood vessels. This was at first attributed to epinephrine (Trendelenburg); but it was shown by G. N. Stewart, 1911, and confirmed by others, that serum stimulates all smooth muscle directly and lacks the sympathomimetic inhibitory action of epinephrine, for instance on the intestines. This constrictor substance has therefore no relation to epinephrine It is formed mainly in the process of clotting (O'Connor, 1912) and increases with the age of the serum (Handovsky and Pick, 1912).

Suprarenal Testing.—Gravimetric and volumetric methods are not applicable, and recourse must be had to colorimetric and physiologic methods. For fairly large quantities, the effect on the blood pressure of mammals is commonly used. A standard procedure is described in the U.S.P. The Trendelenburg method of frog perfusion has also been widely employed. Various other methods are discussed in the papers of G. N. Stewart, 1911; Tiffeneau, 1915; J. Lévy, 1939. Folin, Cannon and Denis, 1913, described a sensitive colorimetric test, which gives good agreement with the blood pressure method. The colorimetric methods were reviewed by Barker, Eastland and Evers, 1932. Suprarenal extracts contain some *choline.* This is responsible for the depressor effects produced by such extracts after the removal of their epinephrine (Hunt, 1900).

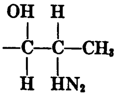
Epinephrine, U.S.P. (Adrenalin, levo-methylamino-ethanol catechol, suprarenalin, l-suprarenin), is slightly sol. in water, alc., ether, fixed or volatile oils. *Adrenalin Tablets,* N.N.R., contain 0.33 or 1 mg. as borate. They form a 1:1000 solution when dissolved in ⅓ or 1 cc. of water. *Suprarenin,* N.N.R., is a brand of synthetic epinephrine (levorotatory).

Epinephrine Solution, U.S.P. (Epinephrine Hydrochloride Solution, Epinephrine Solution, 1:1000), is a 1:1000 watery solution of epinephrine, rendered soluble with hydrochloric acid, sometimes with small quantities of antiseptics, such as 0.1 to 0.2 per cent of sodium bisulfite. This makes them more irritant to the conjunctiva and subcutaneous tissue (Tainter, Throndson and Lehman, 1937), and doubles their toxicity with hypodermic and intramuscular injection, probably by hastening absorption, for it lacks this effect with intravenous injection (R. K. Richards, 1943). The undiluted, aseptic solutions keep fairly well. On dilution they oxidize in a few hours, acquiring a pink to brown color. This is favored by alkalis, delayed by acids. The alkaloid is a reducing agent and gives a pink or red color with oxidizing substances such as iodine (Ewins, 1910). Ferric chloride produces an emerald green color, which turns purple and carmine on adding an alkali. The U.S.P. requires the solution to be assayed by its effect on the blood pressure of atropinized dogs. The solution is intended for local use, and is not necessarily sterile. **Epinephrine Injection,** U.S.P., a sterile watery solution prepared with hydrochloric acid; usually available in containers of 1, 10 and 30 cc. of 1:1000 solution. Average dose, subcutaneous or intramuscular, 1 mg. of epinephrine. *Epinephrine Inhalation,* U.S.P. (Epinephrine Hydrochloride Spray), a 1:100 solution in water, prepared with the aid of hydrochloric acid, is used solely in asthma and hay fever, by oral insufflation of a fine mist. *Epinephrine Suspension in Vegetable Oil,* 1:500, N.N.R., is used in allergies to prolong the action of intramuscular injection, starting with 0.2 to 0.5 cc. and increasing cautiously to 1.5 cc. = 3 mg. of epinephrine. The oil may produce fibroses and scars.

Related Catechol Alkyl Amines.—Many changes may be introduced in the alkyl chain of epinephrine.

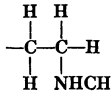


The more important are:



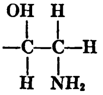
$-\overset{OH}{\underset{H}{C}}-\overset{H}{\underset{HN_2}{C}}-CH_3$

Cobefrine



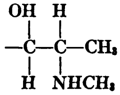
$-\overset{H}{\underset{H}{C}}-\overset{H}{\underset{NHCH_3}{C}}-H$

Epinine



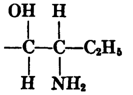
$-\overset{OH}{\underset{H}{C}}-\overset{H}{\underset{NH_2}{C}}-H$

Arterenol



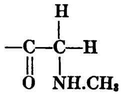
$-\overset{OH}{\underset{H}{C}}-\overset{H}{\underset{NHCH_3}{C}}-CH_3$

3,4-Dioxyephedrine



$-\overset{OH}{\underset{H}{C}}-\overset{H}{\underset{NH_2}{C}}-C_2H_5$

Ethylnorsupra-renine



$-\underset{O}{\overset{\|}{C}}-\overset{H}{\underset{NH.CH_3}{C}}-H$

Kephrine

Arterenol (demethylated epinephrine, noradrenaline; supposedly "Sympathin ME") was investigated especially by Barger and Dale, 1910, and by Stehle and Ellsworth, 1927; *ethylnorsuprarenine* by W. M. Cameron *et al.*, 1938. The latter produces a primary fall of blood pressure, from peripheral vasodilatation together with constriction of the intrahepatic veins, pooling the blood in the splanchnic area. The heart is accelerated and its output increased. Repeated injections reverse the fall to rise of pressure, with increased sympathetic response similar to that of epinephrine. *Cobefrine* has the same side actions as epinephrine and no material advantage (Tainter, 1939).

Kephrine Hydrochloride, N.N.R. (Stryphnon), differs from epinephrine in having a ketone group in place of the secondary alcohol group. It was prepared by Stolz, 1904, as the last step in the synthesis of epinephrine. Its pharmacology was studied by Otto Loewi and Meyer, 1905. Its actions closely resemble those of epinephrine, but are less potent and more persistent, and its solutions are more stable. Local effects require about ten times, and the systemic pressor action sixty times, the dosage of epinephrine (Kollert and Rezek, 1925). It is used chiefly as local hemostatic, especially in the form of impregnated gauze (Albrecht, 1923). The vasoconstriction lasts over an hour. Little is absorbed, so that there are no systemic effects. It is inactive by mouth. It has been injected hypodermically against asthma (2 cc. of 0.5 per cent) (Sumegi and Haintz, 1929). It has no special advantage over epinephrine and may produce considerable anxiety complex.

◆

E'PHEDRINE

This alkaloid was first isolated by Nagai, 1887, from Ephedra equisetina, a plant, (Ma Huang) used as medicine by the Chinese since antiquity. Most of the present supply is probably synthetic (Chen, 1927). Its chemical structure differs from that of epinephrine by the absence of the two phenolic hydroxyls. Its effects on the circulation, intestines, bronchi, iris, and so forth, are superficially similar to those of epinephrine. They require larger doses, but are more lasting, owing probably to its much greater stability and resistance to oxidation. They can be produced by oral administration. Unlike epinephrine, it is not sensitized by cocaine or by denervation. It also stimulates the central nervous system. A number of isomers with similar actions are known. Ephedrine is used therapeutically in hay fever and asthma, where it is less effective than epinephrine, but more convenient; as a mydriatic with minimal effect on intra-ocular tension; and as a stimulant to respiration, especially against barbiturate poisoning in conjunction with metrazol or picrotoxin. (Review, K. K. Chen and Schmidt, 1930, Medicine [Baltimore] *9:* 1–117, includes related substitutes.)

Species of Ephedra grow in different parts of the world. Chen and Kao state that the Chinese species contain only the official levorotatory ephedrine, while the same species and other varieties from Europe yield only dextrorotatory pseudo-ephedrine. Read and Feng, 1927, did not find ephedrine in the California species. East Indian species range from rich to none. Ephedrine exists in the seed of another, totally unrelated Indian plant, Sida cordifolia, which was also used in folk medicine. Ma Huang also contains another alkaloid, *ephedine*, which lowers blood pressure and has other complex actions (Chen, Anderson *et al.*, 1935).

The chemical structure of ephedrine, α-hydroxy-β-methylamino-propyl-benzene, differs from epinephrine chiefly by lacking the two phenolic hydroxyls. These are responsible for the susceptibility of epinephrine to oxidation, while ephedrine solutions are stable indefinitely. This may also explain why ephedrine is active by mouth. Another difference is that the side chain in epinephrine contains only one asymmetric carbon and therefore has only one pair of optical isomers, while ephedrine has two asymmetric carbons and four optical isomers. These have been synthetized (Spaeth and Goehring, 1920). The ephedrine isomers are convertible into each other, but more easily into pseudo-ephedrine. Their chemistry is reviewed by Chen and Schmidt, 1930.

The pharmacologic actions of the ephedrine isomers (reviewed by Swanson, 1932) are generally similar, but they differ somewhat, especially toward antagonists. Quantitatively, the (natural) levo-ephedrine is about twice as active as the dextro, in its peripheral actions and toxicity, so that the (synthetic) racemic (ephetonine) is about three-fourths as potent as the levo. Either may be used clinically (Pak and Read, 1928). Jarowski and Hartung, 1943, conclude that the optimal configuration for physiological activity exists in the isomers when the phenyl-bearing carbon is levo; the carbaminic, dextro.

Pseudo-ephedrine is considerably weaker for the blood pressure and pupil, about equal for the bronchial dilatation and nasal vasoconstriction, and stimulant to the myocardium, where ephedrine is depressant in large doses (Pak and King, 1930).

Synergists and Antagonists.—The resemblance between ephedrine and epinephrine suggests an identical mechanism. This appears contradicted by the observations on antagonism and with denervated organs, although the fundamental significance of the difference is not clear. *Denervation and cocaine,* which sensitize the vasoconstrictor and cardio-accelerator responses for epinephrine, do not do so for ephedrine, or for tyramine (Tainter and Chang, 1927). Indeed, cocaine materially decreases these responses for ephedrine (De Eds, 1927; Pak and Read, 1928); but Thienes, 1930, states that it increases the uterine response. *The ergotamine reversal* of the blood pressure response of epinephrine does not extend to ephedrine with ordinary doses (De Eds and Butt, 1927; Nagel, 1925); but this difference appears to be only quantitative, for ergotamine decreases the ephedrine responses, and reversal may be secured with small doses of ephedrine and large doses of ergotamine (Curtis, 1928; Swanson, 1929). *Ephedrine and epinephrine* are synergistic with considerable potentiation for the pressor response, the blood vessels and the uterus (Csépai and Doleschall, 1928), but the uterine inhibition by epinephrine is counteracted by ephedrine (De Eds, 1927). In perfused mammalian legs, Burns, 1932, found the presence of epinephrine in the perfusion fluid essential for both constrictor and dilator response to ephedrine and tyramine.

Stability in Circulation.—Ephedrine is excreted unchanged in the urine (D. Richter, 1938). Perfusion through heart-lung-liver preparations of dogs for three hours does not destroy or fix any ephedrine, in contrast to epinephrine, which would disappear entirely, and nicotine and strychnine, which would be greatly weakened (Thorp, Essex and Mann, 1933).

Bronchial Action and Asthma.—Ephedrine is employed extensively against bronchial asthma, especially as a preventive (Middleton and Chen, 1926). It is less effective than epinephrine, but can be taken by mouth (20 to 50 mg., $\frac{1}{3}$ to $\frac{5}{6}$ grains) and the effect is more enduring. The best results are obtained in allergic asthma, fair in reflex and least in infections (Leopold and Miller, 1927).

Studies of the bronchial air-way in animals by the lung plethysmograph (Swanson) and by bronchial perfusion (Warnant, 1929; Pak and King, 1930) show that epinephrine, ephedrine, pseudo-ephedrine and hordenine all dilate in high dilutions (1 per 5 millions for ephedrine perfusion), and antagonize both parasympathetic stimulants (pilocarpine, physostigmine and arecoline) and "muscular" stimulants (histamine, pituitrin, ergotamine and anaphylaxis), while atropine relieves only the parasympathetic constriction. Perfusion and relatively high concentrations (1:10,000) with ephedrine and especially pseudo-ephedrine may constrict the bronchioles, as may also epinephrine (Pak and King). Quantitative comparisons of tyramine, hordenine and related amines were made by Alles, 1933.

Allergic Reactions.—Ephedrine (by mouth or locally) is effective in a considerable proportion of patients with hay fever, urticaria and other allergic reactions, but it is not so potent as epinephrine. On the other hand, ephedrine itself occasionally produces dermatoses (ten cases reported to 1933), with eczemas and erythema, sometimes after absorption, but especially after local application, and with positive scratch test which is negative for epinephrine (Abramowitz and Noun, 1933, ref., J.A.M.A., *101:* 1191).

Blood Pressure.—Small doses (0.01 to 0.2 mg. per Kg. intravenously for dogs, Ding, 1929) raise the blood pressure for ten to fifteen minutes. Large doses (6 to 10 mg. per Kg.) and close repetition of small injections produce less rise and actually lower the pressure (Kreitmair, 1927). This is probably due to cardiac injury, for epinephrine and tyramine may still raise the pressure at this point (Chen and Meek, 1928). Clinically, oral administration of 50 to 400 mg. raises the systolic pressure an average of 30 mm. for five hours. The diastolic pressure is also raised. The hypertension, through the vasoafferent reflexes, tends to stimulate the vagus and to depress the vasoconstrictor and respiratory center, as with epinephrine (Heymans *et al.*, 1933). The pressure rise potentiates considerably with epinephrine, as also the effects on most other organs (Koppanyi and Luckhardt, 1931). The persistent pressure rise suggested trials of ephedrine against hypotension, circulatory collapse, shock and hemorrhage; but vasoconstriction can only be of temporary benefit with these conditions. Its intravenous or spinal injection is probably more valuable to counteract and especially to prevent the fall of pressure during spinal anesthesia, as has been confirmed on dogs (Burch and Harrison, 1931). Clinically, 25 to 50 mg. may be injected by vein or hypodermically (Lundy, 1933; Weinstein and Barron, 1936).

Cardiac Effects.—The clinical response is generally unimportant. The heart rate is usually quickened, sometimes slowed (Middleton and Chen, 1926), occasionally arrhythmic. The acceleration is due to peripheral stimulation of the sympathetic innervation, the slowing to aorto-carotid reflexes from the pressure rise. Ephedrine, 30 mg. two or three times daily, is sometimes effective against the Adams-Stokes heart-block syndrome (J. E. Wood, 1932). Severe cardiac disease contraindicates ephedrine, partly because of the anxiety complex which it induces. Large doses are directly depressant to the cardiac muscle; but it does not induce ventricular fibrillation after chloroform, as does epinephrine (La Barre, 1928); nor does it cause myocardial degeneration when used with sparteine as does epinephrine; it does not produce the atheromatous lesions which epinephrine causes in rabbits (di Mattei, 1931).

In dogs, with intact vagi, intravenous or hypodermic injections, to 30 mg. per Kg., usually slow the heart rate, presumably by the pressor aorto-carotid reflex. The minute output, measured by Fick's method, may be increased notwithstanding the slowing (C. P. Wilson *et al.*, 1928). With divided vagi or after atropine the rate is generally quickened; above 30 mg. per Kg. atropine does not prevent slowing, indicating direct muscular depression (Chen and Meek, 1926). The cardiac depression was studied electrographically by Meek and Seevers, 1934. They describe four stages in unanesthetized dogs. Even therapeutic doses may produce cardiac irregularities, especially in the ventricular rhythm in man and dogs. Narcotic doses of barbiturates are somewhat protective. When administered with atropine, ephedrine may increase the sinus rate to 200, often with AV block (Seevers, 1933). Digitalis in doses which have no effect on the electrocardiogram if they are injected alone, doubles the duration of the ephedrine arrhythmia and changes the type to preponderantly ventricular (Seevers and Meek, 1935). Perfused hearts are stimulated by dilute solutions (1:10,000 for turtles, 1:100,000 for rabbits) with increased rate and amplitude. Ten times stronger concentration depresses the rate, but not the amplitude. Still higher concentrations (1:100 for turtles, 1:2000–1000 for rabbits) cause partial heart block and diastolic arrest (Chen and Meek, 1926; Barlow and Sollmann, 1926; Kreitmair, 1927). The effect of ephedrine esters is similar, but generally less stimulant and more toxic (Dulière, 1927). The depression and toxicity appear to be directly muscular (Barlow and Sollmann, 1926). The stimulant phase is primarily sympathetic. Chopra *et al.*, 1931, assume also parasympathetic and muscular stimulation.

The *potency for cardiac acceleration* increases in the sequence of amphetamine < ephedrine < neosynephrine < propadrine < tryamine < arterenol < cobefrine < epinephrine (Crismon and Tainter, 1939). The cardiovascular effects of a series of aliphatic sympathomimetic amines are reported by D. F. Marsh, 1946.

The **vasoconstrictor action** is used especially in rhinitis, sinusitis and hay fever to shrink the congested mucous membrane. This may be accomplished by oral or by local administration, in contrast to epinephrine; indeed, the oral is generally preferred, even with hay fever (Leopold and Miller, 1927). For local use it is applied as sprays, or "drops" containing 0.5 to 2 per cent of an ephedrine salt or 1 per cent of the base in oil. With a 3 per cent spray, the shrinkage of congested turbinates begins within a few minutes and persists up to three hours. It is most effective if used early in the paroxysm (Fetterolf and Sponsler, 1925). The shrinking of the mucosa is felt as diminished obstruction and may be demonstrated by direct inspection or quantitatively by nasal plethysmograph (Swanson, 1931) or thermopyle (Liljestrand and Schmidt 1930). The latter found that the constriction is not followed by increased dilatation. Phenylethanolamine gave more persistent constriction.

Vascular Perfusion.—In general, low concentrations constrict and high concentrations (about 0.5 per cent) dilate, as do prolonged perfusions with dilute (0.005 per cent). The relative response varies with different organs: the spleen gives prolonged constriction; the kidney constriction is followed by dilatation; the intestine, generally dilatation. Pseudo-ephedrine acts similarly and is additive (Chen and Meek, 1926; Loo and Read, 1928). Tyramine produces but little constriction in the perfused frog's leg; this is augmented by epinephrine, but not by pituitrin (Burns, 1932). Observations of blood vessels in a chamber of the rabbit's ear show that ephedrine contracts the arteries, but not the smaller vessels (Hou, 1932).

Splenic contraction and increase of circulating erythrocytes are distinctly less than with epinephrine; indeed, the response is inconstant (Gasparini, 1928). In guinea pigs, ephedrine increases the red cells, leukocytes and platelets even after excision of the spleen. This is probably due to extrusion from the bone marrow (Simpson, Levy and Cadness, 1936).

The urine flow is increased by small doses of ephedrine (½ to 1 mg. per Kg.), probably from the accelerated blood flow caused by the high blood pressure and renal dilatation. Pseudo-ephedrine is more effective. Large doses suppress diuresis, especially in anesthetized animals and under phenobarbital (Chopra, Krishna and Ghose, 1931)

Mydriasis without cycloplegia occurs readily on local or systemic administration (in contrast to epinephrine, which acts more powerfully, however, on the denervated iris than does ephedrine). It is utilized clinically (locally, as 1 to 10 per cent, using 2 per cent of ephedrine sulfate for light iris and 4 per cent for dark, with or without the addition of 0.1 per cent of homatropine) for routine ophthalmic examination when cycloplegia is not required. The mydriasis lasts from three to five hours, with slight cycloplegia for one to two hours; the pupil reacts to light even with the 10 per cent solution. There is slight smarting and congestion of the conjunctiva, lasting half an hour; above 5 per cent it sometimes causes negligible headache and nausea. Pseudo-ephedrine is not used in ophthalmology, as the effects are weak and uncertain, even in the 10 per cent solution (H. J. Howard and Lee, 1927). Chinese and Negroes are less susceptible than Europeans to mydriasis by ephedrine, cocaine and euphthalmine (Chen, 1928).

Local Anesthetic Action.—Frog's sciatic conduction is blocked by 5 per cent ephedrine hydrochloride; intracutaneous injection of 0.1 per cent is anesthetic in man. Rabbit's cornea is not anesthetized by 10 per cent (F. H. Schultz, 1940).

Gastric Motility.—Clinical fluoroscopic studies show immediate increase, lasting eight to ten minutes, followed by inhibition with delayed gastric emptying and slowed passage through the intestines, the effect lasting three to four hours (Trachtenberg, 1931). Oral administration of 0.065 Gm. of ephedrine sulfate doubled the normal emptying time (Van Liere *et al.*, 1936). The gastric acidity is usually unchanged, the neutral chloride is increased.

Gastric inhibition by epinephrine was reported for unanesthetized dogs by J. H. Kinnaman and Plant, 1927; for cats by E. D. McCrea and MacDonald, 1928; minute doses may cause transitory contraction (I. Marcu and Savalesco, 1928).

Intestinal Motility.—In unanesthetized dogs with intestinal fistula, Kinnaman and Plant observed relaxation and suppression of peristalis after hypodermic or oral administration of ephedrine, 5 mg. per Kg. Excised intestine is generally relaxed (Kreitmair, 1927), but may be stimulated. Patients may develop some difficulty in relaxing the *anal sphincter* after taking ephedrine for some time.

The **uterus** is less sensitive to ephedrine than to epinephrine. According to Curtis, 1929, it is generally stimulated, with gradual increase in tone and amplitude, in all animals, regardless of the response to sympathetic stimulation (in contrast to epinephrine). The stimulation is abolished by ergotamine and potentiated by cocaine (Thienes, 1930). Ding, 1929, described uterine relaxation in young guinea pigs. Clinically, ephedrine does not relax the parturient uterine contraction ring, as does epinephrine (Dodek).

Urinary Bladder.—Full doses of ephedrine may produce *vesical retention* (Balyeat and Rinkel, 1932), and patients who have taken the drug for some time may have infrequent micturition. It has been employed with considerable success against *enuresis* of children (0.03 Gm. tablet at bed time, increasing by this amount every three or four nights, if necessary, sometimes to a total of 0.3 Gm., and continuing for several months; Brookfield, 1937). Kittredge and Brown, 1944, report good results from 50 mg. at bedtime for two weeks; but in many cases enuresis resumed on discontinuing the medication.

Excised ureter, in the dog and pig, is chiefly stimulated, followed by depression with large doses. Epinephrine produces similar stimulation with lower concentrations and does not depress (Roth, 1930). Ephedrine is said to *prevent erection* in some individuals.

Glandular Secretion.—The effects are confused by the vasoconstriction, but probably are unimportant. Large doses cause salivation in dogs, perhaps by nausea. The gastric, biliary, pancreatic and intestinal secretions are not increased (Chen, 1926).

Myasthenia gravis is reported to be markedly and progressively improved in almost all patients by prolonged administration of ephedrine, generally in conjunction with aminoacetic acid. Epinephrine is ineffective (Viets and Schwab, 1939). The mechanism of this action is not known. Light and Weiss, 1934, reported that oral administration of 25 mg. of ephedrine three or four times daily produces temporary cessation of *creatinuria*. The contractility of frog's *gastrocnemius* muscle is somewhat increased by 1:1000; 1:100 produces fibrillation (Kreitmair, 1927).

In **Addison's disease**, ephedrine raises the blood pressure, but does not improve the general condition (Rowntree and Brown, 1926).

Respiratory metabolism of unanesthetized trained dogs is decreased by ephedrine (12 to 18 per cent after 100 to 850 γ), in contrast to epinephrine (J. de Moreloose, 1942).

Considerable hyperglycemia is produced, more in dogs than in rabbits. In contrast to epinephrine hyperglycemia, it is checked by barbiturates, and is presumably central (D. Campbell and Morgan, 1933). The *fat and lactic acid* of the blood are generally increased. *Tyramine* causes little or no hyperglycemia (Himwich *et al.*, 1930).

Central Actions.—Ephedrine produces phenomena of *nervous excitement*, often manifested with clinical doses as insomnia and tremors and an *anxiety complex*, especially in neurotic individuals and in women. Large doses stimulate the *respiratory center*, and in animals produce *convulsions*, which occur after decerebration, as with cocaine. This stimulation has been utilized in the treatment of *narcotic poisoning* by barbiturates (Barlow and associates, 1936), morphine (C. F. Schmidt and Livingstone, 1928), and scopolamine (Kreitmair, 1927). It also gave marked or complete symptomatic relief in a series of patients with *narcolepsy* and catalepsy (25 to 50 mg. in capsules, two or three times daily) (Doyle and Daniels, 1932; Daniels, 1934; but *amphetamine* appears to be more effective. Ephedrine increases the discharge of impulses from the central nervous system to the *sympathetic ganglia*, but blocks them within the ganglia, so that they are not effective. The central sympathetic stimulation is independent of the respiratory stimulation (Marrazzi, 1939).

Intracisternal injection causes especially strong stimulation of the respiratory center and is effective against respiratory paralysis by procaine (Isenberger and Rice, 1936).

Temperature.—Injection of 10 mg. of ephedrine causes a rise of 1.5° C. in rabbits (Ding). *Ephetonine* (synthetic racemic ephedrine) produces sweating with fall of temperature by 1° to 2° C. (Seeber, 1933).

Local anesthesia results from direct application of 5 per cent ephedrine hydrochloride to frog's sciatic nerve, or 0.1 per cent intracutaneous injection in man. The cornea is not anesthetized by 10 per cent solution (F. H. Schultz, 1940).

Toxic Effects.—The anxiety complex may be annoying, but no serious effects have been reported from single doses as high as 400 mg. (6⅔ grains), or from 150 mg. every three hours day and night. Prolonged use does not seem to produce cumulative effects (Chen and Schmidt, 1930); indeed, it may induce some tolerance (Althausen and Schumacher, 1927). The fear has been expressed that the psychic excitation of ephedrine would lead to addiction; and large doses administered to animals over long periods have produced delirious and maniacal phenomena resembling those of cocaine, especially in animals habituated to this alkaloid (Seevers, 1930). These have not been reported in the extensive clinical use of ephedrine.

***Ephedrine Hydrochloride,** U.S.P., is obtained from several species of Ephedra or synthetically. It is freely sol. in water (1:3) or alc. Dose, 15 to 60 mg., ¼ to 1 grain; for nasal instillation, 0.5 to 2 per cent; for ophthalmic, 4 per cent. A 1 per cent solution is reported to produce a stinging sensation in the nose, which is absent with the *sulfate*, also official. *Ephedrine Sulfate Tablets*, U.S.P., are usually available as 15, 25, 30 and 45 mg. (¼, ⅜, ½ and ¾ grains). *Capsules* usually contain 30 or 50 mg. *Ephedrine*, U.S.P., the free base, is sol. in water, alc., and liquid petrolatum. *Racéphedrine hydrochloride*, N.N.R., also available as sulfate, contains the racemic (d-1) synthetic alkaloid. It is about half as potent as the official levo-ephedrine, but is used in the same dosage.

Cinnamyl ephedrine is reported by F. H. Schultz, 1940, to produce direct depression of smooth muscle, antagonistic to barium and mecholyl, and lowering blood pressure. It produces *local anesthesia*. It is about ten times more potent than cocaine on rabbit's cornea (but 1 per cent produces irritation); twenty times more potent than procaine on human intradermal injection; slightly more potent than procaine for spinal anesthesia. Frog sciatic is blocked by one per cent. The *d* and *l* are about equally potent, but the *l* is about half as toxic as the *d* (F. H. Schultz and Barbour, 1942).

Other phenyl alkylamines are derived by altering the side chains in ephedrine. The following are the more important:

AMPHET'AMINE (BEN'ZEDRINE)

This synthetic base (alphamethylphenethylamine, betaphenylisopropylamine, racemic desoxy-nor-ephedrine) differs from ephedrine in a somewhat simpler side chain. It is used to produce similar local vasoconstriction in rhinitis and the like, with the convenience that it may be administered by inhalation. Its systemic administration (as the sulfate) relaxes spastic contraction of the digestive tract. It stimulates psychic activity more than does ephedrine, and is employed against narcolepsy and depressive neuroses, but should not be used promiscuously. It has been tried clinically against the respiratory depression of morphine and appears to be more effective than ephedrine, metrazol, caffeine or nikethamine (Handley and Ensberg, 1945). Overdosage causes restlessness and insomnia, and exceptionally serious immediate reactions. It may produce mild addiction. The rise of blood pressure contraindicates its administration in hypertension and in coronary disease. Its pharmacology is described by Detrick *et al.*, 1937. It is partly sympathomimetic, partly musculotropic. In man, after oral administration of 20 mg. of amphetamine sulfate, about 9 per cent is *excreted* by urine in twenty-four hours, 50 per cent in forty-eight hours. The remainder is slowly inactivated in the body; less if the organs have been injured by carbon tetrachloride (K. H. Beyer and Skinner, 1939).

The *vasoconstriction of the upper respiratory mucosae* is comparable to ephedrine, and is less intensive, but more lasting, than with epinephrine. It is useful especially in sinusitis and rhinitis; it is less effective than epinephrine against the allergy of hay fever, and it is probably unsuccessful against spasmodic asthma, as it contracts the *bronchiolar muscle* (Sollmann and Gilbert, 1937).

There is no apparent relation between the pressor and bronchiolar potency of the phenylpropylamine derivatives (B. E. Graham and Cartland, 1944).

Phenylethanolamine

Amphetamine (base) is marketed for this purpose as *Benzedrine Solution*, 1 per cent in liquid petrolatum, aromatized with lavender oil; and as an *inhaler*, charged with 0.325 Gm., with menthol and lavender oil. Only one or two inhalations should be taken at intervals of an hour, to guard against *overdosage*, which causes marked mydriasis, insomnia, inability to relax, dryness of the mouth and sometimes persistent rise of blood pressure. *Skin eruptions* occur rarely (J. S. Ersner, 1943). *Gross overdosage* produces extreme restlessness, rapid pulse or heartblock, pallor, rapid shallow respiration, collapse, sometimes ending fatally after several hours of coma (A. J. Hertzog *et al.*, 1943; H. A. Rosenbaum, 1943; S. P. Waud, 1938, gives a detailed description).

Control of Obesity.—Continued administration of amphetamine or propadrine results in loss of body weight, in rats as well as in man, owing to depression of appetite, which makes it easier to enforce dietary restriction. S. C. Freed, 1947, attributes this to a feeling of well being, doing away with the nervous tension that leads to overeating. Hawirko and Sprague, 1946, recommend d-amphetamine, 2.5 to 5 mg. with each meal, as producing less excitement and insomnia than the usual dosage of amphetamine, 5 mg. of the sulfate at 8 A.M. and 10 A.M. Clinical digestive disturbances include nausea, eructations, flatulence, abdominal cramps, disturbed bowel regularity (Ersner, 1940). A temporary increase of about 15 per cent in *oxygen metabolism* follows oral administration of 20 mg. of amphetamine (G. A. Emerson and Abreu, 1944). *Rats* show no material increase of energy metabolism, and no material effect on digestion. Food intake is impaired for about a week, when appetite returns even if the drug is continued. Propadrine proved less effective than amphetamine, but also less excitant (M. L. Tainter, 1944).

Irradiation Sickness.—Amphetamine and dextro-desoxyephedrine are credited with improvement, presumably by counteracting increased capillary permeability (E. L. Jenkinson and Brown, 1944).

Acute effects on the circulation, as observed in dogs, consist in prolonged rise of blood pressure, marked slowing of the heart (chiefly reflex) and increase of cardiac amplitude. The *urine flow* is increased. The *spleen* contracts briefly, with prompt *erythrocytosis*. The *respiration* is moderately increased from the carotid sinus reflex. Toxic doses injure the myocardium (Dautrebande, Philippot and Charlier, 1939). The vasoconstriction is not enhanced by cocaine or completely reversed by ergotamine (E. M. Boyd and Connell, 1937). Repetition of moderate doses produces fall of blood pressure instead of rise (Alles, 1933; Tainter, 1933). The mechanism of this depressor response is not clear. It is not prevented by division of the vagi, atropine or carotid sinus denervation, but is enhanced by cocaine (Pinkston *et al.*, 1939).

The *frog heart* responds with increased rheobase and chronaxie. The *sciatic nerve* shows increased rheobase and maintained chronaxie. The *gastrocnemius muscle* gives increased rheobase and decreased chronaxie (B. Günther, 1942).

Amphetamine sulfate against gastro-intestinal spasm was introduced by Myerson and Ritvo, 1936, for roentgenologic examinations and to distinguish between spastic and organic lesions. Oral administration of 20 to 40 mg. promptly relaxes pyloric and colonic spasm, the effect starting in five minutes, reaching its maximum in half an hour, and disappearing in an hour. The tonus of the stomach is moderately decreased; its peristaltic action is much less affected and sometimes increased. The emptying time of the spastic stomach is somewhat shortened. In normal men and dogs the beginning of gastric evacuation is hastened to about 40 per cent, probably by increased tonus of the stomach before the pyloric tonus increases. The time of complete evacuation is lengthened by about 20 per cent by inhibition of gastric tonus and possibly increased pyloric tonus (K. H. Beyer and Meek, 1939; Van Liere and Sleeth, 1938). In *seasickness*, J. Hill, 1937, reported prompt improvement in a third of the patients after 10 to 20 mg. of benzedrine sulfate, but systematic trials show that it has no value either for prevention or treatment (Holling *et al.*, 1944).

Amphetamine has relatively little effect on the *small intestines in situ* (Beyer and Meek, 1939). *Excised intestines* are relaxed by small doses; with higher concentrations this is followed by stimulation. Ergotamine, atropine and nicotine decrease the inhibition, but have less effect on the stimulation. Cocaine does not sensitize to either action (Detrick *et al.*, 1937; E. M. Boyd, 1938). Excised intestines of dogs respond with relaxation of tonus and decreased excursions; the colon is much more sensitive than the small intestines (Farah and Pinkston, 1940). Myerson and Ritvo, 1936, reported therapeutic benefits from benzedrine against spastic colitis, but the response is variable and clinically unsatisfactory (D. H. Rosenberg, Arens *et al.*, 1938), and the side effects may be disturbing. It may produce spasm of the *rectal and urinary sphincters* (D. M. O'Connor, 1937). The *gallbladder* is relaxed or not affected (J. Flexner, Bruger and Wright, 1938). The *uterus* of virgin guinea pigs responds with prolonged spastic contraction, similar to ephedrine (E. M. Boyd, 1938).

If a 0.5 to 2 per cent solution is applied to the abdomen of fireflies, their intermittent glow becomes continuous and persists for hours; similarly with the golden glow of the morning-glory beetle. Amphetamine has no effect on the luminescence of ctenophore jellyfish (J. Seifter, 1945).

The minimal lethal dose of amphetamine sulfate ranges from 5 to 150 mg. per Kg. in various kinds of animals. Continued administration at first increases susceptibility to large doses, then induces some tolerance (W. E. Ehrich *et al.*, 1939). Those which survive repeated large doses suffer no apparent injury (W. E. Ehrich and Krumbhaar, 1937). The hypodermic MLD for rats is 25 to 35 mg. per Kg. (Alles, 1933).

Mental Activity.—With normal individuals 10 to 30 mg. of amphetamine sulfate by mouth (and proportionate doses for children, Bradley, 1937) tends to increase mental alertness and motor activity to the point of restlessness, and to facilitate the flow of thought, generally at the expense of concentration, to increase loquacity, induce a rather fictitious sense of fitness, and to diminish fatigue, sleepiness and malaise. These stimulant effects occur in one-half to three hours (much faster with inhalation) and last three to nine hours (Peoples and Guttmann, 1936; Myerson *et al.*, 1936; Davidoff and Reifenstein, 1937). They led to the use of benzedrine as a spur ("pick-me-up" or "pep" pills) against fatigue and sleepiness in periods of stress, but they obscure the natural danger signals of fatigue, and the stimulation may be followed by insomnia, increased fatigue, nervousness, irritability and melancholia.

"Doping," by a single dose of 10 mg. of amphetamine sulfate for a "spurt" of temporary stimulation, may be justified to meet emergencies, in severe and extreme fatigue. It may be repeated in six to eight hours, but not more than three doses should be taken. It should not be used if the emergency continues more than twenty-four hours. If the situation requires good judgment, the dose should be only 5 mg.

Methyl amphetamine is said to be somewhat more effective for "doping." It is used for this purpose in Germany as "*pervitin*," in Argentina as "*estimulex*" (P. O. Wolff, 1943).

Fatigue of voluntary work is inhibited by 10 to 40 mg. of amphetamine more effectively than by ten times as much caffeine (Alles and Feigen, 1942). The effect of 10 to 20 mg. on work output (bicycle ergometer) varies considerably in different subjects, but may attain 60 per cent. The dextro is more effective than the levo-isomer (P. K. Knoefel, 1943). The ability for a spurt of physical performance by fatigued soldiers is definitely improved. If the individual is sleepy, but not otherwise, performance in reading and simple arithmetic is also improved, but not with complicated problems (N. Alwall, 1943).

Doses of amphetamine larger than 20 mg. do not appear to add materially to the exhilaration, but rather to its duration; but large doses develop high blood pressure, tachycardia and relaxation of gastro-intestinal tonus. Up to 80 mg. have been given at a single dose, and 200 mg. in the course of a day (Davidoff and Reifenstein, 1937), without serious ill effects; but one patient who supposedly took 140 mg. developed convulsions, coma for thirty-six hours, hematuria, encephalopathy and pneumonia, yet recovered (Apfelberg, 1938).

Addiction.—Individuals who feel the initial stimulation as elation or euphoria may be tempted to repetitions of the experience, which terminates rather infrequently in addiction, chronic restlessness and hyperexcitability, alternating with melancholia. As there is no tolerance and no violent craving, the drug is easily withdrawn.

Amphetamine on the Activity of Albino Rats.—For the four hours following the injection (of 3 mg. per Kg.), the activity in the revolving cages was increased to seven times that of the controls, but it was followed by decrease in the next twenty-four hours, so that the total activity was the same as that of the controls. No tolerance developed (L. V. Searle and Brown, 1938. The effects have also been studied by Ehrich and Krumbhaar, 1937). Amphetamine *retards learning*, as tested by a maze (W. L. Minkowsky, 1939). In dogs, 1 mg. per Kg. by mouth results in moderate decrease of differentiation in conditioned reflexes (Alpern *et al.*, 1943). Amphetamine and its derivatives neutralize the depressant effect of tyramine and other amines on the *respiration of brain tissue* (sliced or minced) in dextrose solution (P. J. G. Mann and Quastel, 1940).

The relative central stimulation by various sympathomimetic amines has been compared by increase of motor activity in rats (Schulte *et al.*, 1941). The phenylisopropylamines are the more active, amphetamine heading the list. Ephedrine is less potent. Epinephrine produces considerable but brie stimulation. No stimulation was observed with cobefrine, kephrine, neosynephrine, propadrine, synephrine, and tyramine.

Psychiatric Conditions.—Amphetamine sulfate relieves narcolepsy without apparent ill effects, so that the patients may lead a practically normal existence. The dosage should start with 2.5 to 10 mg. (¼ to 1 tablet) before breakfast, and be repeated at intervals as needed up to four times a day; but not in the evening, to avoid interference with normal sleep. If 20 mg. per day are not effective, larger doses are also generally ineffective (M. H. Nathanson, 1937). It is useful as a symptomatic treatment of mild depressive states and somewhat against severe psychopathic depressions. It is helpful in postencephalitic *Parkinson's disease*, especially against the oculogyric crises, the lack of energy, the day drowsiness and the night insomnia; in half to two-thirds of the patients it decreases the muscular rigidity and the tremor. These last are remedied most effectively by using it with atropine or scopolamine (atropine sulfate, 2.5 to 4 mg. three times daily; amphetamine sulfate, 10 to 20 mg. before breakfast and again at noon) (P. L. Davis and Stewart, 1938). Its value in other psychoses and neuroses is questionable. The drowsiness and hebetude of phenobarbital treatment of epilepsy may be prevented by amphetamine sulfate, 5 to 20 mg. by mouth, without increasing the number or severity of the seizures (B. Cohen and Myerson, 1938; L. J. Robinson, 1941). However, it lowers the threshold of electro-convulsions (K. C. Bailey, 1943).

Alcoholic psychoses generally respond favorably; 20 or 30 mg. a day accelerate the improvement, especially in recent cases. The acute hang-over depression may disappear in an hour or so after a morning dosage of 5 to 10 mg. (Wilbur, MacLean and Allen, 1937; Reifenstein and Davidoff, 1937). Reifenstein, 1940, confirmed that it has an analeptic effect on moderate alcholic narcosis, but that it increases the toxicity of near-fatal doses. W. Bloomberg, 1939, reports good results in chronic alcoholism from the long-continued use of amphetamine sulfate, 20 to 30 mg. daily; the euphoria apparently diminishes the urge for alcohol. Reifenstein and Davidoff, 1940, obtained rather variable results. M. Rosenbaum and Lams, 1942, reported poor results. It has also been used against *barbiturate poisoning*. It appears clinically useful in barbiturate coma, injected by vein, 10 to 40 mg. followed every half hour by 10 to 20 mg., as 1 per cent solution. Even 400 mg. appeared harmless (Freireich and Landsberg, 1946). The *relative analeptic potency of* sympathomimetic amines was investigated by Tainter, Whitsell and Dille, 1939. Prinzmetal and Alles, 1939, found the dextro isomer more effective clinically than the levo or racemic (benzedrine). Amphetamine abolishes *bulbocapnine* catalepsy (E. Spiegel, 1938).

In *chronic neuroses associated with depression, fatigue or anhedonia*, amphetamine (2.5 to 20 mg. at breakfast, sometimes repeated at noon) is generally of temporary benefit, sometimes striking, but it often fails on continued use (Myerson, 1936; Wilbur *et al.*, 1937; Reifenstein and Davidoff, 1937). It may correct the *obesity* resulting from anhedonia, but should not be used against other obesities (Myerson and Lesses, 1938). In *dementia praecox* it appears to have no effect on the catatonic or hebephrenic states (Myerson, 1936).

Analgetic Action.—Testing this by electric stimulation of amalgam-filled teeth, Goetzl *et al.*, 1943, and Burrill *et al.*, 1944, found amphetamine quite potent, alone or with morphine. Handley and Abreu, 1942, however, reported amphetamine antagonistic to the analgetic as well as to the sedative action of morphine.

Contraindications to amphetamine are hypertension, coronary disease and manic excitement.

Blood Pressure Changes on Oral Administration.—Clinical doses of 30 to 40 mg. cause considerable rise of blood pressure and also a slight rise in the pressure of the cerebrospinal fluid. The pressor effect is markedly enhanced by atropine and antagonized temporarily by mecholyl. The red and white blood cell count rises, probably mechanically. Beyer, 1939, reported that 30 mg. by mouth increase the basal metabolic rate, averaging 15.4 per cent in two and one-half hours; and continued use often leads to considerable loss of body weight (seven to twenty pounds), owing to the increased activity and decreased appetite (Nathanson, 1937). Penrod, 1941, found the basal metabolic rate slightly raised.

Preparations.—*Amphetamine Sulfate, N.N.R., the sulfate of alphamethyl-phenethylamine sulfate; racemic desoxynor-ephedrine, *benzedrine*: a white, odorless, somewhat bitter powder, freely soluble in water, slightly in alcohol. Initial dose, 2.5 to 10 mg., increasing gradually if necessary, usually not to exceed 10 to 20 mg. per day. Marketed as *tablets* of 5 and 10 mg. *Benzedrine Inhalers* contain 0.25 Gm. of the free base (a volatile liquid), together with menthol and oil of lavender.

Propadrine Hydrochloride, N.N.R., a salt of phenylaminopropanol, whose structure resembles that of ephedrine, with the methyl on the amino group replaced by H. Its actions resemble those of ephedrine closely, being probably somewhat more prolonged, with less erethismus and anxiety complex. It is used locally for vasoconstriction of mucous membranes, as 1 per cent aqueous solution or ⅔ per cent jelly; and orally in asthma, 25 mg. (⅜ grain) every two to four hours. It is claimed that it does not cause urinary retention in prostatic patients. No toxic effects have been reported.

Betaphenylethylamine differs from amphetamine only by a methyl group. It is very stable, but the blood pressure rise is brief, and on oral administration it tends to lower the blood pressure. Small doses stimulate the cardiac muscle, large doses depress. All doses contract the coronary vessels; this is followed by relaxation with large doses (Barbour and Frankel, 1915). It is not mydriatic (Chen, 1928). When phenylethylamine or tyramine is fed to rats, or injected, it increases catabolism and lowers the glycogen content of the liver (Abelin and Jaffe, 1920). Barbour, 1916, made a comparative study of the sympathomimetic and other actions of a series of *phenylethylamine derivatives.* W. S. Hambourger and Jamieson, 1936, investigated the pressor effects of a number of related alkyl derivatives.

Betaparaoxyphenyl isopropylmethylamine (*Veritol*) is reported to increase the plasma volume and to raise the blood pressure without increasing the heart rate. It has therefore been recommended to counteract shock (Zachowski and Ehnimb, 1939).

Phenylethanolamine, 2 aniline-ethanol, is closely related to amphetamine and ephedrine in chemical structure and actions (M. L. Tainter, 1929; Liljestrandt and Schmidt). It produces methemoglobin clinically and in animals (A. D. Bass *et al.*, 1943). The pharmacology of a series of *phenylisopropylamines* was investigated by Alles, 1933; and *phenylpropylamines* by Hartung and Munch, 1931.

Indolethylamine stimulates plain muscles, especially of the uterus, arteries and iris. It also has stimulant central effects (Laidlaw, 1911). Perfusion through excised liver converts it into indolacetic acid. Dogs excrete 30 per cent as indolaceturic acid (Ewins and Laidlaw, 1913). The actions of the beta isomer ("*rutamine*") were reported by Ryô, 1927.

Ptomaine Bases.—Amine bases are formed in the putrefaction of proteins, and many of these ptomaines have been isolated in crystalline form (Barger and Walpole, 1909; Hanzlik, 1916); but the phenomena of so-called "ptomaine poisoning" are due chiefly to bacterial toxins (Ecker and Rademaekers, 1926).

◆

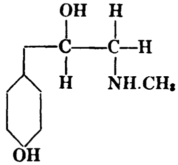
PHENYLEPHRINE

This is the levo form of a phenylethylamine derivative intermediate between epinephrine and ephedrine, containing one OH group in the meta position. Its actions come closer to those of ephedrine. It is fairly stable, and its effects are fairly lasting. It raises the systemic blood pressure on oral administration, but causes less nervousness than ephedrine (Tainter and Stockton, 1933). It does not relax the bronchi, except with concentrations a thousand times greater than with epinephrine, and not feasible in life (McIntyre, 1936).

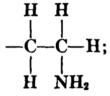
Phenylephrine hydrochloride, N.N.R. (Neo-synephrine), is used locally as ¼ to ½ per cent solution against nasal congestion and as addition to local anesthetics (3 to 5 drops of 1 per cent to 10 cc. of the anesthetic solution). The 1 per cent solution is mydriatic. It may be sterilized by boiling.

Synephrine is the tartrate of a racemic isomer with the OH in the ortho position. It is less potent than neo-synephrine.

Other phenyl alkyl amines representing changes in the side chain of neo-synephrine, but with the OH in *para* position,

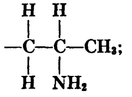


, include:



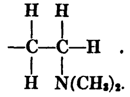
$-\overset{H}{\underset{H}{C}}-\overset{H}{\underset{NH_2}{C}}-H$;

Tyramine



$-\overset{H}{\underset{H}{C}}-\overset{H}{\underset{NH_2}{C}}-CH_3$;

Paredrine



$-\overset{H}{\underset{H}{C}}-\overset{H}{\underset{N(CH_3)_2}{C}}-H$.

Hordenine

Tyramine is parahydroxyphenol ethylamine. Its actions approach closer to those of ephedrine than to those of epinephrine. The pressor effect is less potent than with epinephrine, but more lasting (Dale and Dixon, 1909)

Occurrence.—Tyramine exists commonly in the products of putrefaction, autolysis and fermentation; it is therefore present in the alimentary tract. It was isolated from ergot (which contains 0.01 to 0.1 per cent) and was prepared synthetically from hordenine (its dimethyl derivative) by Barger, 1909. Further syntheses were made by Barger and Wampole, 1910. It occurs also in the common American and European mistletoes (*Phoradendron flavescens and Viscum album*). It has not been demonstrated in other species of Phoradendron (Crawford, 1914; Ostenberg, 1915). It constitutes the "salivary" poison of certain cephalopods (Henge, 1913).

It was also called *uteramine* from its (rather feeble) oxytocic action, and *ergotamine* from its occurrence in ergot. This has led to unfortunate confusion with the ergot alkaloid of that name.

Circulation.—Intravenous injection of tyramine produces considerable rise in blood pressure, lasting two or three minutes. The heart is slowed reflexly. The rise appears to be purely vascular, judging by the diminished volume of the kidneys and intestines, and by the decreased vein flow (Bickel and Pavlov, 1912). The constrictor action is generally considered peripheral since it occurs also on excised arteries, even on the coronaries (Barbour, 1913). However, Baehr and Pick, 1916, claimed that the pressure rise of tyramine and related bases does not occur after nicotine, and Burns, 1930, found that perfusion of tyramine constricts vessels only in the presence of epinephrine. Zipf and Gebauer, 1938, concluded that the peripheral actions involve both the sympathetic endings and the muscle directly. The myocardial contractions are rendered stronger, as with epinephrine, but the effect is shorter (Kruda and Zadina, 1938).

In man, intravenous or hypodermic injection (but not oral or rectal administration) of 20 to 80 mg. of tyramine causes marked rise of systolic blood pressure and vein pressure, slowing of the heart and increase of the T wave of electrocardiograms. The cardiac output is increased, and the volume of circulating blood is considerably augmented by emptying the vein depots. *Polycythemia* and *lymphocytosis* occur as with epinephrine. Hypodermic injections should be made in the loose tissue below the clavicle, as the local vasoconstriction may prevent absorption from other locations. The effects begin in ten to twelve minutes and last five to thirty-five minutes. They are brief with intravenous injection (F. Meyer and Eckers, 1938; Downs and Eddy, 1930). The *cerebrospinal fluid pressure* varies with the circulation (Dixon and Halliburton, 1914). Injections of 5 to 20 mg. ($\frac{1}{12}$ to $\frac{1}{3}$ grain) have been tried *in collapse* without much success. Even with 60 mg., Hewlett, 1918, obtained only a transient response in infective diseases. After operations, there was generally permanent improvement; but it is difficult to exclude spontaneous recovery. Tyramine is fairly effective in arresting superficial *capillary hemorrhage,* both by local and systemic application; but its efficiency is far below that of epinephrine (Hanzlik, 1918).

Vascular Lesions.—The injection of tyramine into mice may produce temporary stasis of the capillary circulation, similar to that of inflammation (J. Wolf, 1923); but tyramine does not blue the comb of the rooster acutely (Crawford, 1913), or produce gangrene on repeated injection (Bickel and Pavlov). Daily injections of 50 to 100 mg. for three or four months into rabbits cause necrotic arteriolar lesions, similar to those of renal ischemia in dogs, and of human malignant hypertension (Duff *et al.*, 1939). Long-continued administration to dogs results in nephrosclerosis (Paunz, 1933).

Uterus.—The usual effects, as observed through the celluloid abdominal window, consist in stimulation of peristalsis and tonic spasm, analogous to that of ergotoxine (Ludwig and Lenz, 1923). The reactions show the same species differences as for epinephrine (Dale and Dixon, 1910; Acton and Chopra, 1925; human uterus, Lieb, 1915). Tyramine has been tried *clinically* as a substitute for ergot in labor, postpartum hemorrhage, operations and various gynecologic conditions. Favorable results have been reported by some (K. Abel, 1914). Others found it unreliable (Guggenheim, 1912). The doses used in these earlier experiments were probably too low. With larger doses (40 mg. plus 16 mg. of morphine, hypodermically) Barbour, 1917, recorded distinct increase of the strength and rate of labor pains, without undesirable side effect. On the contrary, tyramine counteracts the respiratory depression of morphine, so that the respiration is slightly quickened by the combined dosage. The actions of morphine on other functions are not antagonized (Barbour and Maurer, 1920).

Respiratory effects were studied by Bry, 1914.

Bronchioles are contracted by tyramine (Baehr and Pick, 1913; Golla and Symes, 1913). Accordingly, tyramine does not relieve asthmatic attacks (Hewlett and Kay, 1918).

Excised stomach is constricted (frogs).

Excised intestines are stimulated in rabbits; relaxed in dogs; first stimulated and then relaxed in cats (Manysek, 1914).

Spleen is contracted.

Gastric secretion is sometimes stimulated in cats, but not in other animals (Keeton *et al.*, 1920).

Pancreatic juice secretion after pilocarpine or secretin is inhibited by large doses of tyramine (Kageyama, 1916).

Hyperglycemia.—Continuous slow intravenous injection of 0.05 per cent of tyramine into rabbits may raise the blood sugar to 0.1–0.17 per cent, and the urine sugar to 2 per cent (Kageyama, 1916).

Anemia.—Long-continued hypodermic injections into guinea pigs (2 to 8 mg. daily for one to two weeks) produce severe anemia with the characteristics and course of pernicious anemia (Iwao, 1914). A similar result with hemosiderosis of the spleen, mesenteric lymph glands, cecum and bone marrow is produced in rabbits by intravenous injection of 0.1 Gm. of tyramine (Iwao, 1916).

Growth.—McCarrison, 1924, found that long-continued administration of tyramine to young animals retarded growth, and this was associated with diminished weight of the thymus and thyroid and increased weight of the adrenals. The effects did not disappear when the tyramine was discontinued. Adult animals were but little affected.

Fate.—*Tyramine* is in part converted into parahydroxyphenylacetic acid in the body and by surviving liver and uterus. It is completely destroyed by the isolated heart (Ewins and Laidlaw, 1910). The de-aminization of tyrosine in the animal organism was studied by Kotake *et al.*, 1922.

l-Dihydroxyphenylalanine ("*dopa*"), formed in the partial oxidation of tyrosin by tyrosinase, is structurally similar to epinephrine. The melanoblasts of the skin contain a "dopa oxidase" (B. Bloch, 1917), which converts the "dopa" to "dopamelanin"; but it is questionable whether this has any relation to natural melanin. The latter is bleached by reducing and darkened by oxidizing agents, and forms a natural oxidation-reduction system, comparable to glutathione, riboflavin and ascorbic acid, with relatively high potential (F. H. J. Figge, 1940). Intravenous or peritoneal injection of l-dopa (not of the dextro isomer) into rats produces marked and sustained rise of blood pressure, which is abolished by adrenalectomy (E. W. Page and Reed, 1945).

Hordenine, isolated originally from germinated barley by Leger, 1906, is tyramine with NH_2 replaced by $N(CH_3)_2$. As a tertiary amine it establishes a relation to choline. Its actions were studied especially by Camus, 1906. Small doses stimulate the vagus. Larger doses paralyze the vagus center, quickening the heart and raising the blood pressure. The bronchioles are dilated by stimulation of the sympathetic endings, sufficiently powerful to antagonize most constrictor drugs (D. E. Jackson, 1914). Fatal doses paralyze respiration. The substance is not very toxic. It has been used (0.5 Gm. per day) in heart disease and digestive derangements (Sarbazes and Guerine, 1909). It arrests diarrhea in dogs (30 to 40 mg. per Kg., hypodermically; Charmoy, 1912).

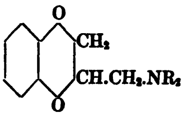
Vanillyl-ethylamine, which is methoxy tyramine, and its derivatives produce varying degrees of stimulation and depression of smooth muscle and of blood pressure. The benzl derivative is depressant without stimulation (W. E. Hambourger, 1932).

Naphazoline (Privine) Hydrochloride—2-naphthyl-(1')-methyl imidazoline hydrochloride, is a potent local vasoconstrictor, used especially in the nose and throat, applying several drops of 0.1 per cent aqueous solution for adults, 0.05 per cent for children. It sometimes produces drowsiness in children (J. I. Waring, 1945). Frequent use as nose drops commonly results in "rebound" congestion of the mucosa, although renewed application continues to produce brief constriction. The rebound is much less common with other vasoconstrictors (S. M. Feinberg, 1945). Dependence has been reported (L. E. Putnam and Herwick, 1946). Naphazoline is not consistently sympathomimetic, and appears to have some cholinergic actions. It raises the blood pressure of cats, less potently than epinephrine; retracts the nictitating membranes; salivates (not inhibited by atropine); and dilates the pupils (Yonkman, Rennick and Schwerma, 1945). The blood pressure rise is decreased but not reversed by yohimbine; it is not potentiated by cocaine. Oral or rectal administration does not significantly change the blood pressure or respiration (Craver *et al.*, 1944).

Mistletoe.—Injection of extracts of European mistletoe, *Viscum album,* produces fall of blood pressure (Gaultier and Grelant) by vasodilatation which has been attributed to excitation of the afferent depressant nerves of the heart. The heart is first slowed by increased vagal tone and then becomes rapid and arrhythmic by heterotopic stimuli (Jarisch and Henze, 1938). H. Richter and Schröcksnadel, 1938, attributed the bradycardia to reflexes from cardiac receptors, stimulating the vagus and inhibiting the accelerator centers. These actions are not characteristic of tyramine, which the plant is said to contain. Holste, 1928, suggested a saponin. Rojo, 1929, obtained a rise of blood pressure, presumably from a different extract.

Cotoin (methyl-trioxy-benzophenone) has been used against diarrhea and to check the night sweats of phthisis, in doses of 0.06 to 0.6 Gm., 1 to 10 grains. It is not antiseptic or astringent, but decreases the tone of excised intestines and uterus (Impens, 1913). In transfused frogs, it contracts the blood vessels and diminishes reflex excitability (Jodlbauer and Kurtz, 1916). It is not toxic to rabbits or to infusoria. Its excretion occurs by the urine, partly as benzoic acid (Jodlbauer and Kurtz). It is derived from Coto, the bark of an unknown Bolivian plant. This and the related "*paracoto*" barks also contain other related trioxyphenones, differing by the number of methyl groups (Jodlbauer and Kurtz, 1916).

Fourneau Sympatholytic Dioxane Derivatives.—E. Fourneau has synthesized a series of dioxanes of the general formula



which have pronounced sympatholytic actions. The most extensively studied are "F 883," diethylamino-methyl-2-dioxane (Fourneau and Bovet, 1933) and "F 933," piperidino-methyl-2-benzodioxane (Bacq and Fredericq, 1935; review, Jeanne Lévy, 1939). F 883 paralyzes the augmentor responses both to epinephrine and to sympathetic nerve stimulation; F 933 paralyzes them for epinephrine, but not for nerve stimulation; F 1081 paralyzes inhibitory sympathetic stimulation (Bovet and Demanche, 1934; Justin-Besancon, 1934).

Cardiac Effects.—F 933 depresses the excised frog heart and the denervated heart of cats, but does not greatly modify their response to epinephrine or accelerator stimulation (W. T. Hill and Myers, 1939). The resistance of the cat and rabbit heart to ventricular fibrillation by electric stimulation is raised by intravenous injection of 5 mg. per Kg. This also prevents the heterotopic rhythms of epinephrine and barium (van Dongen, 1939). The coronary vessels are constricted (L. N. Katz and Lindner, 1939).

Uterus.—In the resting cycle, 2 mg. of F 933, per Kg. have no effect, 5 mg. relax, 10 mg. contract. The relaxant effect of epinephrine is increased. During rut or after estrogen or chorionic gonadotropin treatment, small as well as large doses contract; in early pregnancy or after progestin, relaxation follows even with large doses (Duels, 1939).

Central Actions.—Both F 883 and F 933 produce psychic and motor excitement in dogs, including stimulation of the sympathetic centers; mydriasis, exophthalmos, rise of blood pressure, rapid heart; in spite of the peripheral sympatholytic action of the same doses toward epinephrine. Both substances are analgetic, intensify sleep and narcosis, and inhibit water diuresis (Zunz and Jourdan, 1935; Sivadjian, 1935).

Tuamine Sulfate, N.N.R., racemic 2-amino heptane, is a sympathomimetic amine, with a vasoconstrictor potency about twice that of ephedrine, and more prolonged. Used as 1 to 2 per cent solution on congested mucous membranes, especially in the nose. Inhalation of the vapor, from an inhaler, is also effective in acute rhinologic conditions.

◆

OXYTOCIC AGENTS

The motor functions of the uterus are autonomic, with little if any central control; but its pharmacologic reactions are chiefly toward the direct muscular agents, such as the hormone of the posterior pituitary gland, the ergot alkaloids and histamine. These oxytocic drugs (Greek, oxy = acute, tokos = birth) act essentially alike, the chief difference being in the duration of action, and thereby the facility of control. They provoke or strengthen uterine contractions. If the favorable degree is exceeded, the uterus relaxes incompletely and finally remains in spasmodic contraction. The susceptibility of the uterus to their stimulation decreases in early pregnancy (especially to pituitary), so that they are generally ineffective for emptying the uterus until near term, when its excitability suddenly increases. If the uterus is ready for parturition, moderate doses hasten delivery, but spasmodic doses may interfere with progress and cause rupture of the uterus, especially with pituitary solution. Their use at this stage is dangerous and not generally advisable. Post partum, they cause prompt contraction of the empty uterus and thereby arrest its bleeding. This is their principal field. The prompt and powerful action of pituitary extract, when 0.1 to 0.15 cc. is injected intramuscularly, is an advantage. It may be repeated if necessary; for prolonged action it may be reinforced with ergot, by mouth or rectum. Hypodermic injection of pituitary extract does not raise the blood pressure materially, but if it is important to avoid this entirely, pitocin may be used.

The following tabulation for the graphic clinical data of Barlow and Jones shows the usual time of the onset and duration of the full therapeutic postpartum action:

Agent	Channel	Ordinary Dose	Full Effect	Duration of Effect
Pituitary	intramuscular	0.1 to 0.15 cc.	7 minutes	three-fourths of an hour
Ergot, fluidextract	oral	2 to 3 cc.	10 to 15 minutes	5 hours
Ergot, fluidextract	intramuscular	2 cc.	10 to 15 minutes	4 hours
Ergotamine (Gynergen)	hypodermic	½ to 1 mg.	one-half hour	2 hours
Ergonovine	oral	¼ to ½ mg.	5 to 10 minutes	5 hours
Histamine	hypodermic	⅕ mg.	immediate	one-half hour

Ergot fluidextract is irritant and should not be used hypodermically; it may be employed by rectum. Histamine is not suitable for obstetrical use, because of its marked side actions. Tyramine is not effective clinically (Bourne and Burn, 1927).

POSTERIOR PITUITARY GLAND

The two portions of the pituitary gland, anterior and posterior, differ completely in function.

Effects Produced by Extracts of the Posterior (Infundibular) Lobe of the Pituitary (Pituitrin).—These cause powerful stimulation of smooth muscle, varying in degree, however, in different situations and under different conditions; there may even be relaxation, or a sequence of relaxation and contraction. The effects are peripheral, for they occur in denervated organs, but the peculiarities are not related to the origin of the autonomic innervation, in contrast to epinephrine (Dale, 1910); they appear more allied to those of histamine (Fuehner, 1912) or the protein "shock" poisons. The most important effects are stimulation of uterine contractions, utilized in obstetrics; persistent vasoconstriction, employed in shock; and diminished output of urine in polyurias, effectively controlling diabetes insipidus. In normal animals, the urine flow is increased for a short time after injection. The extracts are administered intramuscularly or intravenously, the latter being more effective (Pankow, 1912), but less persistent (Klotz, 1911).

Actions of minor importance include depression of the cardiac muscle (by coronary constriction); expansion of the melanophores; mydriasis; bronchial constriction; changes in intestinal peristalsis, in the flow of milk, of gastric secretion, of cerebrospinal fluid, in the coagulation of the blood and in carbohydrate metabolism.

The **active constituents** have not been isolated in pure form, but potent preparations have been obtained; for instance, that of Abel, Rouiller and Geiling, 1923, stimulates the guinea pig uterus in the dilution of 1:20,000,000,000, and is thus over a thousand times as active as the very potent histamine. The purified product may exert the characteristic oxytocic, vasopressor, diuretic and antipolyuric properties all in approximately the same ratio as the original pituitary extracts, suggesting that a single substitution is responsible for all these actions. By other and perhaps more energetic processes, fractions may be obtained in which these actions are more or less separated. Kamm and associates, 1928, and R. L. Stehle, 1933, succeeded in preparing two fractions. Those of Kamm are marketed; one, *pitocin* (oxytocin) produces almost pure oxytocic effects, about a hundred and fifty times as strong as pituitary powder, with little vasopressor, diuretic and antipolyuric effects; the other, *pitressin* (vasopressin) produces rise of blood pressure, about eighty times as actively as pituitary powder, and also the diuretic and antipolyuric, the cardiac, respiratory, intestinal and certain metabolic effects, but little uterine stimulation. Both raise the blood sugar and antagonize insulin. When mixed, in the proportions in which they represent the gland, they appear to reproduce the effects of posterior pituitary completely.

Condition in Gland.—Abel, 1930, reasoned that the fractions exist in the gland combined into a single molecule, which may be split by the reagents used by Kamm. This is confirmed by the centrifugal sedimentation rates, which indicate that pituitrin, pitocin and pitressin are cleavage products, of much smaller molecular weight than the native hormone in the glandular press juice (M. Rosenfeld, 1940).

Stability.—Alkaline, neutral and faintly acid solutions deteriorate fairly rapidly, especially on heating, but when the acidity of the extract corresponds to about ¼ per cent acetic acid, they may be boiled (but not autoclaved) without loss of activity (H. S. Adams, 1917). Excessive acidity (0.5 per cent of hydrochloric, or more than 6 per cent of acetic acid) is destructive (A. Stasiak, 1926). The oxytocic fraction is more stable than the vasopressor and antidiuretic between *p*H 2.0 and 4.5, and less stable than these beyond the extremes, in either direction. The antidiuretic is more stable than the pressor at all reactions, indicating that these are chemically distinct (H. Heller, 1939). Digestive ferments tend to destroy the activity of the extracts, although the data are somewhat contradictory (see Rees and Whitehead, 1923); possibly the decomposition is secondary to cleavage of the protecting colloid.

Origin in Hypophysis.—The structure of the posterior pituitary body is chiefly nervous, comprising nerve fibers, neuroglial cells and "pituicytes," highly branched granular cells derived from the neuroglia. It has been suggested that the active constituents are formed in the "pars intermedia" of the hypophysis, and that the pars posterior is merely a depot. Certain animals, however (whale, chick, armadillo), lack the pars intermedia, and in these the posterior (neural) part contains the pressor and diuretic principle in about the same concentration as in other animals, and also the oxytocic principle, but in somewhat smaller ratio. Both must therefore be formed in the posterior gland itself. Neither principle occurs in the anterior part. They enter the general circulation through the blood channels. Expansion of melanophores is not produced by posterior extracts from these animals, as it is with other animals, but is formed in the anterior lobe. This principle must therefore be transported into the posterior lobe from the "intermediate" portion. (Geiling, 1936; Oldham, 1938).

Fetal Glands.—The active principle appears early in fetal life (McCord, 1915).

Absence of Iodine.—Iodine is not present in any part of the pituitary gland, even after excision of the thyroid (Seaman, 1920).

Fate.—After intravenous injection of posterior pituitary extract, 25 to 30 per cent of the oxytocic and pressor principles is excreted by the urine, chiefly within the first ten minutes. The remainder is probably destroyed by the peptidases of the tissues, especially in the liver and intestinal mucosa (E. Larson, 1939).

Uterine Action.—The strongest and most important action of pituitary extract is on the uterus. Experimentally and clinically this responds by increased motor activity, increase of tonus, initiation or reinforcement of peristaltic contractions, or by firm spasm. The degree of response varies with the excitability of the uterus, and increases rapidly toward the end of pregnancy (Lieb, 1914; Knaus, 1926). Its use in obstetrics was introduced by Blair Bell, 1909. It is employed, after delivery of the placenta (0.3 to 0.5 cc. of the U.S.P. pituitary or pitocin solution), intramuscularly or subcutaneously to produce prompt and firm contraction of the uterus, and thus check postpartum hemorrhage. The action is brief, and the injection may have to be repeated; or ergot may be administered at the same time. The use of pituitary (0.1 to 0.3 cc.) earlier in labor, to initiate or strengthen labor pains and hasten delivery, is not advisable, since the powerful contraction may prevent delivery, asphyxiate the fetus, produce excessive compression, intracranial hemorrhage, premature separation of the placenta, deep laceration of the cervix, or fatal rupture of the uterus (Watson, 1923). It is also inadvisable to employ pituitary to hasten the expulsion of the placenta, since it may cause hour-glass contraction (J. W. Williams). Pituitary has been used to induce labor in the last weeks of pregnancy, but it does not produce abortion earlier, and is more effective when the os begins to dilate (Malinowski, 1919).

The degree of uterine response is greatly affected by the *sex hormones* that are preponderant in different stages of pregnancy and of menstruation. It is increased by the estrogenic hormones and inhibited by progesterone. The nonpregnant human uterus responds most actively toward the end of the menstrual cycle (twentieth day after menstruation to last premenstrual day), and least at the beginning of the cycle (third to thirteenth day) (G. K. Schultze, 1931; J. S. Henry and Browne, 1943). In early human pregnancy the uterus is irresponsive to pituitary. The response returns later in gestation, becomes very active during parturition, and is again suppressed during the involution of the uterus in the puerperium (Moir, 1934), parallel to the decline of blood estrin, becoming irresponsive after the tenth day. Some response returns if estrin is administered (W. Bickers, 1942). Analogous alterations occur in animals.

It produces marked stimulation in nonpregnant rabbits and at term. In the first half of their pregnancy it produces no effect or inhibition (Okazaki, 1927). From then to the last four days, abortion could be induced only by enormous doses, and with a delay of several days; but on the last two days of the natural term, birth resulted almost immediately from a sixtieth of the dosage required to induce a delayed labor two days previously (H. H. Knaus, 1926). *Castration* does not greatly modify the response (Athias, 1921). Heckel and Allen, 1936, confirmed that the excised uterus of rabbits which had been castrated sixteen to twenty-one days previously reacts to pituitary solution by contraction. This is more marked if they were injected with estrin; after progestin injection, the uterus fails to respond to pituitary; and if both estrin and progestin were injected, pituitary produces relaxation.

Clinical studies have been made on parturient women by introducing into the cervical canal a Vorhees bag connected with a manometer (Bourne and Burn, 1928; Moir, 1934), and by a tambour pressed on the abdomen over the fundus (Dodek). The hypodermic administration of 0.1 to 0.5 cc. produces marked peristalsis and increased tone of the uterus, perceptible in two minutes and persisting about half an hour, the tone being greater than the top of the contraction waves before the pituitary. The greater the response, the shorter the duration of labor (D. P. Murphy, 1941). The uterine stimulation may be produced by the oral administration of pituitary extract (Hamill, 1921), but the effect is too variable.

Experimental Studies.—In the body and on the excised organ, even very small doses of pituitary have a marked augmentory effect (first described by Dale, 1906), and they increase the excitability to hypogastric stimulation (Frankl-Hochwart and Froehlich, 1910). This occurs in all animals, pregnant or nonpregnant (Gunn and Gunn, 1914; abdominal window, Ludwig and Lenz, 1923). The degree of response in the nongravid uterus varies with the motor activity before the injection (S. R. M. Reynolds, 1930). *Excessive concentrations* of pituitary (also of histamine) depress the excised uterus of mice and guinea pigs; but rat's uterus is not depressed by pituitary in any concentration (Abel and Macht, 1919).

Electrolytes.—Increase of potassium or of calcium ions increases the response of virgin guinea pig uterus to posterior pituitary solution. Decrease of potassium, as also excess and deficiency of magnesium, diminishes the response (Van Dyke and Hastings, 1927). Intramuscular injection of calcium gluconate into cats markedly increases the sensitivity of the puerperal uterus to pituitary injection (Schübel, 1937).

Interaction of Epinephrine and Pituitary.—Epinephrine normally relaxes the excised uterus of guinea pigs and of nonpregnant cats; but if the uteri are first treated with pituitary, the addition of epinephrine causes them to contract (Tate and Clark, 1921).

Other Sexual Organs.—The vaginal muscle and prostate respond like the uterus; the vas deferens (Waddell, 1917) and the fallopian tubes (Gunn) do not react to pituitary, although they are stimulated by epinephrine, pilocarpine and barium. Intravenous injection into *hens* results in premature expulsion of the egg from the uterus (W. H. Burrows and Byerly, 1942). This holds also for the fallopian tubes.

Gastro-Intestinal Movement.—The effects are complex and inconstant, but pituitary solution is used clinically against postoperative *gas distention* and *paralytic ileus* (Bill and Hick, 1909), generally as prophylactic, injecting 0.5 to 1 cc. of pitressin or 1 to 2 cc. of the U.S.P. solution intramuscularly, preceding or immediately following the operation, repeating two or three times at intervals of four to six hours if necessary, and supplementing with enemas. It is used in roentgenography to eliminate gas pockets. The response is uncertain and difficult to appraise.

In normal human subjects, injection of pituitary solution rarely increases the motor activity of the stomach, duodenum or rectum (in two of twenty-three observations, Einsel and Quigley; cessation in all observations, Ochsner *et al.*, 1930; colon sometimes contracted, sometimes relaxed, Steggerda, 1938). The gastric sojourn is prolonged and the acidity diminished (Bergman, 1928).

Unanesthetized dogs give irregular responses of the intestinal tract to hypodermic injection of the two pituitary fractions. *Intravenous injection* of either fraction generally results in defecation, but with differences for the two fractions: with *pitocin* a single defecation occurs within two or three minutes, with relaxation of the circular coat (roentgenologic observation) and without collapse; with *pitressin* the defecation starts in five to fifteen minutes and continues with vomiting and retching, the stool becoming liquid. The circular coat is contracted. Marked collapse develops with fall of blood pressure (Melville, 1936).

In unanesthetized dogs with *permanent ileum fistula,* Gruber and Robinson, 1929, observed, with either pitocin or pitressin, marked temporary decrease of tonus followed by vigorous tonus waves. Quigley and Barnes, 1930, obtained depression for gastric and colonic fistulas. The effect on *propulsion of a bolus* through a jejunal loop was irregular, but predominantly depressant, for the whole extract and for either fraction (Quigley, Highstone and Ivy, 1934). In the *colon,* roentgenographic observations showed marked increase of tonus, maximal in fifteen to twenty minutes after intravenous injection of *pitressin,* but no effect after pitocin (Steggerda and Gianturco, 1936). Injection of pitressin into dogs may be followed by *gastric and duodenal ulcers,* closely resembling the clinical ulcers. They are attributed to spasm of the small blood vessels together with contraction of the gastric muscle (A. J. Nedzel, 1938, 1943). They are more common after vagotomy, less frequent after sympathectomy (M. Berg, 1942).

The *reactions of excised intestines* are complex and variable, similar to those to histamine and peptone, generally with predominant stimulation. They differ with the level of the segment, with the species, with individual animals and with the previous diet (Degener, 1922). With commercial preparations, the effects are further complicated by the depressive action of chloretone (Roth, 1917), and acidity (Gruber, 1926). E. Larson, 1928, obtained with pitressin or whole extract, definite increase of tonus in *rabbits' excised intestine,* largest in the jejunum, less in the duodenum and ileum; with large intestine, the stimulation was preceded by slight depression. With guinea pigs, the stimulation was slight, and dogs and cats usually gave no or little response. *Pitocin* had no effect on intestines of any animals.

In *mechanically obstructed dog's intestine, in situ* and isolated, pituitary produced relaxation, while physostigmine and hypertonic sodium chloride stimulated (McIntosh and Owings, 1928).

Gallbladder.—Pituitary extract may stimulate the contractions of the gallbladder in man, but without necessarily increasing the flow of bile; indeed, this may be arrested (S G. Meyers, 1928). In rabbits it has no effect on the gallbladder contractions, but diminishes the bile flow; perhaps by spasm of the duct. The effect is abolished by chloretone and by barbiturate (Adlersberg and van Goor, 1928).

Frog's Esophagus.—The circular and longitudinal muscles are both depressed by pituitary (Waddell, 1916), not by histamine; while the turtle's esophagus is stimulated by histamine (Bercovitz, 1922).

Saliva.—Intravenous injection into dogs diminishes the flow of saliva, partly by decreased blood flow, partly by direct depression of secretion. The response to pilocarpine is diminished (Solem and Lommen, 1915).

Pancreatic secretion is decreased (Pemberton and Sweet) through vasoconstriction (Edmunds).

Gastric Hyperacidity.—Pal, 1917, claimed that this is depressed to a variable degree.

Urinary Bladder.—The vesical muscle is stimulated, with increased excitability to pelvic, but not to hypogastric, stimulation (Abelini, 1919). Injections were tried in postoperative paralysis of the bladder (Hoffstätter, 1911; Serdinkoff, 1922), but seem to have been abandoned.

Excised ureter is stimulated by dilute, relaxed by more concentrated solutions.

Circulation.—The rise of blood pressure on injection of pituitary extract was described by Oliver and Schaefer, 1895. It may be preceded by a brief fall. The rise is not so high as that obtainable with epinephrine, but it is much more sustained, lasting for ten minutes to half an hour after intravenous injection. If large doses are repeated, at short intervals, the rise becomes progressively smaller (Howell, 1898), and the depressor effect becomes more and more prominent (Schaefer and Vincent, 1908). Pitressin produces the same effects.

Pitocin produces a transient fall of blood pressure and markedly weakened cardiac contractions, in man and various animals, but has little effect in dogs. The depression of cardiac muscle is direct, not by coronary constriction, as is that of pitressin (R. A. Woodbury *et al.*, 1944).

Howell, 1898, showed that the pressor action is confined to the posterior lobe of the gland. The *hypophyseal portion* lowers the pressure (W. W. Hamburger, 1904, 1910); the *pars intermedia* also produces chiefly a fall, preceded and followed by a rise (Lewis, Miller and Matthews, 1911).

The *rise of pressure* is due solely to vasoconstriction, for the aortic blood flow decreases (Tigerstedt and Airila, 1913), and the organ volume diminishes during the rise, with a few exceptions of passive dilatation (notably the kidneys). The response to depressor stimulation is decreased (Auer and Meltzer, 1913). The vasoconstrictor action is peripheral, for it occurs in perfused organs (Rischbieter, 1913) and in excised arterial segments (Bonis and Susanna; Röthlin, 1921, discusses the variations in different areas), and it can be produced locally by application to the scarified skin (Carrier, 1922). According to Krogh, the muscle fibers on the capillaries are far more sensitive than the arterial muscle, in contrast to epinephrine. The action of pituitary appears to be on the contractile substance rather than on the receptive mechanism; for ergotoxine is not an effective antagonist, and the response of different vessels is not parallel to their sympathetic innervation.

The *fall of blood pressure* on repeated injection of pituitary extract or pitressin is not due to vascular relaxation, for it is not seen in perfusion (McCord, 1911). It is probably due to progressive failure of the heart to withstand the coronary constriction.

This interferes even in the first injection, for the pituitary rise is considerably greater if coronary constriction is prevented by epinephrine or ephedrine (Melville and Stehle, 1931). The fall occurs more readily in cats and rabbits than in dogs (Hamilton, 1912). If the intervals between injections are sufficiently long for the heart to recover, or if only small doses are injected, the response remains uniform (Hoskins and McPeek, 1913), thus permitting the bio-assay of the pressor principle (Hamilton, 1912). With extracts, the depression may be exaggerated by the presence of histamine-like substances (E. Larson, 1931).

Effect in Shock and Collapse.—The pituitary rise of pressure is more pronounced and sustained if the pressure has previously been lowered (as by hemorrhage, destruction of brain and cord, traumatic shock, choline, peritonitis; Mammery and Symes, 1908). Its use was therefore suggested in the treatment of these conditions (Blair Bell, 1911). It would be useless in the disorganization of severe shock, but may have some value in milder collapse (0.3 to 2 cc. of the U.S.P. solution, or half this dosage of pitressin every hour if necessary). Edmunds and Cooper, 1925, found it useful in mild experimental diphtheria toxemia, but less effective than glucose injections. Melville, 1932, found the joint effect of pituitary with epinephrine or ephedrine more potent against the low blood pressure of histamine shock, and the like, than either agent alone.

The superiority of pituitary over epinephrine in histamine shock is probably explained by the more prolonged action; but Krogh attributed it to projection of the constrictor action further along the *capillaries* by participation of the Rouget cells. However, Aschoff considers these as adventitious histiocytes, and not muscular; and J. B. Rogers claims that stimulation of the pericapillary cells does not constrict the capillary lumen, but pulls it outward.

Clinical Cardiovascular Effects.—With normal individuals, intramuscular injection of ordinary doses does not produce any decided change of *blood pressure*, but the skin vessels are contracted, causing marked *pallor* (Moffat, 1933). Grollman and Geiling, 1932, observed no effect from *pitocin; pitressin* caused a decided but brief fall of *pulse rate, cardiac output* and *oxygen consumption*, followed by more prolonged rise. Patients with *essential hypertension* may show a slight fall of systemic and slight rise of diastolic pressure (A. H. Elliott and Nuzum, 1935).

Unanesthetized dogs respond to intravenous injection of the pressor principle by considerable fall of pressure, with slowed heart. Later injections do not cause this acute collapse, and it is antagonized by the oxytocic principle (Melville, 1936). Hypodermic injection is not likely to produce this effect. *The influence of various anesthetics* is reported by Raginsky *et al.*, 1930.

Intravenous injection of pitressin into dogs produces transient increase of blood flow through the *cutaneous vessels*, partly by increased blood pressure, partly by active vasodilatation, for it is diminished by nerve degeneration. It is absent in most rabbits (Woodbury and Ahlquist, 1946).

Cisternal injection of pitressin raises the blood pressure, presumably by direct stimulation of the vasoconstrictor center (Heller and Kusonoki, 1933).

Injection into the third ventricle of 1 to 1.5 cc. of pituitary solution causes severe reactions in human subjects, by acting on the hypothalamic nuclei; if these are inactivated by lesions, responses do not occur, nor in deep avertin anesthesia which depresses the diencephalon (H. Cushing, 1931).

Heart.—The contractions of excised hearts are strengthened by pituitary extracts; but in intact animals the cardiac efficiency is depressed by the diminution of oxygen supply consequent on coronary constriction. The rate is slowed by the pressure reflex.

The *output of the heart* is decreased, regardless of the rate, and the efficiency of both ventricles is diminished so that the pressure in the pulmonary artery falls (Wiggers, 1911), and the vein pressure rises with large doses (Rosenow, 1920). The *portal pressure* is lowered and the portal flow diminished by the constriction of the splanchnic vessels (G. A. Clark, 1928). The *rate of the heart* is generally slowed during the rise, quickened during the fall, of blood pressure (also with pitressin; Gruber and Kountz, 1930); chiefly by pressor reflexes (Beco and Plumier, 1913).

The electrocardiogram of dogs shows characteristic changes of the T wave when the blood pressure falls. If the vagi were divided, the P wave is also reversed. These effects are attributed to anoxia of the myocardium by *coronary constriction* and are prevented by ephedrine. Direct myocardial effects have not been demonstrated even with large doses. Phenobarbital sensitizes to the coronary constriction and disturbs normal ventricular conduction, so that pituitrin may induce ventricular fibrillation in dogs (Melville, 1939). The *coronary flow* is slowed both in systole and diastole, even by small doses (H. D. Green *et al.*, 1942), notwithstanding the rise of aortic pressure (Morawitz and Zahn, 1914). Perfused excised hearts also show the coronary constriction, and slowing of the rate, unless excessive acidity of the extract produces dilatation (L. N. Katz and Lindner, 1939). The *amplitude*, however, is generally increased (Gruber, 1926) unless the extract contains the depressant chloretone (Wiggers, 1911). *Excised frog heart* reacts with greatly increased excursions. The rate is quickened by small doses; large doses slow to final standstill (Einis, 1913). The influence of potassium and calcium ions on the response was studied by DaCosta, 1926. *The coronary vasoconstriction can be antagonized* in perfused hearts by epinephrine, ephedrine, histamine, nitrite or chloretone; and with intact animals, epinephrine and ephedrine potentiate the pressor response to pituitary injection, and diminish the fall (Melville, 1933).

Myocardial Degeneration.—Repeated injection of large doses of pitressin result in histological changes, especially in the subendocardial layer of the left ventricular muscle, resembling those produced by toxic doses of digitalis. *Cellular degeneration* occurs also in the *cerebral cortex* and in the *stomach* (W. H. Dearing *et al.*, 1944).

Antagonism to Acetylcholine.—Pitressin inhibits the depressor effect of acetylcholine, the vagus response and the increase of submaxillary secretion (Necheles and Neuwelt, 1938).

Other Vascular Areas.—The pituitary constriction includes the pulmonary, cerebral and coronary vessels, which respond but poorly to epinephrine. The brain volume, however, may be increased by the high blood pressure (Raphael and Stanton, 1919). Pituitary has little constrictor action on the intrahepatic vessels, but lowers the portal pressure and decreases the portal blood flow by constricting the splanchnic vessels (G. A. Clark, 1928). The vessels of frogs are dilated (Froehlich and Pick, 1913).

Blood Volume and Blood Cells.—During the acute pituitary constrictor action, the effects are as with epinephrine (Brednow, 1931): increase of circulating erythrocytes (CO method) and decrease of plasma volume (dye method). Daily administration of posterior pituitary (as of epinephrine) results in polycythemia even after excision of the spleen, attributed to ischemic stimulation of the bone marrow (J. E. Davis, 1942). Massive doses administered hypodermically to rabbits produce severe macrocytic hyperchromic *anemia* (Dodds and Noble, 1935), due to osmotic hemolysis when the plasma is rendered hypotonic by the retention of water in the oliguric stage (Gilman and Goodman, 1937).

Cerebrospinal Fluid.—Tajitsu, 1929, claimed decreased formation of the fluid. Cow, 1915, believed that the pituitary principle occurs sometimes in the cerebrospinal fluid, especially after injection of extracts of the duodenal mucosa, which he considers as a stimulant of pituitary secretion. Mestrez and Van Caulaert, 1927, confirmed the presence of the oxytocic principle in the fluid obtained from occipital puncture in man as well as in animals; but none was found in the lumbar fluid, suggesting that it passes into the blood from the cerebral ventricles.

Lymph flow decrease was described by Peterson and Hughes, 1924.

Urine Flow.—Injection of pituitary extract produces three successive and unrelated effects: (1) brief *anuria*, of little importance, attributed chiefly to spasm of the ureters (Mackersic, 1925); (2) brief *diuresis*, of little practical importance, by the improved renal circulation, resulting chiefly from passive dilatation of the renal afferent arterioles by the rise of blood pressure, and practically parallel to the latter in degree and duration (ten minutes to an hour); succeeded by (3) *oliguria*, which reaches a maximum in the third hour, and fades by the tenth hour. It is due chiefly, if not entirely, to a direct action on the renal tubules, increasing reabsorption. Glomerular filtration is not increased (T. Bjering, 1934). This results in decreased volume and increased concentration of the urine. It overcompensates for the diuresis, so that the daily urine volume is generally somewhat decreased in normal subjects, but especially if the output was excessive, in polyurias. It is utilized for checking diabetes insipidus. If the water consumption is high, the limitation of excretion results in retention, leading to hydremia and to the nervous symptoms of cerebral edema. All the urinary actions are produced by pitressin; pitocin has practically no effect (Bugbee and Simond, 1928).

Primary Anuria.—Although this is usually attributed to ureteral spasm, it occurs also if the ureter is excluded by catheterization of the renal pelvis (J. B. Ross and Stehle, 1930), so that there must be other factors which have not been explained.

The pituitary polyuria was first described by Schaefer and Herring, 1908, who attributed it to stimulation of the renal cells. This is contradicted by the absence of increased oxygen consumption (Knowlton and Silverman, 1918; Gremels, 1929). The *kidney volume*, which decreases during the primary anuria, increases parallel to the polyuria, and decreases again with the later oliguria (D. D. MacDonald, 1933). Richards and Plant, 1922, also obtained diuresis with diminished renal blood flow, but increased kidney volume; they ascribed this to contraction of the efferent arterioles, which would increase the glomerular filtration pressure. *Direct microscopic observation* in frogs showed dilatation and increased number of functioning glomeruli with small doses, the reverse with large doses (Richards and Schmidt).

The dilator response is mainly passive, *i. e.*, by the increased blood pressure and by the displacement of blood from the splanchnic area, for *perfused kidneys* generally respond by constriction (McCord, 1911; Osaki, 1927), sometimes followed by dilatation. The larger renal arterioles are dilated (Cow). These changes occur also if pituitary is reinjected during the oliguric stage, so that the urine flow is temporarily increased.

The *excretion of solutes* is increased, including the urea and ammonium (Stoland and Korb, 1920), and the inorganic ions (Stehle, 1927). *With rabbits rendered polyuric by the continuous injection of sugar* or by phlorhizin, pituitary extract also causes marked but transient increase of urine flow, with increase of chloride output and decrease of sugar content, consistent with increased glomerular filtration (E. E. Nelson, 1934). *Extrarenal factors* may contribute to the diuresis; this is usually accompanied by hydremia (Underhill and Pack, 1925), which is probably due to mobilization of saline ions, chloride, K, Ca, Mg, and phosphate, of the tissues. The excretion of these is considerably increased, independently of the diuresis and even in its absence (Stehle, 1927); in nephrectomized rabbits, pituitary injection increases the Cl concentration of the blood for some hours (F. Buschke, 1928). Rabbits, however, appear especially subject to chloride mobilization by many agencies.

Pituitary Therapy of Diabetes Insipidus.—The polyuria in the disease is due to defective tubular reabsorption of water. Glomerular filtration is not altered (review, J. P. Peters, 1944). The polydipsia is secondary to the loss of fluid, for nephrectomy abolishes the thirst (H. G. Swann, 1940). Pitressin corrects the condition by increasing tubular reabsorption. Hypodermic injections decrease the volume of urine, increase its specific gravity and the percentage of chloride and nitrogen (M. Rosenfeld, 1940), and greatly diminish the thirst. The dosage ranges from 0.5 cc. of posterior pituitary injection or pitressin solution, every second or third day, to 1 cc. three times daily. The medication must be continued indefinitely.

Intramuscular injection of *pitressin tannate in oil*, 5 pressor units in 1 cc., gives a more lasting effect, checking the polyuria for about forty-eight hours (G. W. Thorn and Stein, 1941). Other channels of administration (oral, rectal, intranasal) may produce some improvement, but are less effective, and generally unreliable (Blumgart, 1922).

Dried posterior pituitary gland may be used as a snuff, 0.15 Gm. per day, divided into two or three doses; or 0.5 cc. of pitressin solution may be sprayed into the nose three times daily, at least to supplement the injections (F. M. Smith, 1934).

The *pituitary oliguria* is due entirely to the pressor fraction. It is produced by posterior pituitary extracts of all vertebrates, including amphibians and fishes; but only mammalian kidneys respond to it, coinciding with the existence of the water-reabsorbing structures, the loops of Henle and the terminal segments of the tubules (review, J. P. Peters, 1944).

The time relations of the decrease of urine volume and increase of concentration were described for *normal human subjects* by Miasi, 1922. The diminution of urine volume is proportional to the previous volume: it may be absent (M. H. Rees, 1918) if the daily output was already small, although pitressin generally causes additional concentration of the urine in dogs, even with restricted water and food intake (W. G. Paine and Nelson, 1939). The decrease of urine volume is large if the subject was polyuric (Brunn, 1920), from high water income, diabetes insipidus (Velden, 1913), or from the administration of urea or mercurial diuretics. These are mutually antagonistic to pituitary (W. Raab, 1929). Insulin is also antagonistic to the pituitary polyuria (Koref and Mautner, 1926).

The *concentration of the urine* is increased, but with urea (Addis *et al.*, 1918), urate (Hammett *et al.*, 1920), phenolsulfonphthalein (Bugbee and Simond, 1928), and doubtless other substances, the concentration is not in proportion to the reduced volume, so that retention results. The transformation of benzoic into *hippuric acid*, in nephritis, is reported to be increased by pituitary, independent of any diuresis (Farini and Ceccaroni, 1915).

Posterior Pituitary Injection is used as a *clinical test of renal concentration*; 1 cc. should raise the specific gravity of the urine to 1.023 or higher (W. A. Sodeman and Engelhardt, 1943).

The diminished excretion of water results in *hydremia* (Brunn, 1920) and *edema*. The *osmotic pressure of the serum* is reduced, so that it may become isotonic with 0.561 per cent NaCl and hemolyze the red cells (Gilman and Goodman, 1936). The *increased water content* is peculiarly distributed: it is marked in the central nervous system (medulla, basal ganglia and cerebrum), and small in the muscle and liver; the skin actually loses water (G. E. Ellerbrook *et al.*, 1930). With high water income, the edema of the nerve centers and increased intracranial pressure result in alarming symptoms of "*water disease*": headache, nausea, asthenia, incoordinated convulsions, coma and sometimes death. Intravenous injection of hypertonic salt solution causes prompt improvement (Rowntree, 1924).

The site of the oliguric action is renal, for heart-lung-kidney preparations also respond by reduced output of urine and increased concentration of urinary chloride (Hemingway and Peterson, 1929). *Denervation* of the kidney does not inhibit the oliguria (Oehme and Oehme, 1918), but there appears to be some central correlation, or posterior pituitary injection fails to inhibit water-ingestion polyuria in man during sleep (Labbé and Azérad, 1926), deep hypnosis, progressive paresis and with some brain tumors.

The renal action is conceived as *increased reabsorption of water* from the tubules. The amount of glomerular filtrate is probably not decreased in mammals. In birds there is some decrease in glomerular filtration by large doses, and this is more marked in reptiles. Amphibians and fish do not respond with oliguria (Burgess *et al.*, 1933). The alternative explanation of *increased water affinity of the tissues*, as advocated especially by Stehle, 1927, appears to be contradicted by the absence of retention when the water income is limited, and by the increased water content of the serum and corpuscles when the water is retained.

Pitressin does not interfere with the *absorption of fluid* from the intestinal tract (review, J. P. Peters, 1944).

The urinary sodium chloride excretion is greatly increased by posterior pituitary injection in rats to which water is administered, by 300 to 600 per cent, when the delay of water excretion is only 40 per cent. If salt is administered. the oliguria is changed to polyuria. The salt phenomenon appears to be due to the Na and not to the Cl ions, for potassium chloride does not have this effect (O. S. Gibbs and Fulghum, 1946). Pituitary diuresis lowers the *halide concentration of the serum*, but does not change the distribution of chloride and bromide between serum and corpuscles (A. R. McIntyre and Van Dyke, 1931).

Normal water regulation is adjusted largely by the release of antidiuretic hormone from the posterior pituitary, under the control of the central nervous system (review, M. Pickford, 1945). The importance of the pituitary regulation is indicated by the observation that the urine of rats on limited water income has a potent antidiuretic effect when injected into normal rats, but much less so if the hypophysis was removed before the water limitation was practiced (Gilman and Goodman, 1937; Boylston and Ivy, 1938).

The oliguria is effected by the total osmotic concentration of the plasma rather than by any individual constituent (G. H. Chambers *et al.*, 1945). It occurs also if the plasma is rendered hypertonic by intravenous injection of concentrated sodium chloride or sulfate or urea solution (K. Hare *et al.*, 1945). This diminishes the store of antidiuretic substance in the posterior pituitary (G. H. Chambers, 1945). Oral administration of concentrated sodium chloride solution produces histologic changes in the posterior pituitary (Selye and Hall, 1943). The suppression of urine flow by certain afferent stimuli appears to be due to pituitary stimulation, since this may be abolished by destruction of the pituitary stalk (Haterius, 1939) or by excision of the posterior pituitary (O'Connor and Verney, 1942).

Cow, 1915, who produced diuresis by the injection of *extracts of duodenal mucosa*, assumed that this is due to stimulation of the pituitary gland, and that *water diuresis* results from absorption of this pituitary stimulant.

Small amounts of *different antidiuretic substance* exist in the blood, urine and cerebrospinal fluid even after excision of the pituitary gland (A. M. Walker, 1939). Extracts of human urine contain substances which have no effect on diuresis when injected alone, but which prolong the diuretic effect of posterior pituitary when both are injected hypodermically into rats (R. L. Noble *et al.*, 1939; N. K. Schaffer *et al.*, 1941). Their behavior resembles that of antidiuretic beef liver extracts (Theobald and White, 1933).

Water-Imbibition of Frogs.—If frogs kept in water are injected with small doses of pituitrin, their weight increases ("*Brunn's reaction*"; about 15 per cent in four hours), and the normal loss of water in dry environment is decreased. This action, however, is not connected with the oliguric action, for in contrast to this, the frog edemic effect is about three times greater with pitocin than with pitressin (Steggerda and Essex, 1934; Oldham, 1936). The imbibition is prevented by the addition of 0.4 per cent NaCl to the water. It is greatest at *p*H 7, but there is little difference between *p*H 6 and 8. The imbibition is twice as great in nonhibernating as in hibernating frogs, probably by relation to the sexual cycle. It is dimnished by anesthetic doses of narcotics, but sedative dosies may increase the uptake (E. M. Boyd *et al.*, 1939). Judging from the difference of dosage, the action is presumed not to be due to any of the known hormones (H. Heller, 1941).

Blood Sugar Level.—The injection of pituitary extract produces considerable glycosuria and hyperglycemia, probably by direct action on the liver, for it occurs also after excision of the suprarenals (Geiling, 1928). La Barre, 1930, claims that the hyperglycemia is not produced after excision of the suprarenals, and therefore attributes it to increase of epinephrine output. It *antagonizes insulin hypoglycemia*, and apparently insulin normally mobilizes a protective pituitary secretion, for removal of the pituitary gland increases the sensitiveness to insulin, and this is antagonized by the injection of pituitary extract (Geiling *et al.*, 1927). The hyperglycemia and the protection against insulin are produced by both pitressin and pitocin, with the distinction that the pitressin rise is accompanied by increase of the plasma phosphate, and oxytocin is not (Geiling, de Lawder and Rosenfeld, 1931).

Other Effects on Metabolism.—Pituitary injection increases the *basal metabolism* of normal individuals, but is said to lower it in hypothyroid patients (McKinay, 1921). Pal, 1917, claimed that in *Basedow's diseasle* it decreased the toxic symptoms and the size of the thyroid. It produces *hyperthermia* in pigeons that were rendered poikilothermic by cerebrothalamic ablation; it has no effect on the temperature of normal pigeons (Rogers, 1921). The *growth* of puppies was improved by the injection of posterior pituitary; feeding of the gland had no effect (Downs, 1927).

Respiration is affected chiefly through the circulatory changes. In unanesthetized animals it is generally quickened, with interspersed periods of apnea. With intravenous injection during anesthesia, Paukow, 1912, described primary arrest during the fall of pressure, then an increase and a second stoppage during the rise. Nice *et al.*, 1914, described the characteristic effects as primary increase of depth, followed by shallow and generally slow, but sometimes quickened, respiration. These disturbances set in with the circulatory changes, but are not so lasting. They fail to occur after a few injections have been made. In frogs, tadpoles and fish the center is paralyzed (Hepner, 1915).

Bronchial Muscle and Asthma.—Pituitrin has little if any effect even in large doses (Jackson and Mills, 1919; S. Okada, 1940). Earlier reports of bronchial spasm were probably due to contamination with histamine.

The smooth muscle of *necturus lung* is not constricted by pituitary or by barium (Luckhardt and Carlson, 1921).

Milk.—Injection of posterior pituitary extract into goats increases the yield at the next milking by more complete expression of the stored milk, through contraction of the smooth muscle of the mammary gland. The yield at the next following milking is correspondingly decreased, the daily yield being unchanged (Simpson and Hill, 1914; Gaines, 1915). The response is lost in the later months of lactation (Röthlin *et al.*, 1922). It is absent in cows (J. C. Shaw, 1942) and generally in women; but Hill and Simpson, 1914, reported marked increase of milk volume and fat after injection of 1 cc. of the solution in the fifth month of lactation.

Iris.—Contradictory results have been reported (Pollock, 1920).

Paramecium.—Pituitary extract increases the pulsation frequency of the contractile vacuole.

Melanophores.—The skin of frogs and other amphibians appears darker after the injection of pituitary extract or on immersion of the excised skin, through expansion of the melanophore cells; removal of the hypophysis results in blanching. The melanophores of fish fundulus do not respond to pituitary, although they are contracted by epinephrine. Those of the minnow (phoxinus levis) respond actively. The melanophore principle, intermedin, is formed in the intermediate lobe and is distinct from the pressor and oxytocic fractions (Dryer and Clark; Zondek, 1934; Geiling *et al.*, 1936). It accelerates the oxidase system tyrosine: tyrosinase, which is inhibited by the pressor and perhaps by the oxytocic principle (Fostvedt, 1939). Extracts of other tissues, and histamine, are ineffective (Hogben and Winton, 1922). Apparently identical effects are produced by the chromatophore hormone of the crustacean eyestalk (Abramowitz, 1938).

Toxic Actions.—Aside from the accidents arising from actions on smooth muscle, such as rupture of the uterus or asphyxiation of the fetus, toxic effects are rare and generally unimportant. Tinnitus, anxiety, albuminuria, unconsciousness, eclamptic attacks, mydriasis, amaurosis, diarrhea have been reported.

Anaphylactoid reactions, urticaria, angioneurotic edema, dyspnea, and the like, occur occasionally, but are uncommon (F. A. Simon and Ryder, 1936; Abbett, 1940).

Contraindications: Epilepsy, hypertension, coronary disease and pregnancy are listed.

Standardization of pituitary extracts is essential because of the serious consequence of overdosage, especially in obstetrics. Since chemical assay is not feasible, it is necessary to measure the potency by the effects. The comparison of the response of the excised uterus of guinea pigs with a standard sample of dried pituitary has the advantage that it measures the action that is most likely to become dangerous (Burn and Dale, 1922). Details described in the U.S.P. must be meticulously observed.

The effects on the blood pressure go fairly parallel. Indeed, the activity of the fresh gland is remarkably constant as to pressor and oxytocic properties, and their ratio to each other. The *pressor assay* is described by Hamilton and Rowe, 1917; the assay of antidiuretic action by G. C. Ham, 1943.

Preparations.—***Posterior Pituitary Injection,** U.S.P., *Posterior Pituitary Solution; Pitressin*, a sterile solution in water for injection, prepared from the posterior pituitary lobe of "domestic animals used for food by man," adjusted by bio-assay on excised uterus of guinea pigs, in comparison with the U.S.P. Reference Standard, so that 0.1 cc. has the oxytocic activity of one U.S.P. Posterior Pituitary Unit, identical with one International Unit, or 0.5 mg. of the Reference Standard Pituitary Powder. Some brands are preserved with chloretone. Dose, hypodermically, 2 to 10 units (0.2 to 1 cc.). Usually available as 5 units in 0.5 cc. and 10 units in 1 cc. A solution of double the official strength was marketed as "Surgical Solution." *Pitocin*, N.N.R., is an aqueous solution of the oxytocic fraction, standardized to correspond to the oxytocic activity of the U.S.P. Posterior Pituitary Injection. *Pitressin*, N.N.R., is an aqueous solution of the pressor-diuretic-oliguric fraction, standardized to contain 20 "pressor units" per cubic centimeter, double the pressor activity of Posterior Pituitary Injection. Dose, 0.3 to 1 cc. intramuscularly. *Pitressin Tannate in Oil*, N.N.R., is a suspension corresponding to 0.5 mg. of standard posterior pituitary powder (5 pressor units) per cubic centimeter. Used for prolonged action, 0.3 to 1 cc. intramuscularly (never intravenously) every thirty-six to forty-eight hours. Available in ampuls of 1 cc.

ERGOT AND ITS ALKALOIDS

Ergot (Secale cornutum) is a fungus (Claviceps purpurea) growing in the grain of cereals; the official is obtained from rye. The fungus goes through several stages of development, the resting stage (sclerotium) constituting the drug. It is used to contract the uterus (by peripheral action) and thus check postpartum hemorrhage. It also stimulates other forms of unstriped muscle, especially the intestine and blood vessels. The consumption of grain infested with ergot leads to gangrene and spasmodic effects. Epidemics of "ergotism" were formerly frequent and must have occurred in antiquity, although the causal connection was not recognized. It is rare in civilized countries, since the ergot is removed by the modern methods of treating the grain. The oxytocic effect was learned from midwives and was first mentioned in Lonicer's Kräuterbuch of 1565. Its use in regular medicine dates practically from Stearns, 1807 (N. Y. Med. Repository). Aside from its uterine action, ergot produces abolition of response to augmentory sympathetic stimulation; rise and fall of blood pressure; cyanotic stasis and gangrène and other effects. Their complexity is due partly to the multiplicity of active constitutents, which vary in different specimens, but each of the pure principles also has several apparently unrelated actions.

The **constituents** fall into the following groups: (1) *Alkaloids:* These are responsible for the characteristic actions of ergot. They include: (*a*) The active ergotoxine and ergotamine and their inactive isomers ergotinine and ergotaminine. The minor alkaloids *ergosine* and *ergocristine* have essentially identical actions. (*b*) The active ergonovine (with various synonyms), and its inactive isomer ergometrinine. (2) *Amines:* (*a*) Histamine (misnamed ergotidine and ergamine). (*b*) Tyramine (misnamed ergamine and uteramine). (*c*) Other aromatic amines (Engeland and Kutscher, 1910). (3) *Acetylcholine*, also choline and betaïne. Ergothione is a betaine of thiohistidine (Barger and Ewins, 1911). (4) *Ergosterol*, inactive in itself and not absorbed, but yields viosterol on artificial irradiation. (5) *Ergotinic acid*, a sapotoxin with the actions typical of that group. (6) *Miscellaneous constituents: Sclererythrin*, a red pigment which serves as a test of the presence of ergot in bread; resinous acids, some peculiar sugars, fat (some 35 per cent) and others. The nonalkaloidal constituents are further discussed in other sections (see Index).

All the ergot alkaloids are related chemically as well as in their actions. They are derived from lysergic acid which contains an indole group (W. A. Jacobs and Craig, 1935; S. Smith and Timmis; review, G. Barger, 1938). A synthetic hydroxybutylamide of lysergic acid, "*methergine*," synthesized by Stoll and Hofmann, 1943, has the typical ergonovine action (Kirchhoff and Wilson, 1944) and may be used in the third stage of labor, 0.2 mg. hypodermically or by vein (P. C. Roberts, 1944). The isolation offered unusual difficulties. The active alkaloids are unstable and change easily into their more stable inactive isomers. Oxygen and especially light transform them into dark-colored products of feeble activity. They tend to fix organic solvents in their molecule, analogous to water of crystallization, and this gave rise to misleading statements of elementary composition. Only small amounts are present in ergot, sometimes almost none, especially if it has been exposed to dampness. The constituents vary with different lots of the drug. One or the other alkaloid may be practically absent. Russian ergot contains only ergotamine; Spanish and Portuguese yield little ergotoxine and ergonovine. It is still doubtful whether all the alkaloids have been isolated (Stoll, 1936).

The chemical history of ergot is confused by the unsuccessful investigations and by the multiplication of names for products which later work showed to be impure, or identical with others. The *literature* of the ergot components is reviewed by E. E. Nelson and Calvery, 1938.

Historical on Ergotinine, Ergotoxine and Ergotamine.—Tanret, 1875 to 1879, isolated a crystalline alkaloid, which he named *ergotinine*, and which is the practically inactive isomer of ergotoxine (Kraft, 1906). It is still designated by this name. Tanret also isolated ergosterol and a noncrystallizable alkaloidal fraction, "ergotinine amorphe," and from this Barger, Carr and Dale, 1907, isolated amorphous *ergotoxine* and its crystalline phosphate, and showed its pharmacologic actions. Kraft, 1906, arrived independently at the same results. Crystallized ergotoxine was prepared by S. Smith and Timmis, 1930. *Ergotamine* (Gynergen) was isolated and crystallized by Stoll from certain kinds of ergot, and shown to be closely related to ergotoxine (Dale and Spiro, 1922), but not identical with it (Smith and Timmis). It is convertible into the feebly active ergotaminine (Stoll, 1936).

Historical on Ergonovine.—Alcoholic preparations of ergot, as those of the U.S.P., contain the ergotoxine and ergotamine, but these alkaloids do not pass into watery preparations, as those of the B.P., although these are actively oxytocic. Indeed, the original use of ergot by J. Stearns was based on a watery decoction (half a drachm of powdered ergot boiled with half a pint of water and administered in three doses at twenty minute intervals). Evidently, therefore, these alkaloids do not fully represent the oxytocic activity. Barger, Dale and Dixon, 1909, suggested that the activity of the water extracts is due to histamine and tyramine; but these are not very active by mouth and were not found satisfactory clinically. Clinical demonstration of oxytocic activity, however, was not satisfactory until Moir, 1932, proved the activity of extracts supposedly free from known alkaloids, on the postpartum human uterus, with a graphic method. This served as a starting point for further investigations by Dudley and Moir. In March, 1935, they described a crystalline alkaloid which they considered chiefly responsible for the oxytocic action of ergot, and therefore named it "*ergometrine*" (Dale, 1935). Several other investigators in the meantime had worked independently on the same problem and announced the discovery of this alkaloid practically simultaneously. M. R. Thompson, 1935, claimed to have described its isolation in 1932 and to have crystallized it in 1934, naming it first "X alkaloid," and then "*ergostetrine*." His work was not altogether clear and had been described chiefly in an unpublished thesis. Kharash and Legault announced the alkaloid as "*ergotocine*" in November, 1934, and published clinical data in 1935. This is marketed as "*ergotrate*." Stoll and Burckhardt, 1935, had isolated pure crystals of the alkaloid, but had not investigated its actions. Stoll, 1935, claimed that his is the first description of the pure substance. The identity of these alkaloids has been conceded to their discoverers (Science, 1936, *83:* 206). The question of priority depends upon the point of view. As none of the names complied with the rules of N.N.R., the Council felt compelled to coin an independent name "ergonovine" (J.A.M.A., 1936, *106:* 1008). The *literature* of ergonovine is reviewed by R. G. Smith, 1938.

Impure Principles.—These are still important for understanding the older literature. They are classified by Barger and Dale as follows, in chronological order:

Wenzell, 1864: *Ecboline and Ergotine* = mixtures of the alkaloids, containing choline (Meulenhoff, 1899).
Tanret, 1875: *Amorphous Ergotinine* = impure mixture of ergotinine and ergotoxine.
Dragendorff, 1877: *Picrosclerotine* = ergotinine, possibly mixed with some ergotoxine.
Podwyssotski, 1883: *Sclerocrystalline* = ergotinine.

Kobert, 1884: *Sphacelinic Acid* = inactive resin with adherent alkaloids.

Cornutine = alkaloidal resin, probably containing some ergotoxine and perhaps some active alkaloidal decomposition products.

Ergotinic Acid = a sapotoxin.

Keller, 1896: *Cornutine* = impure mixture of ergotinine with ergotoxine.

Jacobj, 1897: *Chrysotoxin* = inactive yellow coloring matter with small porportion of adherent alkaloid.

Secalintoxin = mixture of ergotinine and ergotoxine.

Sphacelotoxin = impure ergotoxine.

Secalin = impure ergotinine.

Kraft, 1906: *Hydroergotinine* = synonym for ergotoxine.

Vahlen, 1906 and 1908: *Clavin* = inactive mixture, consisting of nearly equal parts of leucine, isoleucine and valine (Van Slyke, 1909).

Marino-Zuco and Pasquero, 1911: *Clavisepin:* claimed to be an active glucoside; not confirmed.

Ergoclavine of Kussner and *Sensibamine* of Wolf are probably mixtures of the ergotamine group (Stoll, 1935).

Ergotine is a name applied to a variety of pharmaceutic extracts.

Characteristics of the Ergotoxine and Ergotamine Group.—The alkaloids *ergotoxine* (Barger, Carr and Dale, 1906; *hydroergotinine*, Kraft, 1906) and *ergotamine* (Stoll; marketed as tartrate under the name "Gynergen") are closely related chemically, and practically indistinguishable pharmacologically; their threshold concentration for direct stimulation, and for inhibition of the epinephrine stimulation of the excised uterus (Dale and Spiro, 1922), is the same; but ergotoxine is nearly twice as potent as ergotamine in the pyrogenic, convulsive and lethal dosage for rabbits (Lozinski, Holden and Diver, 1931; Rothlin, 1932, 1935). One or the other predominates in different specimens of ergot. Both give the color reaction of ergot. They form colloidal solutions in water, and are easily precipitated by salts and acids. They do not therefore pass readily into watery extracts of ergot, but these may contain the ergonovine alkaloids. Alcoholic extracts contain both groups of alkaloids. Ergotoxine is easily changed into its isomer *Ergotinine*, and Ergotamime into its isomer *Ergotaminine*, which are pharmacologically almost inactive. The ergotoxine and ergotamine are actively oxytocic, but clinically inferior to ergonovine. They produce the cock's comb cyanosis and grangrene effects. They are responsible for the sympatheticolytic action (epinephrine reversal, Dale, 1905), and are chiefly concerned in the stimulation of the uterus, the vasoconstriction, the bronchial constriction, the intestinal irritation and the gangrene. (Table and bibliography in Bacq, 1934.) Ergotamine relieves migraine.

Characteristics of Ergonovine.—This has about half the molecular weight of the ergotoxine group. It is the most potent oxytocic constituent of ergot (about twice as potent as ergotamine), and is chiefly responsible for the activity of the aqueous preparations, but is present only in small amount. Its other pharmacologic actions are similar to those of ergotoxine, but generally weaker. It has little sympatheticolytic action. It forms an inactive isomer, ergometrinine (Smith and Timmis, 1935). The free alkaloid is somewhat soluble in water, with strongly alkaline reaction; the salts are freely soluble. It is levoratatory, and gives the color reactions of the ergot alkaloids.

Pharmacologic Actions of Ergonovine.—These include the muscular stimulation of the uterus; evanescent cyanosis of the cock's comb, not proceeding to gangrene; rather slight sympatheticolytic action (epinephrine reversal) on several organs, often obscured and complicated by other effects; slight rise of blood pressure, varying with conditions; depression of frog heart; mydriasis in rabbits; central excitation with general sympathetic excitement and rise of temperature in toxic doses, similar to ergotoxine. The fatal dose is higher than for ergotoxine (G. L. Brown and Dale, 1935; Rothlin, 1935; M. E. Davis, Adair and Pearl, 1936).

Uterine Actions of Ergot Preparations.—In labor, ordinary doses improve the uterine tone, and collect small irregular and noneffective pains into larger effective contractions. Excessive doses produce prolonged tonic contraction (Sharp, 1911). These effects have also been observed directly through a celluloid window inserted in the abdomen of animals (Ludwig and Lenz, 1923). The effects can be produced clinically by the pharmaceutical preparations; or by ergonovine, orally or by injection; or less satisfactorily by injection of ergotamine or ergotoxine. The fluidextract by mouth or rectum is the most economical and accomplishes the full results, unless promptness of action is imperative. Its taste is the chief objection.

The most extensive use of ergot is *after* the delivery, to hasten and sustain the normal retraction, thus obliterating the open sinuses, and checking *postpartum hemorrhage.* When proper doses are used during labor, with the os fully dilated, and no obstruction, they tend to *hasten normal delivery.* Really effective doses, however, are rather dangerous to mother and child. The firm contraction may hinder delivery, and compress and asphyxiate the fetus; rupture of the uterus has been reported; but these accidents are rare. In *early pregnancy*, its effects are much less certain. Contrary to popular opinion, it is not abortifacient unless dangerous doses are long continued. Ergot has also been used in other forms of *uterine hemorrhage* and in chronic metritis, but it has probably little value apart from obstetric conditions.

The relative uterine activity of the ergot alkaloids ranks as follows, in rabbits, taking ergotamine as the unit (Rothlin, 1936): *Tonus augmentation in situ:* ergonovine = 2; ergotamine = 1; ergotoxine = $\frac{1}{2}$. *Epinephrine reversal* on excised uterus: ergotamine and ergotoxine = 1; ergotaminine = $\frac{1}{5}$; ergotinine = $\frac{1}{100}$; ergonovine = less than $\frac{1}{400}$.

Mechanism of Uterine Action.—The action is peripheral, since it occurs also in the excised uterus (Fellner, 1906; human, Rübsamen and Kligermann, 1912). It is directly muscular: the sympatheticolytic action requires much larger doses. La Torre, 1912, found histologic changes in the uteri of dogs treated with ergot. *Calcium excess*, which depresses the tone of the virgin guinea pig uterus, increases the response to the contractor action of ergot (M. Chio, 1922).

Administration of the Pharmaceutical Preparations.—The usual *dosage* is 2 to 5 cc., ½ to 1 drachm, of the U.S.P. Fluidextract. Rectal administration also gives good and prompt effects, and is not especially irritating. The official preparations are quite irritant hypodermically or intramuscularly. The response to ergot taken by mouth or rectum appears in fifteen to thirty minutes and lasts half an hour (L. J. Jones and Barlow, 1934). Opium delays but prolongs the effects; moderate chloroform anesthesia does not modify them (Sharp).

The Liquid Extract of the B.P., an aqueous preparation, merely preserved with alcohol, causes prompt contraction of the human postpartum uterus, on oral administration (Moir, 1932), in doses of 0.6 to 1.2 cc., 10 to 20 minims. Its activity is probably about half that of the U.S.P. fluidextract (Jones and Barlow, 1934). *Commercial aqueous preparations for hypodermic injection* are more or less purified aqueous solutions. They are of uncertain activity (E. E. Nelson and Page, 1928).

Ergonovine (*Ergotrate*) is probably the chief oxytocic constituent of the U.S.P. fluidextract, and exclusively for the B.P. liquid extract. It can be injected intravenously or hypodermically, but acts promptly by oral administration. It produces practically no nausea or other side effects. Its chief limitation is its scarcity and cost. Watery solutions of some of the commercial brands deteriorate rather rapidly.

The clinical dosage of ergonovine by mouth is 0.2 to 0.5 mg., generally 0.3 mg. (or 0.4 of the commercial "Ergotrate"); the intravenous dosage is 0.1 mg. With oral administration, postpartum uterine stimulation begins in five to eight minutes, the full effect is reached in fifteen to thirty minutes and persists for three to four hours, and some contracture remains for five to seven hours or longer. Vomiting does not occur even with three or four times the clinical dosage, in contrast to ergotamine, but with the dosage of 0.5 mg., the uterine contracture becomes painful (Barlow, 1936). In prolonged postpartum bleeding, the dosage of ergonovine may be administered three times daily for several days (M. E. Davis *et al.*, 1936).

Regarding the *scarcity* of ergonovine, Stoll, 1936, stated that the richest source, Spanish ergot, never yields more than 60 mg. of this alkaloid per Kg. Portuguese ergot yields less, and none can be obtained from Polish and Russian ergot. On the other hand, good ergots yield 2 Gm. of the ergotamine and ergotoxine group per Kg. The small yield and limited source of ergonovine would be inadequate for medical use, if this employed ergonovine exclusively.

Ergotamine (*gynergen*) *and ergotoxine as oxytocics* produce the same effects as ergonovine, and the isolated alkaloids can be used clinically, but they are not very satisfactory (Sharp, 1920). Moderate doses (¼ mg. of ergotamine tartrate intramuscularly, 1 mg. orally) are generally ineffective; even 2 to 4 mg. by mouth are not always effectively oxytocic; and with ¾ to 1 mg. there is generally marked nausea and often emesis. The clinical oxytocic action sets in rather slowly, fifteen to twenty minutes after intramuscular injection; the full effect is reached in thirty to forty minutes and persists for an hour or two (Bourne and Burn, 1927).

Other Ergot Constituents on Postpartum Uterine Contractions.—These have practically no share in the oxyttocic action of ergot. *Histamine*, however, to 1 mg. hypodermically, produces uterine contractions in one or two minutes and tonic spasm lasting half an hour (Jones and Barlow, 1936). Its side actions make it undesirable, especially the vasodilatation and the tachycardia. *Tyramine* has little effect on the uterus and is not used clinically.

Ergotamine against migraine is remarkably effective for symptomatic relief. The hypodermic injection generally arrests the migraine attack (in 90 per cent) within an hour; the patient feels weak, generally strongly nauseated, sleeps, and awakens without the migraine, while an untreated attack usually lasts eighteen to twenty-four hours. It does not lose its efficiency with continued use. The best results are obtained if it is administered with the first warning of the impending attack and smaller doses may then suffice. Oral administration may be tried, but larger doses must be used, and it often fails, because it is not absorbed in time. It was feared that continued use would lead to gangrene, but this has not occurred in the many patients who have used large numbers of injections, if the dosage was kept within the ordinary limits, and if the special contraindications were avoided (see below). The injections do not cause material local irritation. *The mechanism of the relief* is obscure. It is not produced by other nauseants, and ergotamine is not effective against other headaches or pains. Ergonovine is considerably less effective than ergotamine intramuscularly, but it is more effective by mouth (Lennox, 1938). The ergotamine treatment was apparently first described by H. W. Maier, 1926 (Lennox and von Storck, 1935).

The *dosage* should start with the hypodermic injection of 0.25 mg. of ergotamine tartrate (gynergen), repeated in two or three hours if necessary; in that case, 0.5 mg. would be injected at once in future attacks; or half this dose may be given by vein. The sublingual administration requires 3 to 4 mg. at the start, followed if necessary by 1 to 2 mg. every hour, not exceeding the total of 10 mg. The oral dosage is 4 to 5 mg. at the start, and if necessary 2 mg. every hour, not to exceed 11 mg. (von Storch, 1938). *The treatment must not be used oftener than twice in a week.* The dose should be kept as small as possible; many patients require less as their condition improves.

Untoward effects are common, but not serious. They are greatest with intravenous injection and least with oral administration. They comprise, in order of frequency: fatigue, nausea, emesis (half of the patients vomit), tingling in hands and feet, muscle pains and stiffness, constricting sensation in throat. Muscular soreness in the thighs was experienced by eight of eleven normal persons taking a 2 mg. tablet by mouth three times daily for twelve to fourteen days (Grinker and Spivey, 1945).

Most of these side actions may be relieved by atropine, 0.4 to 0.5 mg.; the muscle pain and stiffness, by calcium gluconate intravenously, and massage (O'Sullivan, 1936; von Storch, 1938). Tingling, numbness, cold and cyanosis suggest vascular spasm and may be a warning of ergotism. If they recur persistently, the ergotamine should be discontinued for a time; also with substernal pain, until coronary disease is excluded.

The cases of serious sequels, including gangrene, are reviewed by von Storch, 1938. None of these occurred from the administration in migraine, although it has been used by many thousands of patients, up to 24 to 45 mg. per month for five years. The majority of the gangrene cases involved sepsis or obliterative vascular disease, especially coronary. These are *contraindications.*

Carotid Sinus Reflexes.—Ergotamine reinforces the cardiac-inhibiting reflex, but suppresses the reflex changes of the vessels (Heymans and Regnier, 1929). This may perhaps explain the effect on migraine. The *cerebral circulation* in unanesthetized human subjects is moderately increased, probably secondary to the rise of blood pressure, but the increase during migraine headache was not sufficient to explain the relief (W. G. Lennox *et al.*, 1935).

Inefficiency in Related Conditions.—Ergotamine is generally ineffective against *nonmigraine headaches* (Lennox *et al.*, 1936) and quite ineffective in *epilepsy* (continuous oral administration; Loscalzo, 1937).

Dihydroergotamine ("DHE 45") is reported to be as effective as ergotamine against migraine, without producing the untoward effects. It prevents cyclo-propane-epinephrine fibrillation, but does not reverse the epinephrine blood pressure rise (O. S. Orth, 1946). It may be used in pregnancy (M. M. Hartman, 1945).

Ergot as General Styptic.—The efficiency of ergot in postpartum hemorrhage and the vasoconstriction observed in animal experiments led to its use against hemorrhage in other situations. However, as ordinarily administered, it does not affect the blood vessels or blood pressure. Its use is therefore irrational (Bradford and Dean, 1894). It is also useless in pulmonary hemorrhage (Frey, 1909). It has been praised rather uncritically in a great variety of other conditions, which it would be useless to enumerate.

Blood Pressure.—This is practically unchanged by ergot, in man (Sharp, 1911) or animals, unless the ergot is injected into a vein. This produces considerable, but inconstant and complex, changes. The variability is largely explained by the conflicting actions of the different constituents, and by dosage and other conditions.

Sometimes there is a large but brief fall from direct cardiac depression, followed by a slight but prolonged rise from direct cardiac and vascular stimulation (Sollmann and Brown, 1905). The fall is presumably due to histamine and acetylcholine; the rise to ergotoxine or ergotamine and tyramine. Other experiments show little fall and somewhat greater rise (Edmunds and Hale, 1911). This rise is greater if the vasomotor center has been destroyed, and is therefore due to a direct peripheral action on the vessels (Wood and Hofer, 1910). Excised arteries (except the pulmonary) are also constricted (Cow, 1911). The vasoconstriction occurs also in calcium-free solutions (Pearce, 1913). The vasomotor center is not affected by ergot or ergotoxine (Pilcher and Sollmann, 1915). In *experimental hypertension*, produced by raising the intracranial pressure by cisternal injection of saline or kaolin suspensions, ergotamine causes transient lowering of the high blood pressure (C. Lindauer *et al.*, 1938). The pressure in the *pulmonary artery* is increased, whether the carotid pressure is rising or falling (Wood, 1911). Mellin, 1904, Plumier, 1905, and Anderes, 1915, attribute the rise to constriction of the pulmonary vessels. The *coronary vessels* are constricted by ergotamine (L. N. Katz and Lindner, 1939). *Very large doses* of ergot paralyze the vagus center and the vasomotor endings.

The rise of blood pressure with ergotoxine or ergotamine is vascular (diminished organ volume). The constrictor action is exerted directly on the arteries, for it occurs after the medulla has been divided and the vascular ganglia have been excised or paralyzed by nicotine. *Ergonovine* tends to raise the blood pressure slightly, but may lower it in anesthesia. It constricts the vessels of the perfused frog leg (Davis, Adair and Pearl, 1936).

Sympatholytic Action of Ergotoxine and Ergotamine; Epinephrine Reversal.—If a large dose of ergotoxine or ergotamine is injected, and if during the rise of blood pressure the vasoconstrictor nerves are stimulated, electrically, or by epinephrine or nicotine, a *fall* of pressure results, instead of the customary rise. The ergot alkaloid has therefore paralyzed the peripheral sympathetic vasoconstrictor mechanism, leaving the central dilator mechanism active. This *vasomotor reversal* is obtained in pithed cats by 0.5 mg. per kilogram, intravenously. Since ergot itself and barium are still capable of producing vasoconstriction, the arterial muscle can not be paralyzed; and the constrictor paralysis would be referred to the receptive mechanism (Dale, 1905; Sollmann and Brown, 1905). Very large doses finally paralyze the muscle fiber. The antagonism of ergotoxine and epinephrine can also be demonstrated on excised arteries (Macht, 1915) and on the *stomach* (M. Smith, 1918).

The sympatholytic action is especially strong for blood pressure, so that this may be used for the bio-assay of these alkaloids (the Broom-Clark method). It affects also other functions with sympathetic innervation, especially if this is augmentory (for instance, melanophores of fish) (Spaeth and Barbour, 1917), and it also involves some depressant sympathetic innervations (Rothlin). It may be emphasized that it is *not* the most prominent effect of ergotoxine or ergotamine: it requires considerably larger doses than the muscular stimulation and lasts only a few minutes (Polak, 1926). It has been suggested that the phenomenon is due merely to the refractoriness of the high muscular tonus induced by ergotoxine, toward further stimuli. C. W. Darrow, 1943, assumes cholinergic actions. The *central actions of epinephrine, f. i.*, the fever, are not antagonized by ergotoxine (Cloetta and Waser, 1915).

Heart.—The effects of ordinary doses of ergot on mammalian hearts are slight and mainly consequences of the vascular changes; the amplitude is first diminished, then increased. After repeated injections, the heart becomes slowed by a direct muscular action, for the slowing occurs even after atropine. In perfused mammalian heart, Wiggers, 1911, observed diminished systolic contraction and increased tone with decreased amplitude and output.

Ergotamine and ergotoxine increase the excitability of the vagus to electric stimulation and to acetylcholine (Henrijean and Waucomont, 1930). They slow the sinus rhythm and depress auriculoventricular and intra-auricular conduction (Andrus and Martin, 1927). In mammals they have little effect on the response to accelerator stimulation, even with doses a hundred times greater than those that suppress the vasoconstrictor response to epinephrine (H. L. Otto, 1928); but in frogs ergotoxine abolishes the response to accelerator stimulation and diminishes the inhibition on vagus stimulation. Excessive doses arrest the heart; this may be antagonized by atropine, camphor, epinephrine and caffeine, but not by accelerator stimulation (Langecker, 1925). *Ergonovine* is somewhat depressant to the frog heart (Davis *et al.*, 1935).

Ergotamine against Tachycardia of Thyrotoxicosis.—The drug is reported to be effective against the operative tachycardia in these patients, presumably by counteracting epinephrine. It has little or no effect on the other thyroid symptoms, nor does it diminish anoxic tachycardia in normal individuals (Brace and Reid, 1939). In paroxysmal tachycardia, intravenous injection of 0.5 mg. of ergotamine tartrate often returns the heart rate to normal within eight minutes, without untoward effects (E. I. Evans, 1940).

Cyanosis of the Comb of the Fowl.—When ergot preparations are administered to roosters, the tips of the comb and wattles become blue and cold. The effect, which may be preceded by temporary blanching, is perceptible in about half an hour and lasts several hours. This reaction is used for testing the quality of ergot. It is due to the ergot alkaloids, ergonovine being somewhat more potent than ergotoxine and ergotamine (Davis, Adair *et al.*, 1935); histamine produces a similar but much prompter effect (Crawford, 1913); tyramine is ineffective. These changes are probably due to injury of the capillary endothelium, producing vascular stasis.

They are not due to vasoconstriction, for the cyanosis does not occur after other vasoconstrictor drugs; while it is produced by paraldehyde, which lowers blood pressure (Crawford), by cantharidin (Ellinger, 1908), which injures capillaries; and by other drugs which cause vascular injury (large hypodermic doses of cane sugar, piperazine, chromic acid, and the like).

The gangrene action is a characteristic feature of chronic ergot poisoning in man and in many animals. It is readily studied in roosters. It is due to endothelial injury (T. Lewis, 1935), obliterative endarteritis (Kaunitz, 1931), and conglutination thrombosis (W. Jacobj, 1924), analogous to frost-bite (L. Davis *et al.*, 1943; K. Lange, Boyd and Loewe, 1945). The cyanosis of cock's comb is an initial stage of the process. It is produced by ergotoxine and ergotamine. It has followed the therapeutic use of ergot (Caffier, 1927) and of ergotamine, but the latter only if the arterial disease already existed, or in sepsis, or with gross overdosage (critical review, von Storch, 1938). The action of ergonovine does not appear to progress to gangrene (Davis, Adair *et al.*, 1935).

If ergot is given repeatedly to roosters, the bluing persists in the tips of the comb, and gradually involves the entire comb and the wattles. Eventually, these appendages undergo gangrene and may drop off. The extremities may also be involved; in one experiment, the entire wing fell off after a few days.

Histologic Changes.—Von Recklinghausen, 1883, showed that the larger arteries, but not the veins, of the gangrened comb are occluded by hyaline thrombi. The capillaries are congested with red corpuscles. These results were confirmed by Grünfeld, 1890, who gives a good description with colored illustrations. Krysynski observed similar formation of thrombi in a variety of conditions; it is probably the result of a toxic effect on vascular endothelium. No histologic changes are found in the acute cyanosis.

Susceptibility of Different Animals to Gangrene.—Man is quite subject to the gangrene, which begins in the extremities. The fingers, toes, or an entire member may slough off. Pigs react especially by pustular eruptions on the skin; the ears are particularly susceptible. *Horses and cattle* show similar changes. *Dogs and rabbits* do not seem to be susceptible to this action. Bilateral lumbar sympathectomy renders rats more subject to tail gangrene from ergotamine poisoning (Griffith, Comroe and Zinn, 1939). The cause of the varying susceptibility has not been demonstrated. The gangrene always begins in those situations in which the circulation is weakest. It differs in no essential from gangrene produced by any other cause. It may be dry or wet, according to whether liquefying bacteria are absent or present. Salant and Hecht, 1914, describe a *habituation tolerance* to the action of ergot on the cock's comb and to the fatal dose.

Alimentary Canal.—Ergot (2 cc. of fluidextract) and ergotamine (1 mg. by mouth) delay the emptying of the human stomach, averaging 30 and 16 per cent respectively, presumably by direct depression of the gastric muscle (Van Liere and Sleeth, 1939). Intravenous injection of 0.5 mg. of ergotamine tartrate, in man, produces emesis in a few minutes, probably by stimulation of medullary centers; it may be prevented by morphine. Large doses of ergotamine, 2.5 to 3 mg., do not cause vomiting, but protect against apomorphine emesis (S. I. Evans, 1940). Injection of ergot, ergotamine or ergotoxine (10 mg. for rabbits, intravenously) results in marked *increase of peristalsis through the whole alimentary tract.* The sensitiveness to distention is increased (Planelles, 1924), as is also the intestinal motor response to vagus stimulation (Meltzer and Githens, 1916). This produces violent diarrhea and vomiting. The *emesis*, however, is largely central (Eggleston and Hatcher, 1915). The emetic action on pigeons may be used for the bio-assay (C. C. Lieb and Mulinos, 1934). It is a prominent side action in the clinical use of ergotamine. *Ergonovine* is not nauseant clinically and relaxes the intestinal tonus in rabbits (M. S. Davis *et al.*, 1936).

In chronic poisoning, these direct effects are aggravated by vascular stasis, advanced cases showing ecchymosis and ulcer formation. The ulcers involve particularly the lymph follicles, in which the blood supply is poorest. The stasis may lead to effusion of blood into the lumen of the intestine. The appetite is lost. This action on the alimentary canal is also most marked in the animals mentioned, but occurs in others. The *liver* of roosters shows peculiar degenerations, resembling amyloid.

Iris.—Small doses of *ergotamine or ergotoxine* cause mydriasis, probably by sympathetic stimulation. It is increased by excision of the sympathetic ganglion and antagonized by physostigmine. With larger doses, this is followed by miosis (Zunz, 1924). Local application or intra-ocular injection produces mydriasis in guinea pigs, but cats respond by extreme miosis (Koppanyi, 1930). The tonus of excised iris sphincter of cats and oxen is increased by direct stimulation of the muscle, for it is but slightly antagonized by atropine (Yonkman, 1931). *Ergonovine* is mydriatic (local application in rabbits, M. E. Davis *et al.*, 1935).

Urinary Bladder.—Ergotoxine causes contraction of excised bladder of rabbits, but counteracts other stimulants, including pilocarpine (Streuli).

Ureter.—Ergotoxine inhibits or reverses epinephrine stimulation, but does not interfere with the parasympathetic stimulants (Macht, 1916).

Bronchioles are scarcely affected (D. E. Jackson, 1914).

The **central nervous system** is affected both directly and indirectly, and the effects are correspondingly variable. With moderate doses, the flow through the cerebral vessels is increased. Small doses may cause medullary stimulation (vagus slowing; increased respiration, convulsions, and the like). Large doses of ergot cause *death* by medullary paralysis. It has a narcotic effect for roosters. The *respiratory center* is momentarily depressed by intravenous injection of ergotamine (1 mg. per Kg.) in dogs; but it tends to remove the apnea of epinephrine and nicotine (Bouckaerts and Czarnecki, 1927). The *temperature* is raised in rabbits by 3° to 4.5° C., through the intravenous injection of *ergotoxine*, 0.5 to 1.5 mg. per Kg. This is accompanied by convulsions, but as some rise occurs even after curare, it is not entirely muscular. There is no rise in decapitated animals. The action must be central and probably involves both increased heat production and diminished heat loss. Cats also respond by a rise of temperature; rats, mice and pigs by a fall (Githens, 1917); dogs show practically no effect (Youmans and Trimble, 1936). *Ergotamine* produces hyperthermia and convulsions in rabbits, but requires about double the dosage (Rothlin, 1932). Discordant results with ergotamine were reported for rabbits by von Euler, 1929 (lowering of temperature by diminished heat production), and by Bouckaert and Heymans, 1929 (no effect on temperature or heat production).

The **basal metabolic rate** is increased in rabbits by the convulsant tendency of *ergotamine;* but Bouckaert and Noyons, 1926, claimed marked decrease clinically, by hypodermic injection, and amelioration of the symptoms of *hyperthyroidism*, including the tachycardia, exophthalmos and tremor. *Ergonovine* increases the metabolic rate in rats (Davis *et al.*, 1936). The **blood sugar level** does not appear to be affected directly by ergotamine and ergotoxine; the effects that have been reported were probably indirect results of excitement and other actions. Farrar and Duff, 1928, described hyperglycemia in unanesthetized dogs; but this does not occur if the dogs have been properly trained; nor does it counteract epinephrine glycosuria (Youmans and Trimble, 1930). Rothlin, 1930, stated that ergotamine suppresses epinephrine hyperglycemia in rabbits. It has been claimed that ergotoxine (as also atropine) inhibits phlorhizin glycosuria (Goldberg, 1928).

Urine Output.—Arima, 1934, claimed that ergotamine always decreases the urine volume and the output of salts.

Pruritus.—Ergotamine is reported to give relief, sometimes complete and sometimes permanent, of the itching of jaundice and uremia (Brack, 1930; Snell and Keyes, 1933). It is administered by mouth, 1 mg. in the evening. If this is not effective, it need not be continued. If it is successful, three doses may be taken on each of the two following days (Lichtman, 1936). In herpes zoster, A. Stöckly, 1942, advises 0.5 to 1 mg. hypodermically for six successive days.

Acute ergot poisoning is rare in man, but may occur by attempts at abortion. The symptoms are vomiting, diarrhea, vertigo and confusion, precordial distress, dyspnea, muscular pains, paresthesias and anesthesias, disturbances of vision and speech, epileptoid convulsions, small pulse, loss of consciousness. In pregnancy, uterine hemorrhage and abortion of the dead fetus are frequent. Recovery after severe poisoning may require several days. Rosenbloom and Schildecker, 1914, isolated ergotinine crystals from a patient dead of acute ergot poisoning.

Chronic Ergot Poisoning, "Ergotism."—Epidemic ergotism is mainly of historic interest, but gangrene occurs occasionally from therapeutic administration. The initial symptoms are fairly uniform, but in epidemics they develop into two distinct types, the gangrenous and convulsive, which were long classed as separate diseases. Toward the end the symptoms converge. In a third type, urticaria is the dominant symptom (review, G. Barger, 1938). While ergot is chiefly responsible for the toxic phenomena, these may be complicated by vitamin A deficiency (E. Mellanby, 1930) and by toxic constituents of spoiled grain (Stockman, 1934).

Historical.—Endemic ergotism was formerly common The connection with ergot-contaminated flour was discovered by peasants and reported by Brumer in 1695. Since the cause was recognized these epidemics have been less frequent. The last large epidemic in the United States was in New York in 1825. An extensive epidemic occurred in Russia in 1926 to 1927; a mild epidemic in Manchester, England, in 1928. A comprehensive discussion of the history of ergot is given by Kobert, 1889.

The initial *clinical symptoms of ergotism* are nausea and vomiting, headache, itching, feeling of numbness, formication and other disturbances of cutaneous sensation. The skin may be hyperesthetic to some stimuli and anesthetic to others. These sensory changes *begin at the extremities and spread upward.* This distribution favors the view that they are manifestations of changes in the circulation, since these would make themselves felt first in the extremities.

The disturbance in sensations also involves the *alimentary canal,* as *voracious hunger or loss of appetite.* Digestion is much impaired by the disturbed circulation. Diarrhea and vomiting are common. There are violent and persistent *headache* and central disturbances of the *special senses.* The *motor system* begins to show abnormal symptoms, such as *twitchings* and tremors, most marked in the extremities and in the tongue.

The sensory symptoms persist, but do not become worse. The motor phenomena, the twitchings pass into *spasms,* and then into permanent and often painful *contractures,* beginning with the flexor muscles, the fingers and feet being crooked inwards. The contractures may then ascend to the other joints. The facial muscles participate. The type of these contractures shows that their origin is central. They are not absolutely persistent, but come on suddenly, last for about half an hour, then pass off for a time and reappear. There may be involuntary evacuation of the urine, *tenesmus,* and so forth. The *pulse* is hard and small, pointing to a high blood pressure. Its frequency is variable. It is usually slow, probably largely because of the high pressure.

The symptoms of the initial stage are common to the different forms of ergotism; they can be accounted for partly by the changes in the circulation and partly by the direct action of the ergot principles themselves. In the *second stage* the circulatory disturbances become more marked. The disturbances of sensation and the contractures persist; but to these are added the further phenomena of either the spasmodic or the gangrenous form. Different epidemics run to one type or the other, rarely both.

In the *spasmodic form* the contractures pass into *tonic and clonic convulsions* or *epileptiform spasms,* which may last for many weeks, and then be followed by paralysis. There may be degeneration of the posterior columns of the spinal cord, with tabetic symptoms. Psychoses may be present. The anatomical degenerations make the prognosis unfavorable.

The *gangrenous form* may begin with the appearance of pustules. The limbs swell, most frequently the feet, with a feeling of intense heat ("Saint Anthony's fire"), and intense pain, then numbness and "frost-bite" gangrene. The entire member may be involved in the gangrene. The finger, toe or limb may slough away without bleeding.

The form appears to depend largely on the amount of ergot: if this constitutes less than 10 per cent of the bread, the convulsive type predominates; the gangrenous is more common with 30 to 50 per cent. An ergot content of 1 per cent renders flour poisonous; 7 per cent may become fatal.

The *treatment* of ergot poisoning is symptomatic.

Chronic ergotism in animals takes the course of gangrene; with loss of the comb or wings in birds; of the extremities or tail in mammals. Diarrhea, somnolence and paralysis develop concurrently, but not convulsions (Langecker, 1932).

Somewhat inconclusive animal experiments of E. Mellanby, 1931, indicate that vitamin A deficiency increases the severity of the convulsive form. R. Stockman, 1934, produced phenomena resembling convulsive ergotism by feeding monkeys with rye uncontaminated with ergot. Ratschow and Klostermann, 1938, claimed that ergotamine gangrene of rat tail may be prevented by injection of estrogen in females, of testosterone in males.

O. G. Fitzhugh *et al.*, 1944, found the growth of rats retarded when the food over long periods contained 1 to 5 per cent of ergot. There was no gangrene or vascular lesions, but a high percentage developed neurofibromas of the ears.

Related Fungi.—*Claviceps paspali,* growing on a Southern forage grass, Paspalum, produces toxic effects on feeding. They have not been studied in detail (H. B. Brown, 1916).

Ustilago Maydis.—*Corn Smut.*—A fungus analogous to ergot, found on the maize plant, has been employed by the Negroes for abortion, and stockraisers have also observed that it has an ecbolic effect. Bogdanovic, 1934, injecting fresh extracts into rabbits, reported effects resembling those of ergotoxine and antagonistic to epinephrine, but including hyperglycemia, prolonged fall of blood pressure and intestinal inhibition. W. H. Hunt and Thompson, 1938, found that it causes contraction of excised uterus and produces abortion in cats and cyanosis of cock's comb, but it is much weaker than ergot. Its toxicity is also low. It lowers blood pressure, but does not inhibit the pressor response to epinephrine. Perfusion through the frog leg causes constriction. The activity is not due to an alkaloid or acetylcholine or histamine, but resides in an oily fraction.

Deterioration of Ergot.—The ergot alkaloids and amines are rather unstable substances, and ergot loses its activity with age. Ergotism is said to have occurred only during the first four months after harvest (Poulsson). Many pharmacopeias therefore direct that ergot must not be older than one year. The fluidextracts on which the reputation of ergot is mainly based have probably all been aged for a year before being sold (Eldred, 1913). They are said to deteriorate chiefly within the first six months after their manufacture, then very slowly (Assoc. Amer. Drug Manufacturers, 1923). They should not be sold until past the period of rapid decline. This aging destroys chiefly the amines (M. R. Thompson, 1929), and these are not therapeutically important. The uncertain activity of ergot makes it advisable to employ only such preparations as have been assayed, although the assay methods are not very accurate.

Assay of Ergot.—The U.S.P. requires the bio-assay of ergot by the *cock's comb method* in comparison with ergotoxine ethane sulfonate. This depends upon the production of cyanosis under prescribed conditions. It reflects the therapeutic activity better than any other method. It covers all the therapeutically active ergot alkaloids, and excludes histamine and the other amines. Its accuracy, however, is not great.

The *cock's comb* test was described by Lorinser, 1824; used experimentally by Grünfeld, 1892 and 1895, under Kobert; and applied commercially by Houghton, 1898. The details are prescribed in the U.S.P. H. H. Crosbie, 1934, reported how the accuracy may be improved by color photography. *A chemical color reaction*, based on Van Urk's reaction with para dimethyl aminobenzaldehyde (M. I. Smith, 1930), is given by all the ergot alkaloids, including those that are inactive, and therefore does not always parallel the therapeutic activity (Lozinski *et al.*, 1931). The *method of Broom and Clark*, 1923, utilizes the *epinephrine-reversal* on blood pressure or rabbit's uterus. This is a more accurate measure of ergotoxine and ergotamine, but it does not include ergonovine and is therefore unsatisfactory. *Direct measurement of the effects on the uterus* of guinea pigs and cats is not reliable since it includes the histamine.

Preparations.—*Ergot* (Ergota, Secale Cornutum) is a fungous growth, Claviceps purpurea, from rye. Generally collected in Russia or Spain. Should not be older than one year. (The name comes from the French "ergot," a cock's spur, which it resembles in appearance.)

***Ergot Fluidextract** is prepared from defatted ergot with acidulated dilute alcohol. The potency, by bio-assay, should be equivalent to at least 0.5 mg. of ergotoxine ethanesulfontea per cubic centimeter. Dose, 2 cc., 30 minims. The *Liquid Extract,* B.P., is an aqueous solution preserved with alc.

***Ergotamine Tartrate,** U.S.P. (*Gynergen*), is soluble in water, 1:500. Dose, 0.25 to 0.5 mg. hypodermically, 1 to 2 mg. by mouth. *Ergotamine Tartrate Tablets,* U.S.P.; usual sizes, 0.5 and 1 mg. *Gynergen Solution,* in ampuls, 0.5 mg. in 1 cc. *Ergotoxine ethanesulfonate* is sol. in alc., but slightly sol. in water. Must be stored in an atmosphere of nitrogen, in sealed tubes, protected from light. Solutions deteriorate easily. Dose (subcutaneous or intramuscular injection), 0.5 to 1 mg., $\frac{1}{120}$ to $\frac{1}{60}$ grain.

Ergonovine maleate, U.S.P. (*Ergotrate*); soluble in water (1:36). Dose, by vein or intramuscularly, 0.2 mg.; by mouth, 0.5 mg. *Injection,* U.S.P., a watery solution, usually available as 0.2 and 0.5 mg. in 1 cc. *Tablets,* U.S.P., usually available as 0.2 and 0.5 mg.

Ergotine has been applied to different preparations. Those that occur most extensively in the older literature are: *Ergotine Bonjean:* Aqueous solid extract, purified with alcohol. *Ergotine Wernich:* Dialyzed extract, marketed both as a liquid and as a soft extract. *Ergotine Wiggers:* Dried, alcoholic, purified solid extract.

Haskell, 1914, found that "ergotine" and powdered extract produce the typical effects of ergot, but that the effects on the uterus are weakened much more than those on blood pressure.

OXYTOCICS OF MINOR IMPORTANCE

Gossypii Radicis Cortex, Cotton Root Bark.—The dried root bark of Gossypium herbaceum and other species. This was used as abortifacient by the Negroes of the South and also in Africa (G. W. Harley, 1941). It contains resins, but no alkaloids or tannin (Power and Browning, 1914; Zellner, 1910). Clinical and experimental reports are not favorable; the perfused uterus, however, is stimulated (Scott, 1911).

Peony Root.—Holste, 1916, claimed that this contains an alkaloid that stimulates uterine contractions, constricts blood vessels and increases blood coagulation. This needs confirmation.

"Shepherd's Purse."—Extracts of Capsella *bursa-pastoris* obtained a brief popularity as ergot substitute (H. Boruttau, 1920), but promptly relapsed into oblivion. C. Braga described quite complex pharmacologic effects, including relaxation of the nonpregnant uterus and stimulation of the pregnant. Butturini and Marangoni, 1934, found no ecbolic action, but reported effects on cock's comb similar to those of ergot, cyanosis of the tail of rats and transitory depression of blood pressure without epinephrine reversal.

◆

UTERINE SEDATIVES AND HEMOSTATICS

A number of drugs with ill defined actions are popularly credited with "quieting the excitability of the uterus," especially the pains of premature labor; with contracting the os uteri; arresting uterine hemorrhage; regulating dysmenorrhea, particularly at puberty and the climacteric; and even with correcting uterine malpositions. It is difficult to conceive a mechanism by which a drug could produce all these actions, except in the imagination. Many of these complaints are so uncertain in their course, and indeed so largely nervous, that it is easy to imagine any results that are desired.

These remedies were mostly taken from uncritical folk medicine and promulgated during the most uncritical period of therapeutics. They owe their continuance mainly to their extensive use in proprietary *"female weakness" remedies.* These in turn rely for their sale on the liberal use of alcohol and exaggerated suggestive advertising. There is practically no serious evidence of the clinical usefulness of these drugs. Excepting hydrastis and cotarnine, which belong to a somewhat different class, there is no record of any competent clinical investigation by experienced critical observers under hospital conditions. The clinical cases published are generally superficially recorded; they usually show evidence of prejudice and exaggeration, and are often vitiated by the simultaneous use of other measures of more evident value. Pharmacologically, most of the drugs of this class are practically inert, especially as concerns the uterus. Since the excised uterus reacts essentially like the uterus *in vivo,* it may be fairly taken as an index of uterine activity. Pilcher, 1916, investigated in this way the drugs used most commonly in these female remedies, employing the relatively high concentrations of 1:1000 to 1:500. He obtained no definite effects with: *Chamaelirium* luteum (*Helonias* diocia); *Leonurus* cardiaca; *Passiflora* dentata; *Mitchella* repens; *Chestnut* bark. The following gave more or less pronounced effects (but not sufficient to confirm any therapeutic value). *Slight Depression: Valerian; Dioscorea* villosa; *Aletris* farinosa; *Ichthyomethia* piscipula; *Pulsatilla* pratensis; *Cypripedium* pubescens; *Scutellaria* laterifolio; *Scrophularia* marylandica; *Senecio* aureus; *Viburnum* opulus. *Inconstant Stimulation: Acer* spicatum; *Cnicus* benedictus; *Viburnum* prunifolium. *Constant Marked Increase of Tone: Caulophyllum* thalictroides. These results were obtained chiefly on the excised uterus of guinea pigs. The excised human uterus required higher concentrations, but gave the same reactions (Pilcher, 1917). None of the above drugs produced any effect in anything like normal doses on the uterus of living animals (Pilcher and Mauer, 1918).

Excised intestines are affected similarly to the uterus. Caulophyllum, however, lowers the amplitude with little effect on the tone. Valerian (oil) depresses the contractions. Viburnum opulus and prunifolium are inactive (Delzell, Burman and Pilcher, 1916).

VIBURNUMS

Viburnum prunifolium and Viburnum opulus have the widest reputation among these uterine sedatives, but their usefulness is no more demonstrated. Illustrative of this is the fact that the drug sold as Viburnum opulus has, for the last twenty years, consisted of the bark of a maple, Acer spicatum (Farwell, 1913, and others). Viburnum prunifolium, or Black Haw, a rather common shrub, was used somewhat in domestic medicine (Lloyd). It was introduced into medical practice mainly by the clinical papers of Phares, 1866, and Jenks, 1876. Both praised it with extravagant enthusiasm. The next ten years were the high tide of its popularity, as judged by an output of seventy-five articles on the subject. The interest then abated equally suddenly, for the next thirty years produced only some fifteen papers. The whole early literature is typical of the loosest class of clinical "evidence." The mechanism of its reputed action is at most a matter of speculation. The only attempts at investigation date from R. L. Payne, 1888, and Sherman, 1896, and these did not include the uterus. They showed that large doses may produce depression of the whole nervous system, without practical significance. La Torre, 1912, interpreted the histologic picture as contraction of the uterus, compressing the uterine vessels. The first real search for uterine actions was made by Lieb, 1914. He believed that he observed stimulation of the excised uterus. More extensive investigations by Pilcher, 1916; by A. P. Matthews and Hager; by Hager and Becht, 1919, and by Hale, gave generally negative results under all conditions (uterus pregnant and nonpregnant; *in situ* or excised). W. E. Evans *et al.,* 1942, claimed to have isolated a uterine depressant substance from V. prunifolium. Neither viburnum has any effect on excised intestine.

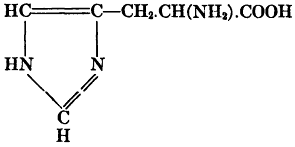
◆

HISTAMINE

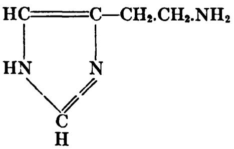
Histamine (*beta-iminazolyl-ethylamine; ergamine, ergotidine*) is partly responsible for the actions of aqueous extracts or ergots. It occurs also, mostly in combined form, in all tissues, and is liberated in putrefaction. It is destroyed in the digestive tract and has little effect when administered by mouth; but when injected subcutaneously or intravenously, it produces intense direct stimulation of the tonus or rhythm of smooth muscle, similarly to pituitary extract; and lowers blood pressure, by dilating the capillaries, similarly to peptone or anaphylactic shock. There is considerable difference in the susceptibility of the various autonomic organs, and this has no relation to their nerve supply. In organs inhibited by epinephrine, the latter is a more powerful antagonist to histamine than is atropine. Histamine is used clinically to test the secretory capacity of the stomach, and for the relief of pain in neuritis, chronic rheumatic affections, myositis and secondary myalgia.

Susceptibility of Different Muscles and Glands.—The stimulation of smooth muscle is most marked in the uterus; the bronchioles are also highly sensitive; the intestine, arteries and spleen are less susceptible; the bladder and iris do not respond (Quagliariello, 1914). Cardiac muscle is mildly stimulated; skeletal muscle is not affected. There is a weak pilocarpine action on glands (Dale and Laidlaw, 1910).

Chemical Structure.—Histamine is derived from histidine by the loss of a carboxyl group:



= Histidine



= Histamine

Occurrence in Tissues.—Histamine occurs in extracts of all tissues, animal and vegetable. Some is perhaps free, but the greater part is liberated by protein cleavage, effected by acids, by ferments or by bacteria. Kidney and liver tissue and their extracts form histamine by enzymic decarboxylation of histidine, kidney being four or five times more potent than liver. It can also be formed by nonenzymatic processes (P. Holtz *et al.*, 1938; E. Werle and Hermann, 1937).

Small amounts of histamine may be estimated by *biological tests* (rectal cecum of fowl, Barsoum and Gaddum, 1935; atropinized guinea pig intestine, C. F. Code, 1937).

From biological tests, Anrep, Barsoum *et al.* (1939) concluded that histamine is normally present in the *blood*, its concentration being especially high in rabbits and low in cats, and 10 to 60 times higher in the corpuscles than in the plasma. In clotting, a considerable amount passes from the corpuscles to the serum (C. F. Code, 1937). The *organ content* is not materially different in rats, guinea pigs and other species (J. Martin and Valenta, 1939).

Formation of Histamine in Muscle.—Burns and a considerable variety of chemical and physical agents cause release of histamine from tissues (H. Bachmann, 1938). The concentration of histamine in the venous blood of skeletal muscles rises when they are exercised, but not when they are resting (Anrep, Barsoum *et al.*, 1939). The heart muscle liberates it continuously, but also proportional to its work (Anrep, Barsoum and Talaat, 1936). Histamine is released in the active contraction of the smooth muscle, induced by acetylcholine, potassium chloride or pituitary extract (Ambache and Barsoum, 1939).

The disappearance of injected histamine from the blood stream occurs rapidly, the greater part within fifteen minutes in rats. The highest concentration is then found in the kidneys, but most has been destroyed. After excision of the adrenal glands, it disappears more slowly from the blood and tissues (B. Rose and Browne, 1938). It leaves the blood less rapidly in dogs (C. A. Dragstedt and Mead, 1935).

Destruction in Perfused Organs.—With Starling heart-lung preparations, histamine was destroyed by all organs that have been studied, most actively by the kidneys, then the liver, then heart, lungs, hind limbs and intestines (Steggerda, Essex and Mann, 1935). Very large oral doses are therefore tolerated without toxic effects (300 mg. by guinea pigs, 225 mg. by man), although 1 mg. by vein produces alarming symptoms in man. The protection is not due to the liver, but to rapid *destruction of histamine in the intestines* (Koessler and Hanke, 1924). This precludes intoxication from any histamine that might be formed by bacterial putrefaction of proteins. None has been isolated from the intestinal contents (H. Burchard, 1934).

Circulation.—In most species of animals the injection of histamine produces an extensive fall of blood pressure, which may be short or lasting, according to the dose. With large doses it is persistent, and presents the essential phenomena of "traumatic shock" (Mellanby). The fall is due to dilatation and increased permeability of the capillaries, analogous to inflammation, with slowing of the circulation by stagnation of the blood. Similar effects occur in peptone, anaphylactic and traumatic shock, and these may be due in part to the formation of substances with histamine actions (Dale and Richards, 1918).

Late Lesions.—Death from severe and prolonged histamine shock occurs usually by cardiac failure. Dogs that survive generally develop degenerative lesions in the aorta, especially the media, and in smaller arteries; also myocardial degeneration, prepyloric gastric ulcers, pericentral hepatic necrosis and focal splenic fibroblastic proliferation (Hueper and Ichniowski, 1944).

Muscular Vasodilator Substance.—Anrep and his associates, 1935 and 1936, claimed that histamine is the dilator substance found in the venous blood coming from contracting skeletal muscle and from the heart, which is responsible for the increased local blood supply during muscular exercise.

The *vasomotor center* is not affected directly, but the fall of blood pressure and the respiratory disturbances usually produce moderate stimulation (Pilcher and Sollmann, 1915).

Denervation.—Dale and Richards, 1918, confirmed that the depressive responses to histamine as well as to epinephrine and acetylcholine are peripheral and are, indeed, generally increased when the nerve supply has completely degenerated.

Susceptibility of Different Animals.—Man, dog, cat, monkey and fowl respond by fall of pressure; rabbits and guinea pigs show a rise (Dale and Laidlaw, 1911). The acute toxicity varies considerably with the conditions (Dale and Laidlaw, 1920). *Rats* are highly resistant to the histamine actions, although the histamine content of their organs does not materially differ from those of the very susceptible guinea pigs and rabbits (J. Martin and Valenta, 1939). Their resistance is lowered by changes of the electrolyte balance analogous to those induced by excision of the adrenal glands (Perla and Sandberg, 1939; Crivellari, 1927), and is restored by administering desoxycorticosterone (B. Rose, 1939). Excision of the thyroid gland is reported to render guinea pigs resistant to histamine and to anaphylaxis. The puerperal state and nursing also increase the resistance to histamine shock (Spinelli, 1929). *Graduated injections of histamine* for two or three weeks raise the tolerance of guinea pigs to five or six times the normal, and furnish considerable protection to anaphylactic shock from horse serum (E. A. Smith, 1939); similarly with *oral administration* (L. Farmer, 1939).

Clinical Symptoms.—Intravenous injection of 0.5 to 1 mg. of histamine into healthy young men causes momentary flushing of the face, succeeded by pallor; metallic taste, dizziness, faintness, frontal headache and rapid pulse, sometimes weak. The headache lasts several hours, the other effects less than half an hour. There is a moderate leukocytosis for three to five hours. Hypodermically, 2 mg. produce the same effects in less degree (Moon *et al.*, 1935).

The *headache* has been attributed to dilatation of the large arteries of the brain (G. A. Schumacher *et al.*, 1940). Migraine headache, which is explained by the same mechanism, is hypersusceptible to histamine (von Storch, 1940).

Clinical Effects on Circulation.—Intravenous injection of 0.001 mg. of histamine per Kg. of body weight causes prompt dilatation of the minute vessels of the face and brain. The time required for this may be used as index of the *blood flow velocity* (S. Weiss *et al.*, 1939). *Continuous intravenous* injection in man at constant rate maintains uniform effects for a considerable time, so that the histamine must be inactivated as fast as injected. A concentration of 1:20,000,000,000 of circulating blood gives recognizable effects. With the standard dose, the heart rate is quickened, without change of blood pressure, but with dilatation of the brain vessels and less dilatation of the skin vessels (Weiss, Ellis and Robb). With 2.75 mg. of the diphosphate in 250 cc. of saline, the A-V conduction time is shortened and the amplitude of the T wave is diminished, roughly proportional to the rate of injection. The changes are insignificant and do no permanent functional damage to the myocardium (G. A. Peters and Horton, 1944).

Heart.—Large doses of histamine injected intravenously or into the heart of dogs, cats, rabbits or guinea pigs dilate the right heart, probably through increased resistance in the lung vessels. Repeated hypodermic injections result in hypertrophy of the right heart. Morphologic changes in the heart tissue are produced both by acute and repeated injections (E. Kirch, 1933).

The *perfused mammalian heart* shows a short and slight slowing, followed by considerable quickening with increased excursions. The isolated *frog heart* is slowed (Eims, 1913) in winter, stimulated in spring (Lissak and Kokas, 1938).

Capillaries.—Observing these with the microscope in the living animals, by Lombard's method, Hooker, 1920, noted that the injection of histamine into cats produces prompt dilatation, sometimes preceded by brief constriction. The effects are not influenced by section of the nerves and are therefore peripheral. Dilatation of the capillaries and small arterioles and venules has also been observed in the omentum of the cat (A. R. Rich, 1921), in the mesentery of mice (J. Wolff, 1923) and in the human skin (Carrier, 1922). The production of skin edema is discussed below. The capillaries of frogs are not dilated (Krogh).

Perfused organs respond by vasoconstriction if the histamine is perfused in saline; but in the presence of blood and epinephrine, histamine dilates, and therefore reproduces the depressor effect of intact animals (Dale and Richards, 1918). The *coronary vessels* are dilated in dogs (L. N. Katz and Lindner, 1939).

Excised arteries are constricted by histamine, in all species and in nearly all situations (Dale and Laidlaw, 1911), including the coronary (Barbour, 1913) and the pulmonary arteries (Anderes and Cloetta, 1916), but not the liver veins (Berezin, 1914).

Pulmonary vessels are constricted in lung sections (Gilbert, 1938), lung perfusion (S. Okada, 1940), and apparently in intact animals, for the pressure in the pulmonary artery rises and the volume of the lung diminishes, even when the pressure in the systemic arteries is unchanged (Anderes, 1915). Woodbury and Hamilton, 1941, attributed the rise of pulmonary arterial blood pressure in cats and rabbits to pulmonary vasoconstriction, but in dogs to increased output of the right heart. Berezin, 1914, stated that the constrictor effect in the excised vessels is removed by atropine, and the like.

Abe, 1920, and Dale attribute the fall of blood pressure by histamine, peptone, serum, to interference with the pulmonary circulation, partly by bronchial spasm and partly by direct contraction of the pulmonary vessels.

Clinical Effects on Cerebral Vessels and Cerebrospinal Fluid Pressure.—Intravenous injection of histamine without anesthesia or with amytal anesthesia dilates the cerebral vessels and raises the cerebrospinal fluid pressure. Under ether, the cerebral vessels are already dilated and histamine does not dilate them further; indeed, the fall of blood pressure may narrow them and lower the cerebrospinal fluid pressure (H. S. Forbes *et al.*, 1929). Similar effects occur in dogs, with small doses (Weinberg, 1933). If a bronchial spasm occurs, this raises the cerebrospinal fluid pressure through asphyxia (Dixon and Halliburton, 1914).

Theory of Deficient Blood Return.—Mautner and Pick, 1915, suggested that the fall of pressure after histamine, peptone, and so forth, could be explained by obstruction to the return of the blood to the heart; for instance, by spasmodic constriction of the intestinal arterioles, and of the lung vessels; or by choking of the liver capillaries (K. Gollwitzer-Meyer, 1932). There is, in fact, congestion of the liver and of the splanchnic vessels in peptone shock or anaphylaxis, but not, according to Dale and Richards, in the evanescent histamine fall. It is therefore more probably a secondary result. Portal obstruction is not the essential factor in the histamine fall, for it occurs in eviscerated animals. The latent period of the fall is also suggestive. It is shortest when the injection is made into an artery, longer with a vein, and longest with the portal vein. This indicates that the action is on a structure between the arteries and veins, that is, on the capillaries. Gantner and Schretzenmayr, 1930, concluded that the vascular dilatation in the extremities, kidneys and splanchnic area suffices to explain the fall of blood pressure without invoking blockade of the liver or lung. The increase of thoracic lymph flow, which comes chiefly from the liver, has been attributed to constriction of the hepatic veins, with consequent rise of pressure in the capillaries of the liver (Yamasaki, 1939).

The *urine flow* is decreased (in dogs) by hypodermic or intravenous injection of histamine, chiefly by the fall of blood pressure, together with the increased excretion of water into the alimentary tract, by the gastric juice, saliva and pancreatic juice. Stasis of the blood into the liver may contribute to the oliguria (Molitor and Pick, 1923). In *perfused kidney*, the smallest effective concentrations of histamine cause constriction, while similar concentrations increase the perfusion flow through the extremities and intestines (Morimoto, 1928).

The *plasma volume* is not materially changed by histamine injection, notwithstanding the rapid fall of blood pressure, in contrast to traumatic shock. Indeed, there is generally some increase, by mobilization of the blood from the spleen and other depots (I. J. Deyrup, 1944; Brednow, 1931).

The coagulability of the blood is not altered, in contrast to peptone (Dale and Laidlaw, 1911; Loewit, 1913).

Leukocytosis.—Hypodermic or intravenous administration of histamine causes moderate increase of the polymorphous neutrophils, sometimes preceded by transient leukopenia. In man, with 0.5 to 1 mg. by vein, the increase averages about 3000 and lasts for three to five hours (Moon *et al.*, 1935). Histamine causes abundant *emigration of leukocytes* from blood vessels, but is not chemotactic (review, McCutcheon, 1946).

Histamine Urticaria.—The application of a drop of histamine, 1:1000, to the scarified skin produces brief pallor, followed by reddening and the formation of a temporary urticarial wheal (Eppinger, 1913). The hypodermic injection of 0.5 to 1 mg. of histamine may be followed by erythema over the entire skin. Thomas Lewis, 1927, divides the response to intradermic injection of histamine into four phases: (1) an immediate "*white reaction,*" a local paling due to the mechanical expression of blood from the minute vessels by the tension of the injection; (2) in about twenty seconds, a "red reaction," a small red spot immediately about the puncture, due to dilatation of the capillaries and venules, occurring also in denervated skin; (3) shortly after this a spreading "red flare," attributed to arteriolar dilatation and active hyperemia by a local nervous reflex; (4) in one or two minutes, a small wheal, a localized edema, due to increased permeability of the capillary endothelium. Similar reactions, but of various degrees, occur in dermatographia, and by the application of a variety of substances, for instance, peptone, morphine and its derivatives, to a small degree by atropine, cocaine, formaldehyde, calcium and a number of amino compounds; in susceptible individuals also by quinine and the like, and by certain proteins and anaphylactic poisons (Sollmann and Pilcher, 1917). No definite relation of the urticaria to other actions or to chemcal constitution has been recognized. The urticaria is a particular, limited type of dermatitis, consisting in congestion by direct dilatation of the local capillaries, reflex dilatation of the neighboring arterioles and increased permeability of the capillaries, leading to local edema. Dogs and goats also respond by wheals to intradermal injection of histamine; cats, rabbits and guinea pigs do not (M. L. Darsie, Perry *et al.*, 1945). Identical phenomena occur in other irritations of the skin, for instance mechanical or thermal burns. Th. Lewis and Grant, 1924, suggested that these are due to the liberation of the histamine-like substance. Menkin, 1936, found that all inflammatory exudates increase the permeability of the skin capillaries, but that this is not due to histamine or a closely related substance, for their effect on intestinal motility is the reverse of that of histamine. The subject of capillary pressure and permeability is *reviewed* by E. M. Landis, 1934.

Diagnostic Applications of Histamine Wheals.—These bring out the yellow color of the skin in *latent icterus* (O. Klein, 1931). The urticarial response is diminished if the arterial blood supply is decreased, as in arteriosclerosis or Buerger's disease (Haxthausen, 1938). It is also a test of peripheral nerve function, since the "flash" hyperemia does not occur where the sensory nerve fibers have degenerated (L. H. Loeser, 1938). The susceptibility of the *bronchial musculature* to histamine does not go parallel to its edemic action on the skin (Samter, 1933), and this is therefore not an index of allergic tendencies.

Role of Histamine in Anaphylactic Shock.—The occurrence of histamine in pituitary extract, peptones, secretin and other organ extracts, and especially those prepared with acid and heat, and the striking resemblance of their effects to those of histamine, suggested that histamine is responsible for their actions (Abel and Kubota, 1919; bibliography). Histamine is released by perfusion of the antigen through the lungs of sensitized guinea pigs (H. Schildt, 1936), and from the red blood cells of sensitized animals when they are treated with antigen *in vitro*, in quantity sufficient to have marked effects (G. Katz, 1940). In guinea pigs, the plasma concentration of histamine rises in *anaphylactic shock* to two to thirteen times and in dogs even to more than eighty times the normal level coincident with the fall of blood pressure (C. A. Dragstedt and Mead, 1936; C. F. Code, 1939); but rabbits, horses and calves do not show a significant increase (B. Rose and Weil, 1939; Code and Hester, 1939). With rabbits, the histamine content of the whole blood falls rapidly in anaphylactic shock; the tissue concentration is not changed (B. Rose, 1940). The blood histamine also falls in marked types of clinical shock and in agonal states (B. Rose and Browne, 1940). Shock by rattlesnake venom and crystalline trypsin injection into guinea pigs increases the histamine content of the blood. Snake venom, staphylococcus toxin and peptone liberate histamine when perfused through the lungs of guinea pigs or cats (Feldberg *et al.*, 1937).

Traumatic shock (produced by contusion of the leg or extruded intestines) is not accompanied by histamine increase (Dragstedt and Mead, 1937). Blood drawn from the traumatized leg does not produce shock when injected into a normal animal (Parsons and Phemister, 1930; J. R. Bell, Clark and Cuthbertson, 1938), contradicting the toxemic theory of shock proposed by Dale, Laidlaw and Richards, 1919. Histamine leads to irrecoverable low blood pressure only if other factors are superimposed (H. Rein, 1937). The clinical phenomena of shock depend on inadequate blood supply of the tissues, due to diminished blood volume, and this due chiefly to hemorrhage and to exudation of the plasma fluid into the injured tissues (reviews, A. Blalock, 1936, C. J. Wiggers, 1942).

Salivary Secretion.—In *anesthetized dogs*, 1 to 7 mg. of histamine intravenously increases the salivary output, partly by a muscular action, pressing out the contents of the alveoli and ducts, and partly by increasing the secretion. Atropine abolishes the latter effect in the submaxillary, but not in the parotid, gland. The submaxillary responds to much smaller doses of histamine. The submaxillary saliva secreted in response to histamine has a higher organic content and a lower ash than that of chorda tympani stimulation. Previous injection of histamine diminishes the response to pilocarpine and to chorda stimulation (Stavraky, 1931).

With *cats,* intravenous histamine injection usually causes submaxillary salivation, which is antagonized by epinephrine (M. E. MacKay, 1929). The increase appears to be indirect, for it does not occur if histamine is injected into the artery of the gland. This, however, greatly increases the response to chorda tympani stimulation, but not acetylcholine. The chorda potentiation is increased by physostigmine, abolished by atropine (O. S. Gibbs and Clanahan, 1937).

Gastric Secretion.—Histamine is the most potent known excitant of gastric secretion, in doses that have little or no effect on blood pressure. *Gastrin,* the secretory-excitant principle of gastric extracts, is probably histamine or a closely related derivative; *secretin,* the corresponding principle of duodenal extracts, is probably also related; indeed, the intramuscular injection of histamine stimulates pancreatic and salivary as well as gastric secretion (Keeton *et al.*, 1920). The stimulation of gastric secretion involves both the acid and the volume. It is used as a diagnostic test, to differentiate between pseudo-achlorhydria, which responds to histamine, and true achlorhydria, which does not respond.

In normal individuals 0.5 mg. of histamine hydrochloride (= 0.85 mg. of the phosphate) intramuscularly produces maximal secretion of acid in half an hour to an hour, persisting for over one and a half hours. In achylia vera, the acid response is absent; in pseudo-achylia it is present, although it may be more or less decreased. The injection produces rather marked side actions: headache, vertigo, flushed face, large urticarial wheal at the site of the injection. It has therefore been suggested to reduce the dosage to half, which is active in normal individuals; but this may fail in pseudo-achylia (Mathewson, 1935).

Histamine should not be injected into patients with *aortic disease.* Death occurred in such an instance within half an hour after the dose of 0.8 mg. (Maijala, 1938).

In *rats,* gastric secretion is not increased, even by 5.5 mg. of histamine phosphate hypodermically (M. H. F. Friedman, 1943).

Production of Gastric Ulcer by Histamine.—Repeated injection of large doses (7½ mg.) of histamine into rabbits produces acute gastric ulcers such as those of pilocarpine, but with more marked vascular changes and edema. They probably result from trauma by the strong peristalsis, and are therefore less marked in fasting animals. Gastric ulcers are also produced by hypodermic injection of methylamine and other *aliphatic amines* which increase gastric acidity. It is more marked if the liver was previously injured by chloroform or phosphorus (Kanatake, 1938).

Histidine against gastric ulcer was introduced by A. G. Weiss and Aron, 1933, on a theory that deficiency of this amino acid might be concerned in the production and persistence of peptic ulcer. They believed that they had confirmed this on the experimental peptic ulcers in dogs, and several clinicians reported benefits in a large proportion of patients from daily hypodermic injections of histidine hydrochloride (5 cc. of 4 per cent), continued for several weeks, with the patients on ordinary diet. However, carefully controlled comparisons (K. A. Martin, 1936; D. J. Sandweiss, 1936; Flood and Mullins, 1936) show that the results were no better, either in kind or degree, than those obtained in alternate patients with the ordinary alkali and diet treatment; either might succeed when the other had failed. There was no constant or marked effect on the acid secretion. The ulcer itself was not improved. About 40 per cent of the patients showed mild subfebrile reactions, not connected with the improvement. The relief appeared to be purely transient and symptomatic, and could indeed be obtained by injections of distilled water. Histidine has no effect whatever on the secretory functions of Pavlov stomach dogs; nor does it alter the tonus or movement of excised intestines (L. B. Goodman and Bearg, 1938); but in guinea pigs, 10 mg. of histidine produce immediate and complete relaxation of the intestinal contractions provoked by histamine. It also antagonizes the stimulation of excised guinea pig uterus by histamine or pituitrin, and generally smooth muscle stimulation by acetylcholine, physostigmine or barium chloride (B. N. Halpern, 1939).

Histidine in Pregnancy Urine.—This has been demonstrated in 90 per cent of gravid women, but only in the latter months of pregnancy (Voge, 1929; Gertler, 1936). It has been attributed to inhibition of liver histaminase (Kapeller-Adler and Haas, 1935).

Histamine on Intestinal Motility.—With anesthetized dogs and cats, intravenous injection also causes marked stimulation, which is diminished but not abolished by atropine. Hypodermic injection requires more than four times the intravenous dosage, and injection into the intestinal lumen is ineffective with two hundred times the dose (McKay, 1930; Gruber and Robinson, 1929). With excised intestines, the stimulating action is much weaker than for most other smooth muscle; dilute solutions may even inhibit (Planelles, 1924). Calcium salts intensify the stimulation (Vanysek, 1914). The histamine stimulation is antagonized by various anesthetics (L. Farmer, 1938). Its inhibition by histidine, arginine and cysteine, in rather high concentrations, differentiates it from other muscular stimulants (D. Ackermann and Mauer, 1944).

Bronchioles and Respiration.—Intravenous injection of histamine produces violent dyspnea and pulmonary emphysema, similar to anaphylaxis (Baehr and Pick, 1913), by acute obstruction of the bronchioles through spasm of their muscle and congestion and edema of their mucosa (D. E. Jackson, 1914). The pulmonary arteries are also constricted. These effects do not occur in rats. The bronchiolar spasm is antagonized by atropine and epinephrine (Sollmann and Gilbert, 1937), also by cocaine, not by ergotamine (Swanson, 1929), nor by histaminase or nicotinic acid (A. J. Gilbert and Goldman, 1940).

Histamine for Diagnosis of Pulmonary Tuberculosis.—Hypodermic injection of 1 cc. of 1:1000 solution, which causes no respiratory disturbance in normal individuals is reported to produce transient moist rales in three to five minutes in 90 per cent of affected patients (Videla and Lamarque, 1935).

Uterus.—Clinically, hypodermic injection of ⅓ to 2 mg. produces prompt and powerful but brief stimulation of the parturient or postpartum uterus, with spasmodic contraction, beginning in one or two minutes and lasting for half an hour (Bourne and Burn, 1927; Jones and Barlow, 1937). Its use is not advisable, as it causes undesirable side actions: marked vasodilatation, rapid pulse, headache, violent vomiting. *The excised uterus* is also stimulated in the human (Kehrer, 1911; Guggenheim, 1914), pregnant and nonpregnant cats, rabbits and guinea pigs (Barger and Dale, 1910); but the rat uterus is relaxed (Fuehner, 1913; constituting a difference from pituitary extract, Tate, 1921).

Excised ureter is stimulated by dilute, depressed by more concentrated solutions (Gruber, 1928). The *urinary bladder* is not stimulated in living animals (Abelin, 1929).

Iris.—Injection of histamine into the carotid artery dilates the pupil of dogs and cats, but constricts it in rabbits. Injection into the anterior chamber produces the same effects, except in dogs, where the dilatation is followed by constriction (Matsuda, 1929).

Blood Sugar Level.—Hyperglycemia is reported from intravenous injection of small doses of histamine in guinea pigs (La Barre, 1926). Histamine activates *carbonic anhydrase.* This is prevented by low concentrations of zinc (E. R. Main and Locke, 1941).

Concentration Gradient.—Histamine produces its effects only when it is applied suddenly; if it is added slowly (*f. i.*, to the excised uterus), it is inactive. A given concentration soon loses its effect, but raising the concentration again induces contractions. Similarly, rapid intravenous injections are much more toxic than slow injections (E. S. Karady, 1941).

Frequent graduated injections of histamine during two or three weeks increase the tolerance of rabbits (Eichler and Killian, 1931), dogs (H. R. Jacobs and Mason, 1936), cats (Karady, 1938) and guinea pigs. They furnish considerable protection against anaphylactic shock from horse serum (E. A. Smith, 1939); similarly with oral administration (L. Farmer, 1939). In dogs, daily intravenous injections sufficient to produce cardiac acceleration (1.3 to 13 mg.) gave no cumulative change of blood count or chemistry, and no tissue damage (G. H. Ettinger *et al.*, 1936). H. R. Jacobs and Mason, 1936, also found no tissue damage in a dog which had received 2322 mg. of histamine intravenously in the course of sixty days. McCarrison, 1924, had claimed that this retards or inhibits the growth of young animals.

Hair growth of underfed albino rats is stimulated by daily hypodermic injection of 1.5 mg. of histamine, as with local irritant (E. O. Butcher, 1940).

Preparations.—*Histamine Phosphate,* U.S.P., the acid phosphate of β-iminazolylethylamine. Colorless crystals, soluble in water (1:4). Average dose, 0.3 mg. intramuscularly. *Histamine Phosphate Injection,* U.S.P., in water for injection, is available in ampuls, 1 mg. in 1 cc. *Histamine hydrochloride* is hygroscopic and tends to deteriorate, especially when in solution (Nelson, 1923).

Imidazol and other histamine derivatives also stimulate smooth muscle, but are less active than histamine (Auvermann, 1918; Dale and Dudley, 1921).

PARAPHENYLENEDIAMINE

This substance, $C_6H_4(NH_2)_2$, also called *orsin,* is used extensively for dyeing hair and furs brown and black. Its use is dangerous since it may result in violent local dermatitis and sometimes in serious systemic poisoning (Cole, 1924), with histopathologic changes in the central nervous system, especially the midbrain (C. Davison, 1943). Dyeing of the eyelashes has caused serious ophthalmia and permanent blindness (J.A.M.A., 1933, *101:* 1558). The susceptibility varies considerably. Para- and ortho-aminophenol, and diaminophenol, related substances used in hair dyes, also cause dermatitis; likewise orthotoluidinic and pyrogallic acid. Paraphenylenediamine, and its dimethyl and diethyl derivatives and metaphenylenediamine, which have similar actions, are employed to accelerate the vulcanization of rubber, and form a toxic hazard in this industry. They are probably decomposed in the vulcanization, but it is not known whether the products formed are toxic (Hanzlik, 1923).

Clinical Phenomena.—The local effects consist in severe dermatitis. The systemic phenomena sometimes observed after the application of hair dyes include vertigo, gastritis, asthenia, diplopia, lacrimation, chemosis, exophthalmos, asthma, exfoliative dermatitis. Industrial workers suffer chiefly from eczema and asthma.

The **peripheral actions** agree in principle with those of histamine; that is, (1) stimulation of smooth muscle, regardless of its innervation. This includes bronchial constriction, which is partly responsible for the asthma; and (2) increased permeability of the capillaries, resulting in the inflammatory and edematous phenomena.

Other Systemic Effects.—Hypodermic injection of paraphenylenediamine into dogs causes hemolytic anemia, reducing the red blood cells to a half or a fourth in forty-eight hours (J. E. Davis, 1946). All the phenylenediamines produce rise of blood pressure, stimulation of respiration, fall of temperature, tremors, convulsions, coma and death. With large doses the animal may die before the edema can develop. Frogs show a narcotic action.

In all the actions, systemic and edemic, the para *isomer* is the most potent and the ortho the least.

Edema Production.—The oral or subcutaneous administration of paraphenylenediamine (0.2 Gm. per Kg.) to rabbits is followed in about one and one-half hours by an intense watery edema of the entire head (Meissner, 1919). This increases to the next day, and gradually disappears by the sixth day, if the animal survives. Not all rabbits develop the edema. It occurs generally in cats and dogs, but not in rats (Tainter, James and Vandeventer, 1929). It is due to increased permeability of the vessels, and may be prevented by diminishing the local blood supply (Tainter and Hanzlik, 1924).

A. R. Johnston, 1928, however, considers the action of amines to be directly on the tissues, and not on the pressure or capillary permeability. The reason for the restriction of the edema to the head is not known. It is not strictly specific, for the edema involves any other part of the body if it is rubbed with turpentine (Gibbs, 1931). In dogs, a single injection of 30 mg. per Kg. produces edema in various situations. The eyes show signs of irritation. Surviving animals develop acute hemolytic anemia, persisting for five to thirty days (J. E. Emerson, 1946). The meta-isomer does not produce head edema, but instead causes hydrothorax, which does not occur with the para-compound.

Quinone-Diïmine.—On exposure to air paraphenylenediamine in solution is promptly oxidized to this compound, $C_6H_4(NH)_2$, which is presumably the dyeing agent. It is also formed in the respiratory tract if paraphenylenediamine is inhaled. It produces violent irritation in sensitive individuals, but soon oxidizes further to "*Bandrowski's base,*" which is less irritant, and then to still less active products. It has been suggested that it is responsible for the pharmacologic actions of paraphenylenediamine, but the evidence is not conclusive. R. L. Mayer, 1928, attributes the actions of paraphenylenediamine, metol (developer), pellidol and related azo dyes to quinone, $O.C_6H_4.O$, formed by their reduction in aminophenol and subsequent oxidation.

Edema by Other Aromatic Amines.—The hypodermic injection of phenylenediamine, metatoluylene-diamine, acetyl-phenylhydrazine (pyrodine) and toluyl-hydrazine produces effusions into the serous cavities. These are not due to hydremia, the blood being rather thickened. Probably the permeability of the capillaries is increased (L. Hess and Mueller, 1915).

Urticaria.—Many amines produce urticaria when applied to the scarified skin; for instance, phenylethylamine, phenylenediamine, hydroxylamine, and the like (Sollmann, 1917).

Drug Purpuras.—Hemorrhages into the skin have been reported as following a variety of drugs, chiefly acetphenetidine, aniline, antipyrine, arsphenamine, atropine, barbiturates, ergot, iodine compounds, mercurials, pyridine, quinine, salicylates. They are sometimes associated with low blood platelet count, but more often not. Some are definitely allergic, permitting passive transfer. This has been reported for quinine and ergot (Peshkin and Miller, 1934).

Toluylenediamine, $CH_3.C_6H_3.(NH_2)_2$.: Injection of 0.05 to 0.08 Gm. into dogs results in bilirubinemia within ten hours (Hiyeda, 1927). McGowan *et al.*, 1936, attribute this to diminished excretion of bilirubin and bile acids into the bile, so that they accumulate in the blood. M Bodansky, 1938, found further evidence of liver injury by meta toluylenediamine, as increase of blood cholesterol to three times and of phosphatase to a hundred times the normal level. The albumin:globulin ratio was decreased to half.

Ethylenediamine, $NH_2.CH_2.CH_2.NH_2$, has a rather low toxicity; the minimum fatal dose for mice is 0.75 Gm. per Kg. hypodermically. With *rabbits*, nearly fatal doses (0.4 Gm. per Kg. by vein or hypodermic) produce lacrimation, salivation, temporary respiratory stimulation, lowering of the temperature, slight general depression and transient diarrhea. The blood pressure falls (often with 1 mg., hypodermically) by a central action. Smaller doses (0.1 mg. per Kg.) produce only a fall of temperature. Daily injections decrease the susceptibility to this effect (Barbour and Hjort, 1920). With *frogs*, it causes chronic convulsions and narcosis. It has rather feeble amine actions on *excised organs*. Intestines are relaxed with epinephrine; but the responses of the uterus and blood vessels may be the opposite of those to epinephrine. Perfusion of rabbit's ear or frog leg sometimes constricts and sometimes dilates the vessels (Anan, 1927).

Ethylenediamine increases the solubility of the *methyl xanthins* (see Aminophylline). It has been claimed that it aids them by dilating the coronary vessels, but this is probably incorrect. K. H. Osterwald and Meurer, 1939, claim that *diethanolamine*, $HN(CH_2CH_2OH)_2$, has a favorable action on cardiac output and coronary flow. They also investigated isopropanolamine.

Ethylenediamine Solution, U.S.P., contains about 69 per cent in water. It has an ammonia-like odor and a strongly alkaline reaction.

Hydrazine ($NH_2.NH_2.H_2SO_4$).—When injected into dogs, hydrazine sulfate lowers the percentage of sugar in the blood and the hepatic glycogen without any glycosuria. The hepatic cells degenerate, but recover if the injection was not fatal. The hypoglycemia appears to be due to increased sugar combustion, as indicated by the respiratory quotient. Injected dextrose is also oxidized more rapidly. There is no specific influence on heat production (Underhill and Murlin, 1915). The production of anhydremia and anemia by hydrazine, *phenyl hydrazine* (see Index) and other hydrazine derivatives was studied by Bodansky, 1924.

Ethylene imine, C_2H_4NH, when absorbed from the human skin or inhaled as fumes, does not produce immediate discomfort, but subsequently there may be severe vomiting and inflammation and edema of the mouth, throat and eyes (Danehy and Pflaum, 1938).

Trimethylamine, $(CH_3)_3N$, acts as a sex hormone, causing frogs to moult their skin and prepare for mating. Very dilute solutions increase flower production in tomato plants. It stimulates the growth of plant tumors after inoculating the plant with tumor bacteria (Havas, 1938).

Triethanolamine, $N(CH_2.CH_2.OH)_3$, has no deleterious effects when low concentrations are ingested with food. Death in acute poisoning is probably due to the alkalinity. It is absorbed through the skin (Kindsvalter, 1940).

Allyl amines, $CH_2{:}CH.CH_2.NH_2$, when inhaled by mice, produces irritation of the nose and mouth, congestion of the eyes, irregular respiration, cyanosis, excitement, convulsions, coma and death. The skin is not irritated by direct application (E. R. Hart and Leake, 1939).

REACTIONS RESEMBLING THOSE OF HISTAMINE

Phenomena resembling closely those of histamine are produced by the injection of many tissue extracts, by peptones, secretin and other products of partial protein cleavage, by blood serum, bacterial products, snake venoms, extracts of traumatized tissue, citrinine (Ambrose and De Eds, 1946), by the injection of many colloids; and in the course of anaphylaxis and of traumatic shock. In some cases the phenomena may be due to the presence of histamine or a near derivative. In most cases, however, the correspondence of the effects is not complete (Loewit, 1913); in some it is only superficial.

SECRETIN

Pavlov showed that the presence of acid chyme in the duodenum is the normal stimulus to the secretion of pancreatic juice. This is due to the production of a peculiar substance "secretin," which may be prepared artificially by macerating the duodenal or jejunal mucosa with dilute acids, soaps, and the like (Bayliss and Starling, 1902); or by contact of these or of irritants with the living mucosa. Secretin does not exist as such in the mucosa, but is formed from an insoluble "prosecretin." Secretin is reported to have been isolated as a crystalline compound with picrolonic acid (Hammarsten, Jorpes and Agren, 1933). It is soluble in water and dilute alcohol (70 per cent); insoluble in absolute alcohol, ether, and so forth. It is fairly readily destroyed by acids, alkalis or oxidation, and by the digestive ferments (Carlson *et al.*, 1916).

Actions.—Intravenous injection of secretin stimulates the flow of pancreatic juice, bile (Downs and Eddy, 1919) and succus entericus, but not of the other digestive secretions; nor do extracts of other portions than the small intestines produce the secretory effect. The pancreatic secretion is accompanied, but not caused, by vasodilatation. The pancreas is not readily fatigued, the flow being undiminished after eight hours of continuous injection. Repeated injections of equal doses give identical response. The flow is not affected by anesthesia. Secretin has no effect on sugar metabolism.

The only other direct action of purified secretion, so far as known, is some augmentation of *bile secretion* (Tanturi, Ivy and Greengard, 1937). Secretin increases the *urine flow*, but this is attributed to the intestinal absorption of the fluid from the increased flow of pancreatic juice and bile; it does not occur if these secretions are diverted. It does not require the presence of the hypophysis (C. A. Dragstedt and Owen, 1931).

Gastrin.—Extracts of the pyloric mucosa contain a substance that stimulates gastric and other secretion. This is probably due to histamine, which has been isolated from the extracts (Sacks *et al.*, 1932).

Enterogastrone.—Undigested fat, particularly in the intestines, inhibits gastric secretion and motility. This has been attributed to the formation of an inhibiting hormone, enterogastrone (Kosaka and Lim, 1933). A similar inhibition occurs when dextrose is present in th upper intestines (Quigley and Phelps, 1934).

Cholecystokinin is a powerful stimulant of the gallbladder which has been extracted from the mucosa of the upper intestines. It is much more potent than stimulation of their autonomic nerves. It is active only on intravenous injection and causes prolonged contraction and evacuation of the gallbladder, in man and animals. It may be freed from histamine and choline and seems closely related to secretin. It is probably not identical with it since some preparations may lack either the pancreatic or the cholagogue action. The effect, however, is not greater than that of the ingestion of egg yolks and cream, so that "it is unlikely that it will prove of therapeutic or diagnostic value" (Ivy, review, 1935).

Choroid extract produces a specific increase in the flow of cerebrospinal fluid (Dixon and Halliburton, 1914).

PROTEOSES ("PEPTONE")

Effects of Albumoses.—Intravenous injections of "Witte's Peptone" (0.5 Gm. per kilogram) produce anaphylactoid phenomena (Biedl and Kraus): temporary but considerable fall of blood pressure (Thompson, 1896 and 1899) by peripheral action, in dogs (but not in rabbits, Pissemsky, 1915); stimulation of the isolated uterus (Dale and Laidlaw, 1910); bronchial constriction, peripheral (Baehr and Pick, 1913); increased flow of lymph and secretions (Popielski, 1909); of milk (Ott and Scott, 1912); discharge of the gallbladder (Klee and Knuepfel, 1914); diuresis independently of the blood pressure (Froehlich and Pick, 1912); fever on hypodermic injection, and other effects. In most animals (but not in rabbits) appropriate doses render the blood noncoagulable and produce hyperglycemia and glycosuria (Y. Henderson and Underhill, 1911). McGuigan and Ross, 1917, however, state that the usual result is hypoglycemia, which they attribute to circulatory changes in the liver. The secretion of bile is increased (O'Kada, 1915). Application of peptone to the scarified skin produces a wheal (Sollmann and Pilcher, 1916). Intravenous injection of small doses of pure proteoses greatly increases the urinary nitrogen for several days (Whipple, 1916).

Resemblance to Histamine.—Dale and Laidlaw, 1911, called attention to the striking similarity of the anaphylactic and peptone effects to those of histamine, and suggested that the active principles may be similar. Certain minor differences exist; *f. i.*, epinephrine removes the bronchial spasm of peptone more effectively than that of histamine (Januschke and Pollak, 1911); histamine does not affect the coagulation of the blood (Modrakewski, 1912).

Desensitization.—Dogs that survive "peptone shock" are immune to repeated injections, even of large doses; some 6 per cent of dogs have a natural immunity to "peptone," while neither native nor acquired immunity for histamine exists in dogs (Abel and Geiling, 1924). There is some mutual desensitization between peptone and anaphylactic shock; *i. e.*, each affords some protection against the other (Dragstedt and Mead, 1937).

Sensitization.—On the other hand, it is claimed that the intravenous injection of a small dose of peptone into rabbits produces sensitization, so that another injection results in prompt anaphylactic shock. This sensitization occurs within ten to twenty minutes, reaches its maximum in half an hour and then decreases slowly to complete disappearance in eight days (de Waele, 1923).

Active Constituents.—Typical peptone effects are produced by preparations free from histamine (Hanke and Koessler, 1920) or other foreign toxic admixtures (Underhill, 1903). In dogs, however, some depressor substance, presumably histamine, appears in the blood in peptone shock and also in anaphylactic shock; and it is asserted that the peptone and anaphylactic phenomena are produced by the liberation of histamine from the tissues (Dragstedt, Mead and Eyer, 1938).

Smooth muscle is generally stimulated, similarly to histamine. In *excised intestine*, the stimulation is relatively slight, and inhibition tends to predominate (Olivecrona, 1921). The *bronchial spasm* in guinea pigs is less intense than in anaphylaxis (Loewit, 1913).

Circulation.—The *mechanism of the fall of blood pressure* is identical with that of anaphylaxis (Pearce and Eisenbrey, 1910; Froehlich and Pick, 1912). It occurs when the circulation is short-circuited to exclude the liver, so that the latter is not essential to the fall (Bally *et al.*, 1941). Injection of albumose or histamine into nonanesthetized animals produces flushing of the skin and mucous membranes (Abel and Geiling, 1924). With rabbits, the vessels of the legs and ears are constricted, while the splanchnic vessels are dilated (Kondo, 1919). The excised mammalian heart is weakened by concentrations of 1:1000 to 1:10,000; stimulated by 1:200 (Pissemsky). *Excised vessels* are generally constricted (Dale and Laidlaw, 1911); the ear vessels are constricted by all concentrations; those of the perfused lung are somewhat dilated (Baehr and Pick, 1913); also the liver veins (Berezin, 1914); the intestinal, renal and coronary vessels are unaffected by dilute solutions, constricted by strong solutions (Mautner and Pick, 1915). The effects on blood pressure and respiration were investigated by Zuntz, 1911. Perfusion of Witte peptone through the *liver* produces obstruction of the hepatic veins, probably by vasoconstriction (Simonds and Brandes, 1929). The peptone shock is said to be much less marked in animals whose parasympathetic mechanism has been depressed by *atropine*, and to be greater in those with natural or induced hypersusceptibility of the parasympathetic (Garrelon *et al.*, 1922; Arloing and Langeron, 1922).

"*Hemoclastic Crises.*"—This term was applied by Widal to a clinical syndrome produced by the injection of peptone, by other active colloids, and by anaphylactic reactions. It consists in leukopenia followed by leukocytosis, diminished coagulability, fall of arterial pressure and lowered refractive index of the blood.

Blood Coagulation.—The direct addition of peptone to blood does not affect coagulation; but intravenous injection generally renders the blood noncoagulable. This is due to an antithrombin, the blood containing all the necessary elements for coagulation, so that it clots, *e. g.*, on simple dilution with water. This antithrombin seems to be nucleoprotein formed in the liver (Denny and Minot, 1915). Its production is not increased by bile, bile salts, secretin or electric stimulation. R. J. Lee and Vincent, 1915, attributed the noncoagulability of the anaphylactic blood mainly to an anomalous behavior of the blood platelets.

Effect on Hemorrhage.—Bleeding from superficial vessels is rather increased by the local application of peptone. Intravenous injection may diminish hemorrhage, parallel to the fall of blood pressure (Hanzlik, 1918). Peptone does not agglutinate red corpuscles *in vitro* (Karsner and Hanzlik, 1920). Injections of Witte's peptone were proposed for the treatment of hemophilia, but caused fatal hemorrhage (Leceboullet and Vaucher, 1914).

Lymphagogue Action and Blood Concentration.—Peptone and other shock-producing poisons alter the capillaries so as to produce loss of blood plasma with increase of blood concentration and of lymph flow.

Lesions.—Broughton, 1919, after intraperitoneal injections of Witte's peptone into guinea pigs, describes inflammatory lesions in the liver, heart and kidneys, similar to those produced by other foreign proteins.

Febrile Reaction and Leukocytes.—Intravenous injection of vaccines or foreign proteins is followed by a chill, fever, muscular and joint pains, sweating and a characteristic leukopenia (about the second hour), followed by leukocytosis (fourth hour to several days), sometimes of marked degree (Gow, 1919). The *leukocytosis* is probably associated with the pyogenic reaction, but is not proportional to it. It is chiefly polymorphonuclear. In distinction from anaphylaxis, there is no eosinophilia.

Modified Response to Autonomic Poisons.—Injection of peptones and other proteins, such as milk and sera, and also cholesterol and other colloids, *f. i.*, colloidal metals, modifies the sensitivity to autonomic poisons. Direct addition of peptone to a pilocarpine solution diminishes the augmentor action of the latter on excised intestine (perhaps by adsorbing the pilocarpine), but if the intestine is treated first with doses of peptone that are inactive in themselves, they respond more strongly than normal to the subsequent application of pilocarpine (van Leeuwen and van den Broeke, 1920). In intact animals peptone injections are followed by increased responsiveness of the peripheral autonomic system, for instance to epinephrine and pilocarpine, and this "allergy" persists for a considerable time (Freund and Gottlieb, 1922). Doelken and Herzger, 1922, claim that milk and serum injections modify also the response to strychnine, nicotine, morphine and the like. Gautrelet reports that the injection of peptone (or colloidal silver and other colloids, to a smaller degree), prevents the synergistic hypotensor effect of nigrosine and thionine.

Peptone Injections against Infective Fevers.—Intravenous injection of peptone, in proper dosage, tends to bring on a prompt crisis in various infective fevers and may thus shorten their natural duration. The same result is secured by the intravenous injection of other agents that produce similar reactions—nonspecific bacterial vaccines (for instance, typhoid) or filtered cultures; colloidal metals, and so forth. This treatment has been employed most extensively in acute rheumatic fever. The clinical relief is generally prompt and considerable. Occasionally, however, the reaction is dangerous. The method is not sufficiently safe for promiscuous use.

Nonspecific Protein Therapy.—According to the review of Cecil, 1935, F. Torres was the first to report successful results in the treatment of typhoid fever by intravenous injection of typhoid vaccine. This produced a sharp febrile reaction, followed by improvement. Kraus, Penna and Bonorino, 1917, obtained similar results in typhoid fever by the injection of colon bacillus vaccine, showing that the response is not specific. Lüdke, 1915, also obtained the reaction and improvement by intravenous injection of proteoses, and R. Schmidt, 1916, by intramuscular injection of boiled milk. Various proteins, native and split, are now utilized, as also artificial infection with malaria. The *agents chiefly used* in America are (1) *Cow's Milk as Foreign Protein.*—Sterilized skimmed cow's milk has been used for foreign protein therapy, 5 to 20 cc. injected intramuscularly every day or every second day, generally for three doses. The *reactions* are similar to those of peptone or other colloidal injections: fever (maximum temperature in six to eight hours); sweating; headache; marked local pain, often lasting many hours, but no abscess formation. This "milk disease" differs from "serum disease" by its prompt onset, and by the usual absence of arthralgia and of rashes. Repeated injections of the milk at unsuitable intervals may result in true anaphylaxis (Casson, 1919). The therapeutic use is reviewed by R. L. Cecil, 1935. (2) *Bacterial vaccines*, generally typhoid, diluted with normal saline, intravenously; initial dose, ten to twenty-five million killed bacilli. (3) *Peptone* is adminstered as 10 per cent sterilized watery solution. This is injected intravenously, taking three to five minutes to inject 10 cc. and observing at the same time the pulse and face of the patient. The same dose may be injected subcutaneously. If the first injection is well borne, 10 cc. of 10 per cent solution are again injected on the next day. If the peptone solution enters the tissue around the vein, painful inflammation is likely to result. Intramuscular injections are also followed by considerable pain. Cardiac diseases contraindicate all foreign protein therapy (Nolf and Depage; Jobling). *Excessive reactions* occur if the injection is too rapid or the peptone too active. They resemble anaphylactic shock and consist in marked tachycardia (increase of 30 to 40 per minute), cyanosis, with air hunger, violent headache, nausea, vomiting. They are usually of short duration. Should they occur, epinephrine, 0.5 mg. to 1 mg., may be injected and repeated as needed (Nolf).

Peptone Injections against Allergy.—Since peptone injections tend to prevent anaphylactic shock in animals, they have been tried to desensitize patients subject to bronchial asthma. Good results have been reported also for other nonspecific protein therapy, but they are uncertain (Samter, 1933).

Wound Repair.—Roulet, 1926, claims more rapid healing if 3 per cent aqueous solution of Witte's peptone is injected around the wound.

TISSUE EXTRACTS WITH HISTAMINE-LIKE ACTIONS

Extracts of practically all tissues, but especially of glands and smooth muscle, produce histamine-like or peptone-like effects: stimulation of smooth muscle and glands and fall or rise of blood pressure. Intravenous injection or direct contact are usually required to produce a response. Popielski, 1913, named these principles "*vasodilatin.*" This implies a chemical identity that has not been established. The reactions correspond closely to those of histamine, often with an admixture of choline actions. Both have been isolated, for instance, from lung extracts (Best, Dale *et al.*, 1927) and may suffice to account for the effects. However, other substances may participate: Adenosine derivatives are present in rather large amounts in extracts from traumatized muscle. Felix and Putzer-Reybegg, 1933, reported isolation from mesentery of a crystalline organic depressor base, unidentified but possibly related to guanidine. Inorganic constituents may also play a part: expressed heart juice, *f. i.*, depresses cardiac activity, simply by its potassium content (Macleod, 1907).

Saline liver extract, injected intravenously, produces a fairly persistent fall in blood pressure, analogous to a histamine or a histamine-choline mixture (Burnett, 1926). R. H. Major, 1925, found it effective, intravenously, against experimental guanidine hypertension. It was tried clinically in hypertension and lowered the systolic and diastolic pressure, but about a fourth of the patients showed "reactions" of varying degree and of the usual anaphylactoid type (MacDonald, 1923). A purified extract which does not give chemical protein reactions was prepared by James, Laughton and Macallum, 1926.

Spleen extract stimulates smooth and cardiac muscle similarly to histamine ("*Lienin*") (Rothlin, 1920). Zuelzer, 1908, 1912, introduced an acid extract, "*Hormonal,*" to be injected against intestinal paresis, but its effects were uncertain and sometimes dangerous, even fatal (Hesse, 1913).

The "vasodilatin" of defibrinated blood was studied by Zipf and Wagenfeld, 1930.

Urinary "Hypotensin."—The intravenous injection of urine causes marked fall of blood pressure, similarly to peptone. The properties of a concentrate are described by E. K. Frey and Kraut, 1928.

◆

ALLERGIC PHENOMENA

These present a complex of effects essentially identical with those of histamine and peptone, *i. e.*, stimulation of smooth muscle, and especially bronchial constriction; paralysis of the capillaries with fall of blood pressure and edematous infiltration; hemagglutination; and their secondary consequences. The resemblance is so strong that it points to the fundamental identity of these processes, the differences consisting essentially in the conditions that evoke the effects, rather than in the effects themselves.

The allergic phenomena may be grouped as true anaphylaxis; serum disease; spontaneous hypersusceptibility (food proteins, pollen and bacterial proteins, drug idiosyncrasies); traumatic shock, burns, neurotic edemas; and the anaphylactoid reactions to intravenous injections of colloids, colloidal precipitants, and probably every kind of solution. It is evident that these agencies differ widely in their chemical properties and reactions, and that the allergic effects are quite different from the ordinary actions which these same substances produce by other methods of administration, or in the absence of hypersusceptibility. The allergic reactions therefore seem to depend on something more widespread and less specialzed and more fundamental than the distinctive chemical properties

It has been suggested that the allergic phenomena result from a disturbance of the equilibrium of the colloids, presumably in the direction of a partial condensation, which would tend to alter the surface tensions and to diminish the permeability of cell surfaces, and thus lead to changes in the distribution of water, solutes, and energy. The degree, the rapidity, even the distribution of these changes, and their secondary consequences, would vary and thus account for the differences that relieve the basic uniformity of the allergic reactions. This attractive theory can furnish a plausible explanation for practically all allergic phenomena, but it has not been established by adequate evidence. On the other hand, the differences that exist, according to the conditions that bring about the reactions, are of so much practical importance that it appears advisable to arrange the details under these conditions. An extensive bibiography of allergic phenomena of pharmacologic importance is given by Hanzlik, 1924.

TRUE ANAPHYLAXIS

Parenteral injection of native proteins sensitizes animals specifically, after an incubation period, so that they react violently to a further injection of the same protein; and the excised tissues of such animals are specifically hypersensitive to the sensitizing protein. If the animal recovers from the attack, it is desensitized, *i. e.*, it ceases to respond to further injections. This protection (antianaphylaxis or anergy) is lost in time; as is also eventually the susceptibility of the sensitized animals. The characteristics of true anaphylaxis are its dependence on specific sensitization, with an incubation period; the sensitization of excised tissues; and the relative violence of the reactions. The phenomena of anaphylactic shock differ from those of histamine chiefly by the absence, in the latter, of the changes of temperature, of blood coagulability and of the refractory state (Karsner). These may have little to do with the "shock," but may rather be collateral phenomena.

Historical.—Anaphylactic phenomena were described by Magendie in 1839, and rediscovered by von Behring, 1892; Richet (who coined the name); Theobald Smith, 1903; and von Pirquet, 1905. Their modern investigation dates from Otto, 1905, and Rosenau and Anderson, 1906. The term "*allergy*" (meaning "altered reactivity") was suggested by von Pirquet and Schick, 1906, for the symptoms in man, following a second injection of horse serum, especially the more rapid onset of serum disease.

Production of anaphylaxis results from the parenteral introduction of all "antigens," *i. e.*, all true proteins, but not from their cleavage products, proteoses, leucine, and the like (Gay, 1913); nor from gelatin; nor from lipoids, and so forth. *Artificial polypeptids* (to heptaglycylglycin) do not produce anaphylaxis (Abderhalden and Weil, 1920).

Sensitization occurs with exceedingly small doses as little as 0.000,000,05 mg. of egg white) intravenously or hypodermically, and exceptionally even by stomach or large intestine, or through the nose (Sewall, 1914). A minimum interval of six to ten days elapses before the sensitiveness is acquired; but then it persists for a long time, weeks or years. Repeated injections during the incubation period may produce immunity. The maximum degree of sensitization is practically independent of the dose of the sensitizing injection; but curiously, the maximum is reached more rapidly with small than with large injections; for instance, in guinea pigs with 0.004 cc. than with 0.1 cc. of horse serum (O. Thomsen, 1917) Injection of the serum of sensitized animals confers *passive sensitization* on the recipient (Otto); immediately, with proper dosage (Doerr and Russ). The **provocative injection** must be considerably larger than the sensitizing injection. It is much more effective by vein. The response is immediate. If an animal recovers from the toxic effects it becomes immediately refractory or immune to further injection, because the anaphylactic antibodies are saturated or exhausted (Weil and Coca, 1913). This *antianaphylaxis* (anergy) persists for a time, but is eventually lost. The animal again becomes hypersensitive, and this hypersusceptibility may last for years. **Desensitization** consists in inducing antianaphylaxis by the injection of doses so small that they do not provoke shock. Insusceptibility also occurs if the injections are repeated at intervals of two or three days before the sensitization has developed. This so-called *refractory state* may persist for long periods.

Susceptibility differs markedly in individuals and in species. *Man* seems to be relatively insusceptible. The rare acute accidents in the injection of antitoxic sera, serum disease, and some varieties of asthma and hay fever (Meltzer, 1910) are probably anaphylactic manifestations. *Guinea pigs* are especially susceptible to the respiratory effects, the small lumen of the bronchi being closed by even slight spasm of the bronchial muscles, leading to pulmonary emphysema and asphyxial death in a few minutes (Auer and Lewis, 1909). In *dogs* and *rabbits* this phenomenon is much less marked, the severe and prolonged fall of blood pressure being the most prominent feature. Death may occur, however, by bronchial constriction (Pelz and Jackson, 1918). *Cats* are rather difficult to sensitize. White rats are peculiarly tolerant to anaphylaxis and to histamine (review, C. A. Dragstedt, 1941).

With *white rats*, the second injection of serum must be made within twenty-one days, else the sensitization fades. Acute death is respiratory, but increased capillary permeability is more prominent than muscular spasm. If death is delayed, marked congestion and hemorrhages predominate (J. T. Parker and Parker, 1924). Rats must be at least ten weeks old before they are suitable for anaphylactic experiments. If they are poorly nourished, they cannot be sensitized to anaphylaxis (Weld and Mitchell, 1941).

Share of Tissues in Anaphylaxis.—Anaphylactic sensitization involves mainly the tissues, rather than the circulating blood. Excised and blood-free organs of sensitized animals are highly susceptible to the sensitizing protein (Schultz, 1910); and a sensitized dog transfused with normal blood exhibits immediate anaphylactic shock when the antigen is injected; while a nonsensitized dog transfused with sensitized blood shows no immediate effect when the antigen is injected (Pearce and Eisenbrey, 1910).

Response of Excised Sensitized Tissue.—Foreigln serums generally stimulate the smooth muscle of norma (nonsensitized) animals; but the muscles of sensitized animals respond to much smaller doses of the sensitizing serum, while their reaction to other serums remains unchanged. Dale, 1913, showed that the excised uterus of sensitized guinea pigs is contracted by extreme dilutions of the specific antigen; the production of the hypothetical toxic substance must therefore occur directly in the sensitized tissue. One dose of the antigen desensitizes the excised uterus to further doses (but not to normal serum). The antigen therefore destroys the hypersusceptibility of the sensitized muscles. The persistence of the normal reaction to normal serum is further proof that this is quite distinct from the anaphylactic response. Prolonged contact with serum of a sensitive animal again renders the uterus sensitive (passive sensitization); but a normal utrrus can not be passively sensitized. If the muscle is eerfd from tissue lymph and other diffusible elements by repeated centrifugation in Locke's solution, the sensitiveness is greatly decreased; it is quantitatively restored if these muscles are treated with normal guinea pig serum. This indicates that some constituent of normal serum is essential to anaphylactic stimulation. Direct reactions of the tissue with the antigen have also been observed in the liver (Weil, 1917) and lungs (Manwaring and Crowe, 1917).

The symptoms of anaphylactic reaction are mainly: Great restlessness; severe fall of blood pressure and consequent shock; fall of temperature (Pfeiffer and Mita, 1910); rigidity of the lungs by violent contraction of the bronchial muscles, resulting in respiratory distress and asphyxial convulsions; stimulation of other smooth muscle (uterus, stomach and intestines); hemorrhagic enteritis; diminished coagulability of the blood (Weil, 1917); increased concentration of the blood, appearance of nucleated reds, and changes in the leukocyte ratio (Richet *et al.*, 1919); leukopenia; eosinophilia; loss of complement; increased lymph flow (Calvary, 1911); local inflammatory reaction.

Repeated anaphylactic shock results in cell destruction in several organs, with subsequent chronic inflammatory changes. In the liver, the results resemble the effects of portal cirrhosis. Analogous but less severe *parenchymatous degenerations* of the myocardium, liver and kidneys may occur in rabbits after a *single injection* of a large dose of horse serum or egg albumen. They develop in ten to twenty-one days, about the time when the antibodie are produced (Longcope, 1921).

Lung Rigidity.—Auer and Lewis, 1909, showed that in guinea pigs dying acutely of anaphylaxis the lungs are rigidly distended and incollapsible even after death, by tetanic contraction of the bronchial muscles. The effect occurs after destruction of the central nervous system and after degeneration of the vagi (Auer, 1910). Schultz and Jordan, 1911, showed that the severity of the bronchial phenomena in guinea pigs is explained by their relatively thick mucosa; so that the contraction occludes absolutely even the larger bronchi. Other animals are generally even more susceptible to the bronchial spasm, but its fatality is not so high. Bronchial spasm is also produced on *excised lung*, perfused either through the vessels (Manwaring and Crowe, 1917) or through the trachea (Warnant, 1929), and may be observed microscopically on *lung sections*. These show that the contraction passes off spontaneously if the sections are left in the solution and cannot then be provoked by further addition of the antigen. It is antagonized by epinephrine or atropine (Sollmann and Gilbert, 1937). In *perfused lung*, atropine, epinephrine and ephedrine are moderately effective (Warnant, 1929); and these and nitrites also in intact animals (Pelz and Jackson, 1918; Barlow and Beams), but their efficiency is limited. Roux and Besredka, 1908, claimed that ether anesthesia antagonizes anaphylactic shock in guinea pigs, but all subsequent workers have been unable to confirm this (C. A. Dragstedt, 1935); nor does chloroform relax bronchial contraction in lung sections (Sollmann and Gilbert, 1937). Rosenau and Anderson, 1909, found chloral uncertain in guinea pigs, which probably means ineffective.

Other Pulmonary Effects.—The airway is also obstructed by *acute congestion and edema of the mucosa*, which is quite conspicuous in the larynx. Excised *pulmonary artery* is markedly constricted by addition of the antigen, in contrast to carotid artery which is not contracted (Sollmann and Gilbert, 1938). Coca, 1919, reported the pulmonary circulation of intact guinea pigs unobstructed; but with rabbits dying acutely from anaphylaxis, the pulmonary circulation is almost impermeable to saline, even under pressure several times greater than exists in the pulmonary artery during life. Arrest of the pulmonary circulation would be the immediate cause of death. Coca attributes this to vascular spasm, rather than to plugging by thrombi or agglutinated corpuscles, as had been suggested by Manwaring and Crowe, 1917.

Experimental Asthma by Inhalation of Antigenic Dust.—Guinea pigs so exposed for five to seven hours may develop regional sensitization; subsequent exposure produces marked but more or less extensive regional reactions resembling clinical asthma, without developing antianaphylaxis (B. Ratner, 1939).

Blood Pressure.—In guinea pigs the circulatory changes are mainly asphyxial (Auer and Lewis, 1910). In other animals there is severe fall of blood pressure, often to 20 to 30 mm. Hg. The mechanism of this "anaphylactic shock" has not been conclusively demonstrated, but is presumably the same as with the analogous histamine fall, *i. e.*, direct relaxation of the capillaries. The blood accumulates mainly in the large veins, especially of the liver and portal system, so that the smaller vessels of the kidneys, intestines and other parts of the body are mechanically drained (Edmunds, 1913); indeed, the fall does not occur if the liver has been excluded from the circulation. The liver therefore has a predominant share, directly or indirectly, in the fall. The vasomotor center is not directly involved. The arterioles or veins continue to contract to epinephrine or barium.

Cardiac Disturbances.—The heart suffers by the low blood pressure and is affected directly, although this usually plays a minor part in the "shock." Electrocardiograms show disturbances of conduction and abnormalities of ventricular contraction, affecting especially the right heart. These may progress to final rigor (Auer and Robinson, 1913). The heart muscle and diaphragm show histologic changes; also with other anaphylactoid agents (Kundratitz, 1913). The isolated heart of sensitized animals is directly poisoned by the antigen (Cesaris-Demel, 1910–1912). Acute heart failure is sometimes seen in intact cats (Edmunds, 1914).

Treatment of Anaphylactic Hypotension.—The continued low blood pressure furnishes an opportunity for investigating treatments of shock. The indications are to relieve the splanchnic congestion and to increase the volume of blood to the heart and medulla. Pearce and Eisenbrey, 1910, found that venous transfusion with blood or saline only increases the splanchnic congestion without aiding the heart or medulla. Cardiac or vascular stimulants alone did not produce permanent improvement; but the combination of slow epinephrine infusion with digitoxin gave good results. J. P. Simonds, 1916, found but little pressor response to epinephrine in anaphylactic or peptone shock. Ephedrine also has only a limited success (Chen and Schmidt); pituitary is practically useless. Mautner and Pick, 1915, reported good results from the vasodilator action of nitrites or caffeine.

Physical changes in plasma have been described: flocculation of the plasma colloids, lowering of surface tension of serum, increase of refractometric index of plasma. Flocculation has been demonstrated *in vitro* by incubation of the serum of a sensitized animal with an antigen (Opie, 1923).

The **uterus** is highly responsive to anaphylactic stimulation in most animals. It is not greatly sensitive in rats (Parker and Parker, 1924). The **urinary bladder** is stimulated in guinea pigs, not in rabbits (Manwaring and Marino, 1926).

Localized sensitization, increasing local irritation from repeated local injections of an antigen, constitutes the *Arthus hypersensitivity reaction* (review, A. R. Rich, 1941).

The **susceptibility to autonomic drugs** is not altered by anaphylactic sensitization, in the case of bronchial muscle (Sollmann and Gilbert, 1937) and other organs; except that the guinea pig heart is more responsive to choline (J. Martin and Went, 1939). The anaphylactic state appears to increase the *susceptibility to nonspecific irritants.* When xylene (1 cc.) is rubbed on the ear of normal rabbits it is merely rubefacient; but when the animals have been injected with subsymptomatic doses of an antigen (sensitizing and provocative), xylene produces vesication and eschar (Auer, 1920).

Mechanism of Anaphylaxis.—Since a sensitizing injection of antigen and a following incubation period are necessary to anaphylaxis, change must occur in the body, resulting in the production of the specific antibody which reacts with further injection of the antigen. The identity of the responses indicates that whatever the nature of the antigen, the resulting process is identical. It has been conceived as due to a definite substance, the "*anaphylotoxin*" of Friedberger, 1910, perhaps a product of protein cleavage by a defensive proteolytic enzyme acting somewhat analogous to trypsin (Rocha e Silva, 1941). Since blood-free tissues are highly reactive to the antigen, this substance would need to be formed in each reacting cell. C. A. Dragstedt (review, 1941) showed that *histamine, heparin* and possibly choline are liberated in the tissues, especially the liver, and given off into the blood; the heparin accounting for the noncoagulability of the blood, the histamine for most of the other effects. However, the reaction of agglutinins and precipitins suggests the formation of a deposit of antibody-proteins, specifically modified plasma globulins, on the antigenic surface of the cells (review, P. R. Cannon, 1940). This is in better harmony with the older flocculation theory of Dale and Lumiere, that the anaphylactic phenomena result from the alteration of cell permeability by flocculation or precipitation of the antigen by the antibody, on or within the tissue cells. The antigen-antibody reactions are explainable as chemical *approximation reactions*, such as electronic van der Waals attraction; the *specificity* arising from structural complementariness which permits such close contact of the molecules that weak forces become operative. This explanation is practically that of the Ehrlich lock and key analogy (review, Pauling *et al.*, 1943).

Relative Share of Blood and Tissues.—In passive anaphylaxis the degree of reaction is usually small or even absent if the antigen and antibody are injected simultaneously, and when they would therefore seem to have the best chance of interacting in the blood. The severest reactions occur if the antigen is injected twelve to twenty-four hours after the antibodies—when, in fact, the antibodies have largely disappeared from the blood and are presumably fixed in the tissues. This makes it probable that the reaction occurs more effectively in the tissues than in the blood. There is direct evidence that the union of antibody and antigen is relatively slow in the blood stream; for they may exist there simultaneously and ununited, for days, combining slowly *in vitro* if the blood is removed. This suggests the presence in the blood stream of some inhibiting substance or conditions, such as are common in colloid reactions. It is known that antireactions are inhibited by excess of either antibody or antigen.

Nonspecific Sensitization.—Thienes and Hanzlik, 1926, found that the reactions of smooth muscle are greatly modified by previous treatment with a wide variety of colloids or colloid precipitants.

Treatment of Allergic Intoxication.—The hypodermic injection of epinephrine (1 mg. for man) tends to relieve the bronchial spasm and the edemic phenomena. If it fails, little else can be done, especially if the blood pressure has fallen to shock level. The chief treatment should be prophylactic; the recognition of hypersusceptibility by skin tests; and, if necessary and feasible, desensitization.

Anesthesia on Anaphylactic Response.—General anesthesia by ether is somewhat protective for guinea pigs (A. R. Koontz and Shackelford, 1939), as also urethane and chloralose; but desensitization occurs even when there are no symptoms (L. Farmer, 1937). The mitigation is probably due chiefly to prevention of the release of histamine from the tissues (G. Katz, 1940); but the response to histamine is also diminished by these anesthetics (G. Katz, 1929; Farmer, 1939). Various histamine antagonists (see Index) are being tried.

Injection of *potassium salts* with sheep serum definitely decreases anaphylactic fatality in sensitized guinea pigs. Sodium and thiocyanate ions have no effects (R. G. Carlson and Whitehead, 1943).

ANAPHYLACTOID HYPERSENSITIVITY

This title covers a group of conditions formerly classed as "idiosyncrasies" or "dyscrasias." The subjects respond to small quantities of special substances by more or less violent symptoms of the anaphylactic type, but occurring without antigen sensitization. Accidental sensitization can not be excluded in every case of protein reactions; but the spontaneous reactions are generally distinctive, and many are produced by substances that are not antigens. The following conditions may be counted in this group: asthma, hay fever, serum disease, serum collapse, food idiosyncrasies, urticaria, erythema, eczema, angioneurotic edema, drug idiosyncrasies, "nitritoid" crises. The sensitivity may be *hereditary; i. e.*, there is generally a family history; but it may not become manifest until later in life. It is often not so narrowly circumscribed as true anaphylaxis; *i. e.*, the patient is often hypersensitive to several factors, and one susceptibility may give way to another, from time to time. The serum does not contain specific antisubstances; nor can the susceptibility be transferred by injection of the serum. The subjects can be desensitized, locally or systemically, by graduated injections; but the desensitization is of short duration.

Skin Test of Hypersensitivity.—The human skin is highly sensitive to the capillary poisons and therefore furnishes a useful index of allergic hypersensitivity. Its diagnostic importance in the eruptive fever rests on a similar basis. It is not improbable that this extensive sheet of epithelial cells and the related mucous membranes play an important part in defense reactions.

The specific responses of the skin to local inoculation are of two types, but the difference between them is probably mainly one of degree (Strickler, 1922). (*a*) The urticarial reactions produced by histamine, peptone, and the like; and by the substances to which the subject is hypersusceptible. They consist mainly in edema, with a little erythema and itching, all of short duration. (*b*) Those indicating the presence of an infective agent in the body; for instance, the tuberculin tests. These are accompanied by cellular reactions and are more or less persistent. The skin reactions are a qualitative, but not quantitative, index of hypersusceptibility; *i. e.*, the degree of the systemic reaction is not always proportional to the degree of the skin reaction (Caulfield, 1921). However, in the same individual, changes in susceptibility, for instance, by desensitization, are fairly paralleled by the skin test. The skin may also be desensitized locally (Mackenzie and Baldwin, 1921); but not in the nonspecific urticarias of histamine, and so forth (Sollmann).

Allergenic preparations of N.N.R. are extracts or solutions of substances to which patients may become sensitive. They are used for diagnosis, prophylaxis and treatment; for instance, of pollen asthma.

DRUG IDIOSYNCRASIES

A number of drug idiosyncrasies show striking correspondence with the distinctive characteristics of allergic reactions in general: (1) The possibility of desensitization, which has been described for several of the reactions, but not for all. (2) The idiosyncrasy phenomena do not resemble the ordinary effects of the drug, but belong to the allergic type: urticaria and acute edema of the mucous membranes, asthma, skin eruptions and catarrh, collapse. (3) Very small doses are effective. (4) The hypersusceptibility does not extend to the ordinary actions; for instance, idiosyncrasy to quinine or acetyl-salicylic acid does not increase their analgesic and antipyretic action. The idiosyncrasy may be present on the first use of the drug, or it may develop later.

Drug idiosyncrasies may be arranged under the following types: some of these probably do not belong to the "idiosyncrasy" class, but it seems impossible at present to draw a sharp line. Type 1. *Urticarial* (skin or mucous membranes): quinine, acetyl-salicylic acid, morphine, etc. Quinine and acetyl-salicylic acid can be desensitized. Type 2. *Plant Dermatitis:* Primrose, Ivy, etc. Desensitization reported. Type 3. *Acquired susceptibility to Dermatitis:* procaine? Type 4. *Iodism and Bromism:* variable susceptibility, depending probably on associated irritations. Type 5. *Nitritoid Reactions:* arsphenamine, usually after several injections: dyspnea, cyanosis, suffusion of face. Type 6. *Sympathetic Collapse:* cocaine group, epinephrine. Type 7. *Retinitis:* atoxyl, optochine, aspidium. Type 8. *Hepatitis:* chloroform, phosphorus, arsenic, aspidium.

Sensitization with simple chemical compounds has been reported for arsphenamines, but others were not able to reproduce the results. It has also been reported for primulin and poison ivy (Rackemann and Simon, 1934). Landsteiner and Jacobs, 1935, succeeded in sensitizing guinea pigs to chlorodinitrobenzene, trinitrobenzene and a considerable number of simple benzene derivatives, but a number of closely related substances were negative. Most of the positive substances produce local irritation, and they incline to the belief that some protein compound is produced and that the sensitization is to the denatured protein component (Landsteiner and Chase, 1940). Passive transfer of human hypersusceptibility has been reported to guinea pigs (Bruck, Klausner) for iodine and iodoform and also for diphenylendiamine, but further confirmation is desirable.

"REACTIONS" TO INTRAVENOUS INJECTIONS

The physical conditions and especially the colloid equilibrium of the blood are disturbed by any sudden alterations in its composition, and consequently the intravenous injection of a considerable variety of substances produces anaphylactoid phenomena. Even normal saline solution and transfused blood may produce some "reaction." The degree of disturbance and the violence of the symptoms vary with the nature of the substance, the speed of the injection and the susceptibility of the individual. Generally there is only a brief fall of blood pressure or "nitritoid reaction," or chill; but there may be violent asthma and asphyxial death. As it is not possible to predict the degree of reactions, all intravenous injections imply some risk. Even the milder reactions are undesirable side effects that complicate the therapeutic actions, except in the relatively few instances when they are evoked intentionally.

The *phenomena of intravenous reactions* resemble those of histamine and differ from the ordinary pharmacologic actions of the substances, if these are otherwise active. They generally have little or no action on excised organs, which consorts with the view that the primary disturbance is in the colloidal condition of the blood. They occur without incubation and are not transferable. Hypersusceptibility plays a large part in some, a small part in others. The details of the effects vary with the agents and with conditions, but the difference is in degree more than in kind. The literature is reviewed by Hanzlik, 1924.

Symptoms in Man.—Those of the milder type bear a superficial resemblance to the response to nitrites, and have therefore been called "*nitritoid crises,*" although their mechanism is probably quite different. They consist in excitement and anxiety, flushing of the skin, sweating, precordial distress, tremors, cough and dyspnea; vertigo, headache, nausea, vomiting; chill and fever; joint pains. The serious cases rapidly develop intense asthma, cyanosis, fall of blood pressure, collapse and asphyxial death. The sudden deaths are more commonly caused by colloids and toxins, injected by vein, and sometimes even hypodermically. They are reviewed by Lamson, 1924. The phenomena in animals are essentially similar (Hanzlik, 1924). *Pulmonary distention* is generally present in the fatal cases, at least in animals. Bronchial spasm, however, plays a minor share. More commonly the bronchial stenosis is the result of pressure from pulmonary or peribronchial edema, or from obstruction of the vessels by agglutinated corpuscles or platelets; and in the case of agar, by the coagulated colloid. The type of the bronchial obstruction is rather characteristic of each agent. The *fall of blood pressure* may be due partly to capillary injury, as with histamine; but as edema is generally not very marked, it is probable that other factors are more important, especially the obstruction of the pulmonary circulation by the agglutination. It is conceivable that the heart muscle is also disturbed directly. *Blood changes:* Agglutination of the corpuscles and especially of the platelets is a frequent condition; the carbohydrate colloids produce it even *in vitro* (Karsner and Hanzlik, 1920). The coagulability of the blood is generally diminished and the surface tension is altered.

Causative Agents.—Flocculation of colloids in the blood may result from any agent that tends either to precipitate, or to be precipitated by, blood. The substances reported to produce these effects may be grouped according to their physical characters: (1) *Colloidal Suspensions:* Bacteria and other micro-organisms and vaccines (including faulty distilled water), barium sulfate, camphors, carbon (india ink), fuller's earth, kaolin, oils, resins, etc. (2) *Suspensoid Colloids:* Colloidal metals and metal oxides, arsenous sulfide, dialyzed iron, gold, silver, etc. (3) *Carbohydrate Emulsion Colloids:* Acacia, agar (gelose), pectin, starch, tragacanth, etc. (4) *Proteins:* All kinds more or less. (5) *Toxins.* (6) *Dyes of More or Less Colloidal Character:* Congo red, gentian violet, mercurochrome, etc. (7) *Precipitant Agents:* Acids, formaldehyde, metallic salts, tannin, etc. (8) *Precipitable Substances:* Arsphenamine, especially acid; barium salts, etc. (9) *Crystalloids:* Bromides, iodides, and especially hypertonic solutions; methenamine, glucose, sodium chloride, sucrose, etc.

NORMAL SERUM

In the process of clotting and by changes in the formed elements, serum acquires the property of stimulating smooth muscle. It also provokes other anaphylactoid reactions and may cause true anaphylaxis. Blood serum contains the elements required in the clotting of blood

Its injection sometimes appears to be effective in controlling persistent bleeding in hemophilia, severe anemias, purpura and the like (Weil, 1907). The results, however, are inconstant. There are the same after-effects and dangers as with antitoxic sera: and these dangers must be taken more seriously, since the benefits are more problematical.

Administration as Hemostatic.—Normal horse serum is injected hypodermically, 10 to 20 cc.; the results are said to appear in twelve to twenty-four hours and last one to three months (Richardson, 1908). The intravenous injection of *human serum* or, better, of human blood, is often more effective (Ottenberg and Libman, 1915). In hemophilia, it increases the prothrombin (Addis, 1916).

Smooth muscle is stimulated (Schultz, 1912), as by peptone or histamine, but there are specific differences (Dale, 1913). The proteins of the serum constrict the blood vessels, but do not act on the stomach, intestines and uterus: alcohol extracts of serum dilate the vessels and tend to increase the activity of the intestines and uterus (Clark, 1921). A specific *constrictor substance* is formed in shed blood, probably by changes in the formed elements rather than by clotting (G. N. Stewart and Zucker, 1913). Janeway *et al.*, 1918, found that the vasoconstrictor principle is derived from the breaking up of the blood platelets. It is not a protein, but a water-soluble crystalloid. The vasoconstriction may play a part in hemostasis. The principle which stimulates the *intestine* and *uterus* preexists. With *perfused hearts* (rabbits), Cushny and Gunn, 1913, reported that the addition of serum produces a preliminary stimulation, with stronger and usually faster contractions; and subsequent depression with weakened and slowed contractions, sometimes heart block and eventually arrest. The coronary vessels are constricted. Similar effects are produced by the plasma of the operated animal, by starch solution and other agents.

SERUM REACTIONS

Allergic reactions are of common occurrence in the therapeutic use of serums. They vary widely in type, severity, time of onset, and in frequency, depending on the susceptibility of the patients, the dose, the channel of administration, and the repetition of the injections. They fall into three distinct, though related groups, according to the mechanism of their production: (1) spontaneous hypersusceptibility with immediate reactions; (2) responses to repeated injections; and (3) serum sickness, the normal delayed reaction to a single injection.

The *incidence* depends chiefly on the quantity injected, but about 10 per cent of patients are not disturbed even by large doses. Negroes are said to have relatively low susceptibility. The serum of some horses gives more trouble than that of others.

Spontaneous Hypersusceptibility to Serum; Acute Serum Shock.—Occasionally the first injection of serum produces a violent allergic reaction. The phenomena start promptly, shortly after or even during the injection, but sometimes with a delay, up to half an hour. The milder cases react with a few urticarial wheals, itching, apprehension; the more severe, with generalized urticaria, edema of the face, tongue, throat and bronchial mucosa, presumably bronchial spasm; dyspnea and cyanosis; sometimes collapse and more rarely death. This may occur with relatively small doses of any of the serums, crude or refined. Serious symptoms are recorded in something like 1:10,000 injections of antitoxic serums, death in 1:100,000 (Park, 1913). A history of previous allergic tendencies (asthma, hay fever) can generally be elicited (for instance, in two-thirds of the thirty histories of serum death collected by Gillette, 1909). The spontaneous nature of the hypersusceptibility is also indicated by the fact that the reactions are much more violent than the usual responses of normal subjects to repeated injections.

Treatment.—Epinephrine, 1 mg. hypodermically, should be injected on the first appearance of the symptoms. The addition of atropine, 2 mg., is advisable. The prognosis is bad, and safety consists in the use of proper precautions *before* the serum is injected: inquiry for a history of allergic hypersensitivity (asthma, hay fever, food idiosyncrasies). An endermic test should be made if possible. If positive, desensitization should be attempted, although it is much less effective in man than in guinea pigs. In the absence of a skin test, it is advisable as a routine procedure to inject 0.5 cc. of the serum half an hour before the full dose. Atropine may be injected in advance and epinephrine should always be ready (review, Mackenzie and Hanger, 1930).

Reactions to repeated injections of serum correspond to true anaphylaxis. They vary according to the interval between the injections. If the second injection is given before the antibodies are present in the blood (generally about ten days, but varying in the individual), the "refractory state" of anaphylaxis results; *i. e.*, the outbreak of "serum disease" is postponed for about a week; and so on with repeated injections; although in the end the serum disease may develop, sometimes with apparently increased severity. If the second injection is made after antibodies have been developed, *i. e.*, after some ten days, it provokes a more prompt and more violent reaction than that of normal serum sickness, the degree depending on the quantity of antibodies present, and on the amount of antigen introduced at the second injection. The phenomena range from the accelerated development (two to four days) of mild serum sickness, to alarming, but rarely fatal, asthma and collapse immediately, or within twelve to twenty-four hours (Pirquet and Schick, 1905). Local necrosis may also occur. Practically all individuals are sensitized by therapeutic doses of serum; needless injections of serum should therefore be avoided, although the reactions are generally much less dangerous than with spontaneous hypersensitivity. The anaphylactic hypersensitivity and the violence of the reaction decrease with time: severe immediate reactions occur in two-thirds of large injections made within two months; after three months, there is generally only accelerated serum sickness; after a year, generally only normal serum sickness. The endermic test is likely to be positive for years.

Serum sickness constitutes the "normal serum reaction." It sets in after incubation of usually six to eight days, but is sometimes delayed for two or three weeks.

It starts with swelling of the lymph glands and moderate leukocytosis (later leukopenia), skin rashes, generally urticarial or erythematous, and local edemas, rise of temperature, malaise, gastro-intestinal disturbance, headache and arthralgia, water and chloride retention (Rackemann *et al.*, 1916), but without albuminuria; delayed blood coagulation (Shattuck, 1917). It is sometimes preceded by prodromal sensitiveness and slight redness of the skin at the site of the injection. The condition lasts from one to twenty days.

Treatment.—The urticaria can generally be diminished by epinephrine (1 mg., hypodermically). Netter, 1906, claimed that the rashes are less frequent if calcium chloride is administered: 1 Gm. daily by mouth, on the day of injection and on the two following days. The efficiency appears doubtful.

Mechanism.—The serum reaction appears to be due to the interaction of the antibody (precipitin) with the antigen that is still present in the organism; for the time of onset coincides with the appearance of the precipitin in the blood, and with the outbreak the remaining antigen suddenly disappears from the blood (MacKenzie and Leake, 1921), after which the antibodies continue to increase (Longcope and Rackemann, 1916).

◆

SPECIFIC SERUMS, VACCINES AND ALLERGIC PREPARATIONS

The immunologic agents used in diagnosis and treatment form a separate and distinct branch of knowledge and could not receive adequate consideration here. They are therefore omitted.

◆

HISTAMINE ANTAGONISTS

The actions of histamine may be antagonized somewhat selectively by a variety of substances, *benadryl* and *tripellenamide* (*pyribenzamine*) being especially potent. They inhibit the histamine stimulation of smooth muscle and the edema formation, and are useful against allergic reactions, especially urticarial dermatoses, atopic dermatitis, penicillin and sulfonamide reactions, and some other dermatitis. Their effectiveness against hay fever, vasomotor rhinitis and asthma is limited, tripellenamide being apparently more potent. The effect in any case is temporary and palliative, not curative, and they often fail. Both have a high incidence of side reactions, especially sedation and drowsiness, more with benadryl (review, S. M. Feinberg, 1946).

Their potency against histamine and against allergy are not parallel, an argument against the histamine theory of anaphylaxis (W. Jadassohn *et al.*, 1944). The *Fourneau substances 929 F and 1571 F* antagonize histamine stimulation of smooth muscle, but not of gastric secretion (Bourque and Loew, 1942). They are fairly effective, but are too toxic for clinical use. The newer French compounds, *antergan* and *neoantergan*, are chemically related to benadryl and tripellenamide (Feinberg). Various *amino acids* (arginine, histidine, cystine) block the histamine action on excised smooth muscle, but only with large doses which are probably not attained in the body (Rocha e Silva, 1944). These also inhibit anaphylactic contraction of excised intestine (Landau and Gay, 1944).

Benadryl, beta-dimethylaminoethyl benzhydryl ether hydrochloride, "S 51," is reported the most potent of the known histamine antagonists (W. A. Selle, 1946). It also antagonizes acetylcholine, like atropine (E. R. Loew *et al.*, 1946). Intravenous doses which have little direct effect on the *blood pressure* of dogs, inhibit the pressure fall of histamine and of acetylcholine, increase the pressor response to epinephrine, stimulate respiration, decrease duodenal motility, and have no effect on the uterus (Sherrod *et al.*, 1946). *Large doses* cause a sharp fall of blood pressure, arrest of respiration and decreased pressor response to epinephrine, histamine and barium chloride (I. H. Page and Green, 1946).

Benadryl relieves the fatal *bronchial spasm* induced in guinea pigs by atomized histamine (Loew, Kaiser and Moore) and by anaphylaxis; partially the histamine fall of blood pressure and the intestinal spasm of barium and acetycholine. It also antagonizes the secretory stimulation of histamine (E. R. Loew *et al.*, 1946). With intact dogs it is more effective than its dipropyl homolog "S 82" (F. W. Ellis and Newsome, 1946). The blood pressure antagonism to histamine is directly proportional to the dose; the curve suggests that benadryl is adsorbed at the same site as histamine and so competes with it (J. A. Wells *et al.*, 1945), but this lacks direct proof.

Clinically, it is often, but not always, effective against hay fever, acute or chronic urticaria and various spasms of smooth muscle. It may be administered by mouth (50 to 100 mg. one to five times daily) or hypodermically (A. C. Curtis and Owens, 1945). There is a wide margin between the therapeutic and toxic dose, but minor side actions are common: sleepiness, dizziness, dry mouth, nausea, weakness, nervousness, mental lethargy, confusion, rarely neuritis (reports, J.A.M.A., 1947, *133:* 392).

Tripellenamide (*Pyribenzamine*) **Hydrochloride,** N.N.R., pyridyl-benzyl-dimethylethylenediamine hydrochloride, "63 C," counteracts the effects of histamine and anaphylaxis. It potentiates epinephrine against human bronchial asthma (Koepf *et al.*, 1946). It enhances the pressor action of epinephrine and stimulates uterine and duodenal motor activity. In contrast to benadryl, it does not inhibit the acetylcholine fall of blood pressure. It produces analepsis and local anesthesia (Yonkman, Chess *et al.*, 1946). It occurs as white stable crystals, nonhygroscopic, readily soluble in water (130 Gm. in 100 cc.), with practically neutral reaction. It is marketed as tablets of 50 mg. The dosage may start with 50 mg. by mouth, four times daily, after meals. If this is effective, smaller doses should be tried; if it is ineffective, the dosage may be increased progressively to 150 mg. four times daily. Its side actions are similar to those of benadryl. Homologs "2786 RP" ("*antergan*") and "2339 RP" have almost quantitatively identical actions (Sherrod *et al.*, 1946; W. Ramanamanjary, 1944; Bonvallet and Decourt, 1944). W. H. Feinstone *et al.*, 1946, describe the histamine antagonism of a new pyrimidine compound, *hetramine.*

Antispasmodic properties of substituted *phenylpropyl piperdines* are reported by T. J. Becket *et al.*, 1946.

Benzofuranone derivatives (*amethone*) have antispasmodic actions, with a potency for rabbit's ileum of about a tenth that of atropine against acetylcholine, and twice that of papaverine against barium chloride. They antagonize histamine bronchiolar spasm and tend to prevent anaphylactic shock (R. K. Richards, Everett and Kueter, 1945).

Aldehydes, formaldehyde, acetaldehyde, paraldehyde, aldol and acetophenone, in fairly low concentrations, relax histamine contraction of the guinea pig intestines and uterus. Carbohydrate aldoses and ketoses do not share this action (A. I. Kendall, 1927).

Histaminase (marketed as "*torantil*") has been proposed for the treatment of allergy, with the hope of destroying the histamine. The clinical results are equivocal (review, Rackemann, 1940), and it fails to modify histamine shock (B. Rose and Browne, 1941) and anaphylactic shock (A. F. Knoll, 1940). Histaminase (diamine oxidase) is not the only, and perhaps not the principal, agent of histamine destruction in the tissues (B. Rose, Karady and Browne, 1940).

Histamine injections do not result in tolerance. Injection of *histamine-azo-protein* has given questionable results.

◆

BLOOD COAGULATION

Mechanism of Coagulation.—The pertinent facts of blood coagulation may be described in terms of several rather complicated and conflicting theories. Briefly, the coagulation consists in the transformation of the dissolved *fibrinogen* of the circulating blood into insoluble *fibrin* by the action of *thrombin* (fibrin ferment). *Fibrinogen* is an acid globulin, formed exclusively in the liver (Foster and Whipple, 1922). *Thrombin* is not contained in the circulating blood, but is formed from prothrombin by the action of thrombokinase, which requires the calcium ions present in the blood. Thrombin is a protein, probably a hydrolytic cleavage product of prothrombin, perhaps itself a proteolytic enzyme, for it converts 2000 times its weight of fibrinogen into fibrin. Its properties are similar to those of trypsin (J. H. Ferguson, 1943); other proteolytic enzymes, papain and snake venom, may take its place in coagulation.

Prothrombin has the properties of a globulin, composed of two fractions, A and B (A. J. Quick, 1943). Both are formed in the liver (F. L. Munro *et al.*, 1945). The plasma normally contains about 40 mg. per 100 cc. Its activation by thrombokinase appears to consist in cleavage into smaller albumin molecules (Astrup and Darling, 1942). *Thrombokinase* (*thromboplastin, zymoplastic substance*) is a lipoprotein closely allied to cephalin. It is furnished by the disintegration of the tissue elements, blood cells, blood platelets and injured tissue cells over which the blood has flowed. It consists of impure cephalin or cephalin protein compounds. Blood coagulation gives rise to vasodilating substances, apparently compounds of adenylic acid and later to vasoconstricting substances which stimulate smooth muscle (review, A. J. Quick, 1944). *Reinjection of the defibrinated blood* of a rabbit is fatal, but not if it has stood fifteen to thirty minutes. The toxicity is probably due to thrombin (Lenggenhager, 1936). Thrombokinase is inactivated by incubation with plasma (L. M. Tocantins, 1943).

The prevention of intravascular coagulation is attributed to the continuous production of several anti-substances, especially *antithrombin*, associated with the albumin fraction, similar to hirudin, which prevents the action of thrombin on fibrinogen; and *antiprothrombin*, similar to heparin, which holds prothrombin in inactive combination. The addition of citrate or oxalate to shed blood prevents coagulation by inactivating the calcium. *Hemophilia* involves deficiency of thrombokinase, apparently by abnormal stability of the blood platelets (Birch, 1931). *Purpura vera* is characterized by a decreased number of platelets. *Decrease of fibrinogen* occurs in the severe hepatitis of phosphorus or chloroform poisoning, and after repeated bleeding or other blood dilution.

Diagrammatic Synopsis of Blood Coagulation Factors: Fibrinogen + thrombin → fibrin.

Prothrombin + calcium ions + thrombokinase → thrombin.

Thrombokinase = cephalin; brain, lung and tissue extracts.

Antithrombin, hirudin, colloid dyes: inhibit action of thrombin on fibrinogen.

Antiprothrombin, heparin: prevent conversion of prothrombin.

Peptone, anaphylaxis: promote formation of heparin.

Dicumarol: inhibits formation of prothrombin.

Vitamin K, menadione: promotes formation of prothrombin.

Biliary deficiency: prevents absorption of natural vitamin K.

Hepatitis: produces fibrinogen deficiency.

Hemophilia = thrombokinase deficiency.

AGENTS PROMOTING BLOOD COAGULATION

Vitamin K: Naphthoquinone Derivatives.—Deficient income or absorption of this vitamin lowers the prothrombin content of the blood and disposes to hemorrhages and ecchymoses, first observed on chicks, and confirmed in certain clinical conditions, especially in biliary obstruction, since bile salts are necessary to the absorption of the natural substance. The hemorrhagic tendency is promptly remedied by the oral administration of the vitamin, together with bile salts if bile is also deficient.

H. Dam, 1935, noted a hemorrhagic tendency and slowed coagulation time in chicks, due to deficiency of prothrombin, and curable by the administration of certain fat-soluble extracts from putrid fish meals, from liver and alfalfa (Almquist and Stokstadt, 1935; S. A. Thayer *et al.*, 1937). The protective substance, which Dam named vitamin K, is present in other leaves, tomatoes, egg yolk and other foods, so that deficiency is not likely to occur in human diets. Green leaves are probably the richest natural source. It is most abundant in the photosynthesizing parts of plants (review, H. J. Almquist, 1941). It can also be synthesized by bacteria. It has been identified by Dam and Karrer, 1939, by Doisy *et al.*, 1939, and by L. B. Fieser, 1939, as ethylphythyl naphthoquinone, and named *phylloquinone* or *phytoquinone*. Two naturally occurring forms have been isolated, K_1 and K_2. Various *other naphthoquinone derivatives* have the same action; for instance, "*phthiocol*," 2-methyl-3-hydroxyl-1,4-naphthoquinone (Almquist and Klose, 1939); hydroxy naphthoquinone, and especially *menadione, 2-methyl-1,4-naphthoquinone*. which is three or four times more potent than the K vitamin because it is more rapidly absorbed (Ansbacher and Fernholz, 1940). The potassium salt of its disulfuric ester is readily absorbed from the intestines even in the absence of bile, nor do bile salts hasten its absorption (E. D. Warner and Flynn, 1940).

Actions.—Vitamin K and the related naphthoquinone derivatives stimulate the liver to the production of prothrombin, which is used up in forming fibrin. The potency may be *assayed* by the method of Thayer and Doisy, 1938. It counteracts dicumerol if adequate doses are used (Cromer and Barker, 1944). The naphthoquinones, like other quinones, interfere with oxidative chain reactions and are potent bacteriostatic agents for both gram-positive and gram-negative bacilli (Colwell and McCall, 1945). No *toxic effects* are produced in mammals by menadione in doses corresponding to 125 times the maximum clinical dosage per weight (S. Ansbacher *et al.*, 1942). The fatal dose for dogs is 110 mg.; for rabbits, 120 mg.; for mice, 500 mg.: all per Kg. of body weight. Half of this, or prolonged administration, produces marked anemia. High doses cause hyperprothrombinemia (R. K. Richards and Shapiro, 1945; Molitor and Robinson, 1940).

Vitamin K deficiency occurs in adults chiefly through interference with its absorption, when sufficient bile salts do not reach the intestines in obstructive jaundice and biliary fistulas (Quick *et al.*, 1938; Brinkhouse *et al.*, 1938; review, Howell, 1945); in severe intestinal disorders; and to some degree by the use of mineral oil laxatives (Javert and Macri, 1941). Extensive injury of the liver prevents the formation of prothrombin even with ample vitamin K supply and absorption. Prothrombin deficiency cannot be produced in adults by diets poor in vitamin K, since adequate amounts are synthesized by the intestinal bacteria. Sulfonamides interfere with the formation (A. Kornberg *et al.*, 1944). In *newborn infants* the bacterial source is not available until the intestinal flora becomes established. Meanwhile their prothrombin content falls progressively during the first three days after birth (H. N. Sanford *et al.*, 1942). This may be prevented by administering the vitamin or 1 mg. of menadione, either to the mother four to ten hours before parturition, or to the child for several days (Mull *et al.*, 1941); but it is not established that this decreases the incidence of postnatal hemorrhagic conditions.

Clinical Use.—Hemorrhagic conditions are likely to arise when the prothrombin level of the blood falls below a third of the normal. If the fall is due to deficient vitamin K income or absorption, the deficiency may be corrected by administering vitamin K with bile, or the related naphthoquinones. They counteract the prothrombin fall of intensive salicylate administration (R. K. Richards and Shapiro, 1945). They would not be effective against hemorrhagic conditions in which prothrombin is not decreased, such as purpura and hemophilia (review, Snell and Butt, 1939).

Administration.—Menadione, 1 to 4 mg. by mouth (Roads and Fliegelman, 1940), has the advantage that bile is not necessary for its absorption. It may also be administered intramuscularly in oil (Tage-Hansen, 1939), or by vein if necessary (J. H. Olwin, 1941). A single injection of 2 mg. in 20 cc. of isotonic saline keeps up the prothrombic level for at least four days. It may cause brief local pain, but is not toxic and does not injure the liver; the presence of liver damage, however, interferes with its action (J. W. Norcross and McFarland, 1940).

Menadione, 2 mg. daily during the last week of pregnancy, prevents hemorrhagic diseases of the newborn due to prothrombin deficiency.

***Menadione,** U.S.P., 2-methyl-naphthoquinone (menaphthene, menaphthone): a bright yellow crystalline powder, nearly odorless, slightly soluble in water, soluble in organic solvents and in oils, irritating to respiratory tract and skin. The alcoholic solution is vesicant. *Dose,* 1 to a maximum of 2 mg. daily, for not longer than four weeks. In biliary deficiency, bile or bile salts should be administered. *Menadione tablets,* U.S.P.; usually available as 1 mg. *Menadione Sodium Bisulfite,* U.S.P., replacing the 4 oxygen with $OH.SO_3Na$, and containing about 50 per cent of menadione, is soluble in water (1:2). It is used in *Menadione Sodium Bisulfite Injection,* U.S.P., in water for injection. *Dose,* intramuscularly or by vein, 2 mg.; usually available as ampuls of 2 mg. in 0.5 cc. or 4 mg. in 1 cc.

Vitamin K_1, N.N.R., 2 methyl-3 phytyl-1,4-naphthoquinone, is isolated from natural sources or prepared synthetically. Its effect is perhaps more prolonged than that of menadione. It is insoluble in water; soluble in organic solvents and vegetable oils. *Dose,* 4 to 10 mg. by mouth, with or without bile salts.

Phthalic acid has a marked antihemorrhagic effect on rats with ligated bile ducts (Kudriashev, 1943), and lowers the prothrombin time in dogs treated with dicumerol (Jaques and Dunlop, 1945). It does not have vitamin K effects on chicks (H. Dam, 1943).

Cephalin and thromboplastic tissue extracts were introduced to check capillary hemorrhage, by packing with compresses saturated with the solution. Their value is questionable, since the traumatized tissue itself furnishes them in abundance, even in hemophilia. Intravenous injection is dangerous and subcutaneous injection is ineffective. N.N.R. lists several *Brain Extracts* and a *Lung Extract.*

Occurrence.—Cephalin is closely related to lecithin, differing only by a methyl group (Koch and Woods, 1905), but lecithin does not hasten coagulation. Cephalin is widely distributed in the body, so that coagulant extracts can be prepared from all tissues. It is especially abundant in the brain, and "thromboplastins" are generally prepared from that source. Mills believes that the cephalin of other organs is combined with protein into more active "tissue fibrinogen." Such extracts, for instance from fresh lungs, produce intravascular coagulation when injected into the blood stream (Fischl, 1916; Mills, 1919), while cephalin does not produce this effect.

Systemic Phenomena.—*Brain extracts* produce anaphylactoid phenomena on injection, and agglutination of red corpuscles *in vitro;* but pure cephalin lacks these effects (Karsner and Hanzlik, 1920). *Extracts from fresh lung* kill promptly by intravascular coagulation (P. Morse, 1920).

Calcium ions hasten the conversion of prothrombin into thrombin, but changes of calcium ions sufficient to affect this in either direction would be incompatible with life (Crane and Sanford, 1937).

Various substances have been administered by mouth to increase the coagulability of normal blood, in aneurysm and gastric ulcer and other chronic internal hemorrhages. Tainter, Throndson and Richardson, 1939, confirmed that *gelatin* (to 45 Gm. per day), fibrinogen and histidine do not alter the coagulation time.

AGENTS THAT IMPEDE BLOOD COAGULATION

Heparin is the name applied by Howell and Holt, 1918, to a purified liver extractive which prevents the coagulation of blood when a small quantity, less than 1:100,000, is added (W. H. Howell, 1928), or when it is injected into a vein (10 mg. per Kg.). In man, 100 mg. prolonged the coagulation time to three times the original, returning gradually to normal in about two hours (Hartman and Mason, 1924). It is produced and stored by the basophilic mast cells which are scattered generally along the walls of the small vessels, especially of the veins and intercapillary spaces. Glisson's capsule of the liver is rich in these cells, but lung tissue is even richer and is a better source of heparin (C. D. Snyder, 1942). Crystallized heparin is a mucoitin polysulfuric acid ester, consisting of equimolecular parts of glycuronic acid and acetylated glycosamine (E. Jorpes, 1939; Charles and Scott, 1940). It is strongly acidic and forms stable salts with proteins, in stoechiometric proportions (L. B. Jaques, 1943). Heparins from various species differ materially in potency without detected chemical difference (Jaques *et al.*, 1942; review, W. H. Howell, 1941; A. J. Quick, 1944).

Actions.—Heparin antagonizes thrombokinase, preventing the conversion of prothrombin into thrombin. It is not itself antithrombic, but with a cofactor present in serum albumin it inactivates thrombin (J. H. Ferguson, 1937). It prolongs the clotting time, but not the prothrombin time. It inhibits proteolysis of casein by crystallized trypsin, and the destruction of thrombin by trypsin or protease (Gazko and Ferguson, 1940). It prevents the agglutination of platelets (probably by its anticoagulant action; Bürker).

Heparin injection does not materially prolong the duration of hemorrhage (Hartman and Mason, 1924), presumably because the thromboplastic action of the tissues is stronger. Intravenous injection has no effect on the blood pressure and respiration, provided the heparin is adequately purified; otherwise there may be violent reactions.

Heparin is concerned in maintaining the normal fluidity of the circulating blood (Howell). In peptone and anaphylactic shock, its blood concentration is increased, diminishing the coagulability (Jaques and Waters, 1941). It inhibits the release of histamine by trypsin, protease or specific antigens, from the blood cells to the plasma (C. A. Dragstedt *et al.*, 1942). *Salmine sulfuric acid* (a protamine) neutralizes the effect of heparin *in vivo* and *in vitro.* Intravenous injection immediately arrests excessive bleeding from heparin (Jorpes, Edman and Thaning, 1939).

Fate.—The effect of heparin on intravenous injection is prompt, but not sustained. The excess disappears rapidly from the blood. Urinary excretion reaches a peak in twenty to fifty minutes and accounts for 10 to 35 per cent of the injected dosage (Copley and Schneedorf, 1941; J. E. Jorpes, 1943).

Clinical Use of Heparin.—This is employed as anticoagulant in *blood transfusions.* Its addition to drawn blood has no advantage over citrate; but it may be injected by vein into the donor, 1 mg. per Kg. of body weight (or 1.5 cc. of 5 per cent per 75 Kg.), without toxic effects to donor or recipient (even with 10 mg. per Kg.). It lengthens the clotting time immediately, but its potency varies with individuals (Sappington, 1939). Its chief indication is for the *prevention of thrombosis* (C. H. Best, 1938; G. Murray, 1940), after operations, especially in blood vessel surgery, in vascular disease of the brain, coronaries and central vein of the retina, in polycythemia, and in frost-bite (K. Lange *et al.*, 1945).

Intravenous administration should be started three hours after completing the operation and continued until the patient can move actively in bed. Hypodermic injection is less suitable (L. B. Jaques, Charles and Best, 1938). Heparin and dicumerol may be used jointly, the latter for more lasting action. Neither agent dissolves clots that have already formed. The effects must be carefully controlled by coagulation and prothrombin time, as overdoses may result in serious hemorrhage. Penicillin increases the effect of heparin in variable degree, sometimes fatally (Hines and Kessler, 1945).

Heparin solution is marketed in 10 cc. vials, 10 mg. per cubic centimeter; one cc. keeps 5000 cc. of plasma liquid for four hours at 37° C. It is generally administered in normal saline by intravenous drip, 20 to 30 mg. in twenty to sixty minutes. The action may be prolonged by intramuscular injection of a beeswax mixture (Bryson and Code, 1944).

Other anticoagulants which are useful in the laboratory are less suitable for clinical use; hirudin, because of low potency and limited supply; dyes and the other agents, because of the generally narrow margin between the effective and toxic doses (review, Prandoni and Wright, 1942).

Hirudin.—The cervical glands of the common leech (Hirudo) secrete a substance (hirudin, hemophilin) which delays or hinders the coagulation of blood inside and outside the body, by preventing the action of thrombin on fibrinogen. This substance is not destroyed by boiling or by alcohol. It appears to be a deutero-albumose. The leech secretion also contains a histamine-like substance which produces capillary dilatation and increases the bleeding (B. A. Lindemann, 1939).

Therapeutic Use.—Leeches were at one time used extensively for the abstraction of blood in local inflammations. Dry or wet cupping was then substituted, but they are still employed occasionally; two to four of the animals are applied. Each leech draws from 5 to 7 cc. of blood. It is sometimes difficult to stop the bleeding. For experimental use, an extract may be prepared when needed, by crushing the leech heads with sand, macerating with saline for two hours, and centrifugalizing. Each kilogram of animal requires the heads of three leeches, extracted with 3 cc. of normal saline. The solution loses activity on standing, more slowly in the cold.

Immunization.—Daily intravenous injection of hirudin into mice creates an anticoagulant substance, effective *in vivo* and *in vitro*, destroyed at 65° C. It also inactivates fluorides, but not the calcium precipitants. The mechanism of its action has not yet been explained (Vera and Leo Loeb, 1914).

Toxic Effects.—Fresh preparations may be injected intravenously in sufficient quantity to render the blood noncoagulable, without damage to the animal. Some commercial samples of hirudin, however, are highly toxic, especially to dogs, probably through the presence of putrefactive bases. The symptoms from 20 to 25 mg. per kilogram in dogs consisted in severe bloody diarrhea and continued vomiting, with hemorrhagic lesions of the viscera (Marshall, 1915). Engelmann, 1911, injected 0.3 Gm. into a number of eclamptic patients intravenously with and without toxic symptoms. Small quantities were also used in the transfusion method of Satterlee and Hooker, 1914. Lewisohn, 1915, obtained alarming symptoms after 0.1 Gm. of Hirudin-Sachsse.

Dicumerin (Dicumerol).—Oral administration of this substance inhibits the formation of prothrombin. Its effects do not become manifest until the stock of prothrombin has become exhausted, in about forty-eight hours. It greatly prolongs coagulation and prothrombin time, impairs clot retraction, and increases the sedimentation rate of erythrocytes. It is otherwise practically nontoxic.

It is the causative agent of "*sweet clover disease*," a fatal hemorrhagic condition which occurs in cattle fed, on spoiled melilotus hay or silage (reviews, A. J. Quick 1944; Prandoni and Wright, 1942).

Chemical.—Dicumerol, 3.3′ methylene-bis(4-hydroxycoumarin), is formed from the coumarin that exists in the plant. It was isolated by K. P. Link *et al.*, 1940, and synthesized by Stahmann, Huebner and Link, 1941. Many derivatives are similarly anticoagulant, but are less potent (Link, 1945). It is only slightly soluble in water, but forms soluble salts with alkalis. Rather high alkalinity (beyond *p*H 8) is necessary to keep it in solution. It is readily absorbed from the alimentary tract.

The *prothrombin level* of the blood is lowered slowly by a single dose of dicumerol, reaching a minimum in forty-eight to ninety-six hours, then gradually returning to normal in about a week. A critical minimal dose is necessary; increase of the dose above this does not hasten the prothrombin fall (Quick, 1943). A single dose of 3 to 5 mg. per Kg. for rabbits may lower the prothrombin by 80 per cent (Roderick, 1931; Quick, 1937; Overman *et al.*, 1942). Daily repetition for twenty days lowers it to 10 per cent without marked deleterious consequences.

The effects do not result in permanent injury if they do not go too far, and the usual doses do not appear to produce other toxic actions. Coagulability is restored by discontinuing the administration or by injecting normal serum or blood. In contrast to heparin, it has no effect when added to blood *in vitro* (reviews, Quick, 1944; Prandoni and Wright, 1942).

Toxic Effects.—More prolonged administration, or a single intravenous injection of 250 mg. per Kg., results in dangerous and fatal hemorrhages into various organs, especially at points of stress in the subcutaneous tissue and intramuscular fascia, and into the gastro-intestinal tract, pleura and lung (C. L. Rose *et al.*, 1942). Capillaries, arterioles and veins are widely dilated (Bollman and Preston, 1942). Central liver necrosis may develop, probably secondary to the local bleeding, if the animal does not die from the hemorrhages or from pulmonary edema. High levels of ascorbic acid may partly counteract moderate levels of dicumerol (review, K. P. Link, 1945).

The *mechanism* by which dicumerol lowers the prothrombin level is not established, but probably consists in inhibition of the enzymatic reactions that produce prothrombin, perhaps inability to utilize vitamin K; but it can be antagonized by administering excess of K vitamin. It also affects the fibrinogen level; this tends to be lowered by large, and raised by smaller, doses (U. D. Irish and Jaques, 1945). It inhibits platelet agglutination (M. Spooner and Meyer, 1944) and so tends to prevent thrombosis.

The clinical indications of dicumerol are as prophylactic against intravascular clotting in postoperative thrombophlebitis and embolism. Oral administration tends to prevent venous thrombosis, for instance after ligation of a vein or injection of a sclerosing agent. It may be useful in endarteritis. It does not take the place of heparin in urgent conditions, but is useful for prolonged action. It does not dissolve formed clots (R. K. Richards and Cortell, 1942; Stafford *et al.*, 1943; H. D. Zucker, 1944).

The *dosage* must be controlled by daily determinations of prothrombin. About 0.3 Gm. may be administered orally on alternate days (Stats and Bullowa, 1942; Overman *et al.*, 1942). Rectal administration in theobroma suppositories is sometimes fully effective, but is not reliable (O. O. Meyer and Spooner, 1943; O. Wilander, 1938).

Other Anticoagulant Agents.—Intravenous injection of *Witte's peptone* (0.3 to 0.6 Gm. per Kg.) acts by stimulating the formation of heparin (Quick, 1936). Various *azo-dyes* are used in experiments on animals, especially Chicago Blue 6 B, Niagara Sky Blue, Chorazol Sky Blue and Chlorazol Fast Pink BKS; also an amine dye, Pontamine Fast Pink.

The clotting time is not lengthened, but rather shortened, by intravenous injection of sodium oxalate, or intramuscular sodium citrate (J. A. Richardson *et al.*, 1941).

◆

ANIMAL VENOMS

Various animals form toxic substances belonging to different groups. They are reviewed by H. E. Essex, 1945.

Snake Venom.—About a sixth of the known species of snakes are venomous, all in orders of Colubridae and Viperidae. Their salivary secretion contains a complex of toxic substances, the most important being proteoses, some with enzyme actions. The proteose is largely responsible for the systemic, the protease for the local actions (Houssay, 1923). They are related to the venoms of bees, spiders and scorpions. E. Faust attributed the actions to non-nitrogenous sapotoxin-like substances, but these have not been confirmed (review, O. Gessner, 1938).

Local actions predominate with some venoms, systemic effects with others. Most venoms produce intense cellulitis at the site of the bite, with marked ecchymosis and swelling, and sometimes gangrene. They generally affect the *blood* profoundly, some increasing and others decreasing the coagulability (Hanut, 1939). Several cause hemolysis. Many lower the blood pressure similarly to histamine. The leukocytes may decrease to 25 per cent of the normal count.

The *systemic actions* are nervous, and mainly central. The most conspicuous is a bulbar paralysis. There is a period of incubation (in man, of about four hours' duration); the patient then becomes drowsy, and then presents an ascending paralysis of the cord—*i. e.*, in the order of legs, arms, larynx and tongue. This may be preceded by convulsive movements. There is also salivation and vomiting. The *respiration* becomes dyspneic, giving rise to asphyxial convulsions and forming the cause of death. The fatal dose of rattlesnake venom for man would be about 0.15 to 0.3 gm., hypodermically. The heart beats for some time after the respiration stops. *Vascular paralysis* leads to fall of blood pressure, partly by direct proteose action, partly by liberation of histamine (Kellaway and Feldberg, 1937). Direct cardiac injury has not been demonstrated. *Blood coagulation* is accelerated by many viper venoms and by some colubrides. It is attributed to cytolysis of platelets and increase of thrombin. It has been suggested for the treatment of hemorrhage, but is not superior to less toxic hemostatic agents. Cobra venom inhibits blood coagulation, its protease destroying the fibrinogen (W. Billing, 1930). Excised *smooth muscle* is generally contracted in a manner similar to but not identical with histamine (C. H. Kellaway, 1929). *Curare-like effects* are produced by nearly all snake venoms, more with cobra than with vipers. They appear more potent in living animals than in excised muscle, and are responsible for the fatal arrest of respiration. They are not antagonized by physostigmine (Yagi, 1918) and are not reversible except by antitoxin (Kellaway, 1932). Snake venoms have no effect on infusoria, bacteria, or on plants, but they are toxic to all animals above the hydra.

The *danger of snake bite* depends on many conditions. The actual *mortality* in the United States is about 16 per cent without treatment, 3.75 per cent with antitoxic serum. In East India, the annual deaths are said to be 20,000 to 25,000 persons (R. Hutchison, 1930).

The treatment of snake bite must be prompt. The specific *antisera* are effective, and as they are not strictly specific, polyvalent and even nonspecific antivenom sera are useful (Kellaway, 1930). The antitoxins remain potent for a long time if properly kept. Local measures directed to slowing the absorption of the venom, or to its chemical destruction, are of questionable value, even if used immediately, and quite useless if there is any delay. These include ligation, expression, suction, cauterization and excision of the site of the bite; rubbing with crystals of potassium permanganate, or hypochlorite or iodine solutions. These agents are liable to do more damage to the tissues than to the venom, under practical conditions, although they detoxicate it *in vitro*, as do also formaldehyde, soaps, and bile (O. Gessner, 1938). Blood transfusion may be useful to the depressed circulation. Analgetics and sedatives, barbiturates, morphine and the traditional alcohol, help to relieve the pain and fright. Strychnine is harmful.

Cobra (Naja) venom, injected intramuscularly in minute amounts, is reported to produce marked central analgesia, resembling that of morphine, but devoid of addiction and withdrawal phenomena (Calmette, 1933; Taguet, 1933; Macht, 1936, 1938). It has been employed against severe intractable pain, in malignant conditions, tabetic crises, angina pectoris, tic douloureux, Parkinson syndrome and arthralgias. Blind tests in comparison with saline injection indicate a limited efficiency, but it may be completely ineffective (D'Amour and Smith, 1941; Talkov and Bauer, 1943). Some hours may elapse before the action is apparent. It is probably neurotoxic. It may cause severe side actions, nausea and vomiting, diarrhea, pain at the site of injection, sometimes very intense (Steinbrocker *et al.*, 1940; preliminary report, Council on Pharmacy and Chemistry, 1940, J.A.M.A., *115:* 1196).

The *systemic actions* of cobra venom were investigated by Cushny and Yagi, 1916. It is strongly hemolytic. Frogs showed mainly a slow curare action. This was also the cause of death in mammals. Superlethal doses also act directly on all forms of muscle, producing first stimulation, then depression. Autonomic nerves, ganglia and myoneural junctions were not affected; nor was there any direct action on the central nervous system. Gautrelet *et al.*, 1934, observed fall of *blood pressure*, chiefly by direct action on the capillaries, increasing their permeability. *Excised intestines* responded to small doses by hypertonus, to large doses by relaxation. Cobra venom *hemolysis* is inhibited by normal mammalian serum, accelerated by inactivated horse serum.

Rattlesnake venom is hemolytic and lowers blood pressure similarly to histamine. It was studied by Essex and Markowitz, 1930. It is not toxic to rattlesnakes. The serum of these snakes, however, is not antitoxic. It, as also the bile, has only a low toxicity (Walker and Marshall, 1915).

Moccasin venom produces intravascular clotting, probably by liberating thrombokinase from the vascular endothelium. It causes clotting when added to oxalated, citrated or hemophilic blood *in vitro*. Injection of a diluted solution has been tried in purpura and other hemorrhagic conditions, but its indications and limitations have not been sufficiently studied. It often causes considerable local reaction (report, Council on Pharmacy and Chemistry, 1940, J.A.M.A., *114:* 2218).

Copperhead venom renders the blood incoagulable and produces a curare effect, with paralysis of respiration.

Scorpion stings, by Centruroides sculpturatus and gertschi, are common in the southwest United States. The poison acts on the nervous system, central, peripheral and autonomic, and is also hemolytic. The effects are more pronounced in children; stings are almost invariably fatal in infants younger than a year, unless they are treated at once. They are dangerous to older children, and a serious inconvenience to adults. The *symptoms in children* consist in pain and extreme restlessness; spastic muscles of the abdomen, arms and legs; quickened heart;

considerable fever; cyanosis; asthmatic, wheezing respiration. Death occurs apparently by exhaustion. In nonfatal cases the symptoms subside within twelve hours. De Magalhaes, 1939, found cavities in the medulla oblongata of fatal cases. *In adults*, the symptoms are similar but less severe. The site of the bite is usually numb. *Rats* die promptly with convulsions (H. E. Essex, 1945). Injection of extracts into anesthetized cats produces fibrillary and clonic contractions of skeletal muscles; hyperpnea, then respiratory paralysis; vasoconstriction; increased salivation, dilated pupils, piloerection. The muscular action is largely peripheral; relatively weak and slow stimulation produces tetanus; small doses antagonize curare, higher doses have a curare action (Del Pozo and Anguiano, 1946). *Treatment* consists in specific antiserum, which has given encouraging results. Barbiturates and bromides give symptomatic relief. Morphine is dangerous and not very effective (M. L. Kent and Stanke, 1939).

The stings of *European scorpions* produce chiefly local irritation (Flury, 1922).

Poisonous Spiders.—The bites of several species may produce local irritation, usually serious. The venom of the *black widow spider*, Latrodectus mactans, however, produces serious results, with violent systemic and local effects, but is rarely fatal for man. It contains a nonhemolytic neurotoxin.

The systemic symptoms may simulate acute abdominal disease, with increased pulse rate, rise of blood pressure, abdominal rigidity, and painful cramps in the leg muscles. Treatment is symptomatic, and includes morphine and barbiturates. Recovery confers complete immunity to the systemic actions, but increased susceptibility to the local effects. An effective antiserum has been prepared (Gajardo-Tobar and Vildosola, 1944).

Bee venom owes its action to a nitrogen-free cyclic acid anhydride somewhat related to cantharidin (Fury, 1929). It is a potent endothelial poison, and produces violent local pain, severe fall of blood pressure on intravenous injection, marked stimulation of smooth muscle, paralysis of perfused hearts, and hemolysis (Essex *et al.*, 1930). Death may occur by low blood pressure or arrest of respiration, preceded by paralysis and convulsions. In rabbits, it causes leukopenia and generally decrease of erythrocytes. Stings of five bees are fatal to mice, twenty to guinea pigs (Derevici and Derevici, 1939). The susceptibility varies with individuals and may be increased or diminished artificially. With sublethal doses, the blood pressure recovers and is then resistant to further injections (tachyhylaxis). It is rendered nontoxic by sulfhydryl compounds, such as reduced glutathione (Brit. Med. J., 1940, 623).

Bee venom has been used therapeutically against arthritis, neuritis and trachoma, but its value is doubtful (review, J. L. Hollander, 1941).

Mosquito venom possibly resembles that of bees (review, J.A.M.A., 1942, *120*:726).

Mussel Poison.—Eating of Mystilus californicus may produce toxic effects, with death in six to ten hours by failure of the respiration and heart (M. Prinzmetal *et al.*, 1932). The toxicity varies; it may be entirely absent and then appear in a few days. It is not bacterial (E. Meyer *et al.*, 1928).

Ascaris Poison.—Ascaris and other intestinal parasites yield a propeptone that is extremely toxic. The symptoms resemble those of peptone injection. Local application to the conjunctiva produces irritation. This substance is not hemolytic (Torai and Hajime, 1917). Ascaris lumbricoides also contains a *hemolytic* substance. This is confined to the digestive tract of the worms and is probably used for the digestion of blood by the parasites. Its action is inhibited by serum, so that it is probably not concerned in anemia.

◆

ANTERIOR PITUITARY HORMONES

The anterior and the intermediate portions of the pituitary gland lack the acute actions of the posterior lobe (Burn and Dale, 1922). The anterior, however, performs vastly more important functions in life. It secretes a considerable number of important hormones which act upon other glands of internal secretion, whose hormones in turn react upon the anterior pituitary activity, so that this small gland serves as a regulating center of endocrine activity. It exists fully differentiated in the most primitive vertebrates, but not below these (review, A. Gorbman). Its *excision* is not fatal, but leads to marked changes, including arrest of growth (dwarfism), and retention of juvenile characteristics; atrophy of the gonads (sexual infantilism); involution of the thyroid and suprarenal and other endocrine glands, decreased metabolic rate, deposition of fat in depots, hypersensitivity to insulin; and some other effects. Administration of the gland or extracts corrects all the derangements of its excision. With normal young animals it leads to excessive growth, precocious sexual development and thyroid hypertrophy (reviews, P. E. Smith, 1935). The several actions of the anterior pituitary are produced by distinct *hormones*. Six, the lactogenic, adrenotropic, growth, luteinizing, thyrotropic and follicle-stimulating, have been isolated in considerable purity. They are proteins (review, A. White, 1946). The gonadotropic and lactogenic hormones will be discussed under sex hormones. Commercial preparations are relatively crude. There is no critical evidence that they have clinical value (S. C. Freed, 1941).

Growth Hormone.—Probably all dwarfism is due to deficient anterior pituitary functionation. With cretins this may perhaps be depressed by ineffective hyperfunctionation of the thyroid gland. Resumption of growth of dwarfed children has sometimes followed the clinical administration of effective anterior pituitary preparations (Engelbach and Schaefer, 1934), but these are difficult to supply. The growth hormone is naturally less important in adults; but as this hormone is present in the adult gland, continued function may perhaps be assumed for the normal tissue replacement. *Overproduction* of the growth hormone is responsible for gigantism, a symmetrical overgrowth in youth, and for acromegaly, an asymmetrical overgrowth in adult life. These have been confirmed experimentally, acromegaly in dogs (not in rabbits and rats), and gigantism in rats. The hormone appears to be found in the eosinophile cells of the gland. Its action differs from that of other hormones and vitamins it involves: chiefly stimulation of the epiphyseal cartilages, but the soft tissues and viscera are also affected (P. E. Smith, 1940). The growth is attributable to increased formation and diminished catabolism of protein (C. N. H. Long, 1942). In animals that have ceased to grow it may accelerate skeletal aging and result in osteoporotic changes (O. Riddle, 1935).

Excision of the anterior pituitary lobe of young animals produces immediate stasis of growth, fixing the infantile proportions and structual peculiarities, such as milk dentition, lanugo hair, open epiphyseal cartilages. Aging of dwarfs follows peculiar patterns; for instance, shrinkage of epiphyseal cartilage. When the pituitary growth hormone is injected, growth resumes and reaches normal proportions or more. Ablated animals are far more sensitive to the growth hormone; but its effects can also be shown on normal *rats and mice*, for these rodents have a latent power of growth and are almost unique among mammals, becuase their epiphyses remain cartilaginous. Administration of pituitary enables them to grow to double the normal size; but the effect is limited to a certain maximal rate which is never greater than the most rapid postnatal growth rate, and this is not increased by increasing the dosage; after a year or a year and a half it becomes progressively slowed. When the administration is stopped, there is an abrupt fall of weight, but the bony frame remains enlarged (Evans and Long, 1921; Evans, 1933).

Tumor Growth.—It is reported that extirpation or irradiation of the hypophysis slows the rate of growth of experimental tumors, and that this is accelerated by administering the gland to such animals (Hayashi, 1930; F. Bischoff, 1935).

The **thyrotropic hormone** (thyrotropin) is essential for the normal development and function of the thyroid gland. *Deficiency* produces thyroid atrophy and lowered basal metabolism, which are promptly relieved by anterior pituitary administration; and *excess* results promptly in thyroid hypertrophy and the phenomena of hyperthyroidism: increased basal metabolism, increased heart rate, exophthalmus, increased iodine content of the blood and decrease in the gland; and also hastened metamorphosis of tadpoles.

Guinea pigs and rabbits are highly susceptible, rats very little. The thyrotropic hormone may be assayed by the histologic changes it produecs in the thyroid gland (J. G. Heyl and Laqueur, 1935), especially by the increased mitoses revealed with colchicine (P. Bastenie, 1940). Deficiency symptoms are prevented in rats by leaving 10 per cent of the gland tissue (25 per cent in monkeys), although there is little or no regeneration (P. E. Smith, 1940). It induces hyperplasia of thyroid tissue even *in vitro* (Eitel, Krebs and Loeser, 1933). The thyrosecretory and thyroplastic responses may be due to different hormones (Heyl, 1934). The hyperthyroid phenomena do not occur if the thyroid gland has been removed, so that the pituitary does not produce them directly, but by stimulation of the thyroid gland, for which the anterior pituitary hormone is indeed the most effective, and perhaps the only effective stimulus. The toxicosis develops more rapidly than by direct administration of thyroxin (E. Schneider and Widmann, 1932). Iodide administration diminishes the hyperthyroid symptoms of guinea pigs treated with thyrotropic extract (Friedgood, 1936), without interfering with the hyperplasia (E. M. Anderson and Evans, 1937). It is quite possible that cretinism and myxedema are due primarily to pituitary deficiency—they are relieved by anterior pituitary hormone as well as by thyroxin—and that Basedow's disease is due to pituitary hypersecretion. Conversely, the thyroid deficiency produces pituitary hypertrophy, perhaps because this produces more thyrotropic hormone to spur the thyroid to compensation. The thyroid involution which follows prolonged thyroid administration is presumably due to diminished production of thyrotropic hormone. Thyrotropic hormone is increased in the blood of patients with hypothyroidism (Bodart and Fellinger, 1936); contradictory results have been reported for hyperthyroidism. If injections of thyrotropic hormone into normal animals are continued for some weeks, they become ineffective and the blood of these animals contains inhibitory substances, whose injection into normal animals renders these also refractory to the thyrotropic hormone. Similar *antihormones* are formed by and to the parathyrotropic hormone and to the gonadotropic hormone of pregnancy urine, but not to thyroxin or insulin (review, D. L. Thomson, Collip and Selye, 1941).

Diabetogenic (Hyperglycemic) Hormone.—This is antagonistic to insulin and decreases the hypoglycemic response to insulin injection. Hyperactivity of the pituitary may be a factor in diabetes. Excision of the anterior pituitary impairs the normal mechanism for regulating the blood sugar level. The nature of the interrelation is not clear (reviews, J. A. Russell, 1938; B. A. Houssay, 1942).

Injection of anterior pituitary extracts into normal dogs produces hyperglycemia (Evans, 1935; Collip, 1934), acting probably on the liver to cause glyconeogenesis and glycogenolysis. It is also ketogenic.

Deficiency, as by excision of the anterior pituitary, greatly increases the response to insulin and prevents or greatly diminishes the hyperglycemia and acidosis of total pancreatectomy (Houssay and associates, 1931 to 1933), although dogs with the double operation become cachectic and die after six to nine months. Their blood sugar level is unstable; it rises greatly after feeding, but is less responsive to epinephrine. Injection of small amounts of anterior pituitary provokes a marked rise of blood sugar, glycosuria and ketonuria. The neutralization is not due to inactivation of the hormones by each other, but to algebraic summation of their effects, which may have quite different points of attack (review, J. A. Russell, 1938).

Dogs with only the pituitary removed (and with intact pancreas) also show instability of the blood sugar level. This is normal if they are well fed, but falls easily to a fatal level on fasting. They are also hypersensitive to insulin. They can be restored by anterior pituitary injection after a considerable latent period. The blood sugar raising principle may be isolated from normal human urine. (*Adiposity*, which often follows removal of the hypophysis, is not due to this, but to injury of the tuber cinereum.)

Ketogenic Hormone.—Injection of anterior pituitary greatly increases the ketone content of the blood, especially the beta oxybutyric acid (F. Hoffmann and Anselmino, 1931), and the excretion of acetone substances (H. Burn and Ling, 1928 to 1930). The ketogenic hormone appears to be distinct from the hyperglycemic hormone. It may also be present in urine (C. Funk, 1933).

Adrenotropic Hormone.—Excision of the anterior pituitary is followed by marked atrophy of the suprarenal cortex (P. E. Smith, 1930). This may be prevented by the injection of hypophyseal extracts (Evans and associates, 1932). The hormone can be separated from the thyrotropic (Collip, Anderson and Thomson, 1933). The suprarenal medulla is not affected.

Parathyrotropic Hormone.—The evidence for this is not altogether satisfactory (Collip, 1940).

PINEAL GLAND

This is a vestigial remnant of a primitive dorsal eye, but presents some evidence of glandular structure, with sympathetic innervation. It begins to involute early between the seventh year and puberty, but its degeneration is never complete. The literature on the pineal gland abounds in apparently contradictory results (an extensive bibliography is given by Rowntree, Clark and Steinberg, 1936). The phenomena seem to be confined to the prepubertal years, *i. e.*, before the gland has undergone involution. *Neoplasms* of the pineal gland are said to be often associated with precocious physical, mental and sexual development and general overgrowth of the body. Only a few cases are on record, and the reliability of the connection is not established. *Extirpation experiments* have not yielded conclusive results. The early effects are inseparable from traumatism. There are no late changes in adults; in young animals, ablation is said to lead to precocious development (Sarteschi, Foa), but the effects, at best, are not striking.

The gland contains a moderate amount of estrogenic hormone, but it is questionable whether this has any physiologic importance (Silberstein and Engel, 1933; Saphir, 1934). *Intravenous injection* of extracts has no pronounced action on the circulation (Dixon and Halliburton, 1909). It is also practically inactive on excised heart and uterine or intestinal muscle (Fenger, 1916). Ott and Scott, 1912, claimed that it increases the milk secretion in goats. This needs to be confirmed.

Continued Oral or Hypodermic Administration.—Hastened growth and development of young animals and early adolescence have been reported, with the end result of dwarfism associated with sexual precocity (Dana and Berkeley; McCord, 1913; Rowntree *et al.*, 1936); but Sisson and Finney, 1920, failed to secure any effects, at any period. Dana and Berkeley administered dried pineal (3 to 6 mg., $\frac{1}{20}$ to $\frac{1}{10}$ grain, three times daily) in backward young children (to twelve or fifteen years). It had no effect on growth, but they claimed improvement of the mental development. Feeding *tadpoles* with pineal hastens *growth and differentiation*. There is also a constituent (purified by D. Beall, Shapiro and Zwarenstein, 1937) which contracts the melanophores under the skin, thus rendering the color much lighter (McCord and Allen, 1917). *Paramecia* fed with pineal divide twice as rapidly as controls (McCord, 1917). Pineal extracts increase the pulsation frequency of the contractile vacuole, as do also epinephrine and pituitary solution (Feather, 1919).

THYMUS GLAND

The development and involution of this gland are interrelated with the functional activity of the thyroid and of the gonads (Marine, 1924), but the nature of the relation is not clear. *Daily injections of thymus extract into rats* hasten adolescence and increase the growth of the offspring during the period of immaturity. These effects become much more marked if the administration is continued through successive generations. The precocious rats show considerable increase of plasma calcium (11.4 to 13.3 mg. per cent) and inorganic phosphorus (4 to 7.4 mg. per cent) (review, Rowntree, 1935). A diet deficient in choline produces rapid involution of the thymus in rats, and this regenerates when choline is added (Christensen and Griffith, 1942). The thymus is pathologic in many patients with myasthenia gravis, and its excision gives good results in some cases (M. Nellen, 1943). Thymus administration has been tried, but with doubtful results, in Graves' disease, rickets, tuberculosis, hemophilia, infantile atrophy and marasmus. Feeding with thymus hastens growth and retards metamorphosis of *tadpoles* (Gudernatsch), but only as does any other food (Swingle, 1917; Uhlenhuth, 1917). Thymus produces convulsions when fed to *salamander larvae* that are devoid of parathyroid (Uhlenhuth, 1918).

SEX HORMONES

Sexual activity is regulated by a number of hormones which circulate in the blood. The ovaries and testes remain dormant unless they are stimulated by the gonadotropic hormones which originate in the anterior pituitary gland and during pregnancy in the chorionic tissue. The sex glands themselves produce three series of hormones, estrogenic, androgenic and progestational. Several of these have been isolated and their chemical structure identified, and some have been synthesized. They are steroids, relatively simple phenanthrene derivatives, with a five-membered ring attached to one end of the molecule. They are probably formed by degradation of cholesterol, although this has not been proved (review, F. C. Koch, 1937). They are closely related to each other, to the sterols, to vitamin D, to the group of carcinogenic substances and to the bile acids, digitaloid glucosides and morphine. They are also produced by other tissues (notably the chorion) and by plants. The sex hormones formed by the male and female gonads are closely related, and both are found in the blood and urine of both sexes, so that the female blood also contains androgenic hormone, and the male blood contains estrogenic hormone, but in different proportions.

In childhood, small amounts of anterior pituitary gonadotropic hormone keep up a limited output of estrogenic and androgenic hormones which bring about the normal gradual development of the genital apparatus. At *puberty* the output of the gonadotropic hormone increases with corresponding activation of the sex glands and increased output of estrogen and androgen, respectively, which results in the rapid development of the secondary sexual characteristics. At *sex maturity,* the female sexual cycles appear and are reflected in the hormone concentration of the urine (reviews: R. T. Frank, 1935; P. E. Smith, 1935). The estrogenic substances themselves do not stimulate ovarian activity; on the contrary, they tend to inhibit the production of anterior pituitary hormone and thereby tend to inhibit ovarian functionation, but this requires rather large doses, and prolonged administration is necessary for it to become notable. *Ovulation* itself apparently is not controlled by any special hormone, but by the concurrent actions of the follicle-stimulating and luteinizing hormones at the correct stage of follicular development. At the *menopause,* when the sexual cycles cease, the hormone level varies; some women show permanent increase of gonadotropic hormone, perhaps by stimulation of the anterior pituitary through ovarian deficiency.

Therapeutic Uses.—The oral administration of fresh or dried ovary, in substance, or corpus luteum against the disturbances of menopause, which had a vogue for a time, is quite ineffective even in animals (Novak, 1922; E. Allen and Doisy, 1922), although it may act powerfully on the imagination.

The pure principles, when properly administered, produce definite effects and have somewhat restricted therapeutic uses. S. C. Freed, 1941, lists the endocrine preparations available commercially, and their trade names.

Administration.—The absorption of the steroid hormones from the gastro-intestinal tract is relatively poor, and some are destroyed in the liver. Bile plays no important role in their absorption (H. Selye, 1943). Sublingual administration gives rather better absorption, but is still wasteful and uncertain (G. W. Corner, 1944). They should be introduced parenterally by intramuscular injection of oil solutions or by implantation of the crystals. The latter prolongs the actions. Nonsteroid hormones are quite effective by mouth.

Subcutaneous implantation of sterones.—Loose crystals are more effective than compressed pellets (U. J. Salmon *et al.*, 1941). The surface of the latter becomes infiltrated with protein derivatives that retard absorption (S. J. Folley, 1942). The time required for 90 per cent absorption of pellets in rats is about eight weeks for hexestrol; twenty-one weeks for diethylstilbestrol dipropionate; thirty-one weeks for testosterone dipropionate (T. R. Forbes, 1943). When incorporated in melted cholesterol, the absorption is much slower and more uniform (Shimkin and White, 1941).

Menstruation depends on cyclic changes in the balance of the estrogenic and progestational hormones, determined chiefly by the anterior pituitary gonadotropin. Estrogen increases progressively in the intermenstrual period and leads to hyperplasia and hyperemia of the endometrium. When the follicle ruptures and the ovum is discharged, the corpus luteum produces progesterone and the estrogen concentration drops and its influence is modified (E. Shorr, 1940), so that the hyperplasia is suddenly arrested, with partial destruction of the endometrium and consequent bleeding. The progesterone prepares the mucosa for the implantation of the ovum (review, Bartelmez, 1937).

Menotoxin.—Normal human menstrual discharges are highly toxic when injected into rats and rabbits, producing focal hemorrhages and necroses of the adrenal cortex and other organs. The toxicity varies with the amount of endometrial debris. It is due to a euglobulin, presumably a product of autolysis. It is highly antigenic for rabbits, producing a potent protective serum (O. W. Smith and Smith, 1944).

During the first two days of menstruation, various cutaneous glands secrete increased amounts of unidentified substances which are toxic to plants, causing wilting of cut flowers (B. Schick, 1920) and inhibiting growth of lupine seedlings (Macht and Lubin, 1924). The nature and origin of these substances are not known. There is no evidence that they are formed in the uterus.

Hormonal Control of Pregnancy.—The rupture of the ovarian follicle decreases the output of estrogen, and the formation of the corpus luteum increases the output of progesterone, which arrests menstruation and depresses uterine irritability. Toward term, the estrogenic hormones again obtain the upper hand, stimulate uterine contractions and prepare the growth of the duct system of the mammary gland.

The regulation of these hormones is rather obscure. The corpus luteum is essential to the implantation and retention of the fertilized ovum, and its destruction terminates pregnancy. The follicular estrogen production is controlled by the gonadotropic hormones from the anterior pituitary gland and placenta: The placenta is rich in estrogen and still more in progesterone. Estrogenic hormones can apparently be formed in the placenta, for they increase in early pregnancy, even after ovariotomy (in human subjects).

Placental extracts stimulate uterine contractions, and when combined with pituitary extracts, *premature labor* is induced (Ludwig and Lenz, 1923). Extracts of the mammary gland likewise stimulate the uterus (Ott and Scott, 1909). They do not increase the milk flow, at least in the human (Schaeffer and Mackenzie, 1910).

The *natural continuation and termination of pregnancy* is conditioned by the interplay and balance of the mutual antagonism between progesterone and the estrogenic hormone. In rats, guinea pigs and rabbits, pregnancy can be readily interrupted, especially at its early stage and toward term, by the injection of estrogenic hormones, and prolonged by the injection of progesterone (D'Amour and Gustafson, 1933). In unanesthetized rabbits (S. R. M. Reynolds and Firor) the pregnant uterus is refractory to motor stimulation by theelin to the twenty-sixth day, but on the twenty-seventh day this induces abortion. In human pregnancy the injection of theelin has but little effect and is unreliable for terminating pregnancy, even when large doses are administered with pitocin toward term (A. L. Robinson *et al.*, 1933). This is not surprising, as pointed out by Edgar Allen, 1935, in view of the large amounts of estrogenic substance normally present in pregnant women (in contrast to the experimental animals), so that the percentile concentration would be increased relatively little, even by large doses.

The hormonal content of pregnancy urine is high for all sex hormones, but the proportions undergo characteristic changes as pregnancy progresses. The *gonadotropic hormone*, which is the object of the Aschheim-Zondek test, increases promptly, and its effects (ovarian and testicular changes in infantile mice and rats; ovarian changes in mature rabbits) are apparent within a few days after conception, so that the test is decisively positive at the first missed period. It reaches its maximum around the fourth or fifth month of pregnancy and disappears promptly at parturition, within three days, but not as abruptly as the estrogenic hormone. Its source is partly from the anterior pituitary and partly from the placenta, especially the chorion (Hart and Cole, 1934).

The *estrogenic hormone* increases progressively during pregnancy and is especially abundant in the latter half, so that it is more satisfactory for diagnosing the late, rather than the early, stages. It lasts until birth and is concerned in the increased motor activity of the uterus that terminates with parturition. Its source is chiefly in the placenta, and it diminishes rapidly at birth.

Progesterone is more abundant in early pregnancy.

Lactation Hormones.—The growth development of the duct system during pregnancy is caused by the estrogenic hormones. Stilbene, androgenic hormones and desoxycorticosterone, and indirectly, the gonadotropic hormones have the same effects, and all produce the same changes in nonpregnant and in castrated animals; they generally fail, however, after excision of the hypophysis; but mammary growth can be induced in hypophysectomized male mice if both estrogen and prolactin are administered (W. U. Gardner and White, 1941). The development of the secreting alveoli is caused mainly by progesterone; and the actual milk secretion is initiated and maintained by a special anterior pituitary hormone, *prolactin* (review, O. Riddle, 1940).

Lactation is therefore promptly terminated by hypophysectomy. Excess of estrogenic hormones tends to inhibit lactation, which may be a reason why milk secretion is deferred until the end of pregnancy. Copious lactation can be initiated only when a well developed mammary gland is subjected to a high lactogenic content of the anterior pituitary. The latter is low during pregnancy, but increases by two to four times immediately post partum (Meites and Turner, 1942). Neither progesterone nor the fetus plays any part in the lactating mechanism (reviews: Selye *et al.*, 1930; Evans, 1935). After the milk secretion is established, its maintenance depends on the reflexes from the act of suckling (Selye, 1934; review, W. E. Petersen, 1944).

The composition of the milk changes but little with its quantity, nor does the milk sugar level vary with the blood sugar in diabetes (E. Tolstoi, 1935).

The *duckbill* presents the simplest mammary gland, as a large number of structures resembling sweat glands, each opening directly through the skin. The *cow's udder* is a system of collecting ducts opening into a cistern for each quarter (W. E. Petersen, 1942).

Prolactin, the lactogenic hormone of the anterior pituitary, has been isolated as a crystallized protein with homogeneous physical properties (A. White *et al.*, 1942). It is not so potent as the crude extracts which probably stimulate the body generally (Meites and Turner, 1942). Prolactin may be assayed on guinea pigs or by the proliferation of crop glands in pigeons (O. Riddle, 1935), the desquamated epithelium furnishing the "pigeon milk" (Dabrowska, 1932). The results are not parallel for different hypophyseal preparations (W. R. Lyons, 1941), and the pigeon method is generally used (Meites *et al.*, 1941). The crop glands respond to local application (Lyons and Page, 1935). In mammals pretreated with estrone and progesterone, the mammary cell changes characteristic of lactation can be induced by injecting lactogenic hormone into the mammary duct (W. R. Lyons, 1942). Lactogenic hormone maintains the functions of the corpus luteum in rats (Evans *et al.*). It has no other significant effects on the gonads or other tissue (R. O. Green *et al.*, 1942).

Administration of prolactin extract to stimulate deficient *lactation* has been tried clinically with fair but variable success (review, W. E. Petersen, 1944). S. G. Wilson, 1943, reports that 100 international units, twice daily, double the output of milk in the first five postpartum days. Injection of *anterior pituitary extract* into cows results in considerable temporary increase of milk (S. J. Folley, 1944).

Estrogens, including ethylstibestrols, increase the growth of the duct system, with slight lobular proliferation. Males require larger doses than do females (W. E. Petersen, 1944). They supplement progesterone to produce alveolar growth (C. W. Turner and Frank, 1932). Excessive doses cause cystic changes in the main duct of rabbits (W. R. Lyons and McGinty, 1941). Meites and Turner, 1942, showed that estrogens, diethylstilbestrol and *testosterone* increase the output of lactogenic hormone, and small doses of estrogens may increase milk production (Folley and Malpress, 1944). Large doses inhibit milk secretion and engorgement of the breasts, if administered early in the puerperium before lactation is established, but they are not effective later. This is used clinically (review, W. E. Petersen, 1944). *Adrenal ablation* inhibits lactation completely. This is prevented by administering cortical extract (J. L. Carr, 1931), but not by desoxycorticosterone (R. Gaunt, 1941). *Thyroxin,* 0.2 mg. per Kg. per day hypodermically, increases the milk volume of cows 28 per cent, the fat output by 50 per cent (S. J. Folley, 1944).

GONADOTROPIC HORMONES

These act by steering the production of the direct sex hormones in the ovaries and testicles, and perhaps in other situations especially at puberty, and in the female during the cycles of menstruation and pregnancy. They circulate in the blood and are excreted by the urine, where they may be used for the diagnosis of pregnancy, and from which active extracts may be obtained for therapeutic use. They are formed by the anterior pituitary gland and by the chorionic villi of the placenta and of chorionic tumors, and perhaps by other tissues. They differ somewhat according to the origin; considerable confusion arose before the dual origin was understood. The *anterior pituitary gonadotropic hormone* is responsible for the actions of the blood and urine of normal men and women, and of women after menopause, natural or artificial. The *chorionic gonadotropic hormone* occurs in the blood in the presence of living chorionic tissue, normal (in pregnancy) or pathological. Human chorionic gonadotropin is excreted by the urine; but little of that of mares' serum (review, E. T. Engle and Levin, 1941). The properties of the latter resemble those of the anterior pituitary more than of the chorionic.

Anterior pituitary gonadotropin appears to contain two distinct active principles: (1) *The folliculotropic hormone* (*"Prolan A"*) acts chiefly on the germ cells in *females.* It stimulates the normal growth and maturation of the graafian follicles and the production of estrone, probably by the cells of the theca interna, and thus leads to estrus and ovulation. *In males,* it stimulates the seminiferous tubules, and induces spermatogenesis. (2) The *luteinizing hormone* (*"Prolan B"*) acts on the connective tissue derivatives. *In females* this causes luteinization of the follicles, ovulation, the progressive development of the corpus luteum and the production of progesterone. *In males* it stimulates the interstitial cells of the testes and the formation of androgenic hormone. The existence of two distinct pituitary gonadotropins has been disputed, and the different effects attributed to dosage, more being required for luteinization.

Luteinizing hormones have been reported from fish and birds which do not form corporea lutea (review, Gorbman).

Excision of the anterior pituitary arrests the genital development in immature animals. In adults it produces some regression and atrophy of the reproductive system (Crowe, Cushing and Homans, 1910). *Administration of anterior pituitary extracts* promptly revives the development, more effectively in the female. Injection of anterior pituitary extracts or implantation of the gland into normal immature rats or mice stimulates the development of the ovaries, with other signs of precocious sexual maturity, within four days (Zondek and Aschheim, 1926; P. E. Smith, 1926). The gonadotropic hormones are generally believed to be formed by the basophilic cells of the anterior pituitary.

Long-continued injections of pituitary gonadotropic extract (over three months) into young puppies produce the phenomena of the clinical syndrome of pituitary basophilism: adiposity plethora; checked growth of the body, teeth and hair; subnormal basal metabolism; high serum calcium, low sugar tolerance, massive glycogen storage in the liver (K. W. Thompson and Cushing, 1934).

Relation to Parathyroid and Calcium.—Injection of the anterior pituitary extract produces histologic changes in the parathyroids and rise of serum calcium, attributable to mobilization of estrogenic and thyrotropic hormones (Riddle and Dotti, 1936).

Creatinuria.—Injection of gonadotropic extract increases the output of creatine, the corpus luteum opposing the transformation into creatinine. This accounts for the creatinuria of pregnancy (Schrire and Zwarenstein, 1934).

Chorionic gonadotropin is almost wholly responsible for the gonadotropic action of pregnancy urines. It is prepared commercially from pregnancy urine and from placenta. It is formed in the chorionic cells. It has been called follutein prolan (A and B), antuitrin, antophysin and prehormone. It induces follicular growth and corpus luteum formation in rodents, but not in human or primate ovaries. In these it tends rather to produce degeneration changes, a striking difference from anterior pituitary gonadotropin. It stimulates the interstitial cells of the testicles to the elaboration of androgenic hormone, which induces growth of the accessory sex organs, in man and monkeys as well as lower animals. It has little if any effect on the germinal epithelium. It is formed by the chorionic placental cells, even when growing *in vitro* as tissue cultures, possibly by the Langerhans cells (Gey, Seegar and Hellman, 1938). It is a glycoprotein containing 12 per cent of galactose.

The *pregnancy test of Aschheim and Zondek*, and its modifications, involve the rapid growth and rupture of ovarian follicles by the gonadotropic hormone of the pregnancy urine. This has been confirmed in women. If the gonadotropic fraction of the urine of pregnant mares is injected before laparotomy, the follicles mature and rupture and corpus luteum is formed, within twenty-four to thirty-six hours after injection (M. E. Davis and Koff, 1938). Injection into very young female rats results in *masculinization*, similarly to testosterone (Bradbury, 1939).

Therapeutic Uses.—Injections of chorionic gonadotropic extracts are used to secure the descent of the testicles in certain cases of functional cryptorchidism (Shapiro, 1930). It has been used against uterine bleeding, but with questionable results. It has little or no value in ovarian disturbances or other conditions (report, Council on Pharmacy and Chemistry, 1940, J.A.M.A., *114:* 487).

In *cryptorchidism*, gonadotropic treatment is effective in 20 to 50 per cent of the patients, but with most of these the testicles would probably descend spontaneously with the natural increase of testicular hormone at puberty (W. W. Johnson, 1939). The administation of the gonadotropin shows whether the testicles can descend, without waiting for puberty; and if it is ineffective, surgical treatment may be undertaken earlier and with better results.

The treatment is best given between the second and third years, injecting 200 to 500 international rat units hypodermically two or three times a week, for one to two months. If it is not effective by this time, surgery becomes indicated (B. Webster, 1935; W. O. Thompson, Bevan *et al.*, 1937; C. I. Deming, 1937; Zeithaml, 1938). The injections may cause precocious sexual development (increased growth of penis, scrotum and prostate) and should be stopped before this becomes marked (W. O. Thompson and Heckel, 1938).

Chorionic Gonadotropin, N.N.R., *Follutein*, *Korotrin*, is a water-soluble substance obtained from the urine of pregnant women, standardized in international units equal to 0.1 mg. of a standard powder. Marketed in vials of 500 to 10,000 units. Dose in cryptorchidism, 200 to 500 units two or three times a week for not longer than eight weeks.

ESTROGENIC HORMONES

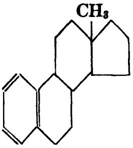
Estrus, the restricted period of mating activity in the females of most mammals, is ushered in by rapid growth changes in the genital tract and the mammary glands, and multiplication and cornification of the vaginal epithelium. These changes may be evoked by the injection of the estrogenic hormone isolated from the follicular fluid, or from pregnancy urine or other sources or prepared synthetically (review, Edgar Allen, 1935).

Historical.—R. T. Frank, 1922, demonstrated estrogenic activity in the fluid of the graafian follicles. E. Allen and Doisy, 1923, confirmed and extended these observations. When Aschheim and Zondek, 1927, demonstrated estrogenic substances in the urine of pregnant women, this furnished a source of supply sufficient for extensive purification, and from this material Doisy, Veler and Thayer, 1929, isolated the crystallized principle which they named *Theelin*, from the Greek adjective theelys, female. Shortly thereafter the same substance was isolated independently by G. F. Marrian, by Butenandt, and by E. Laqueur and associates. The English termed it "*Oestrin*," and Laqueur "*Menformon*." It has also been called "*Folliculin*," which is confusing since it is generally prepared from other sources than ovarian follicles. Theelin is a phenathrene ketone, "ketohydroxy estrin." Two closely related derivatives have also been isolated from pregnancy urines: Theelol or trihydroxy estrin (Doisy and Thayer, 1931), and a hydroxy estrin benzoate (MacCorquedale, Thayer and Doisy, 1935). These differ in their relative actions on immature and on spayed rats (indicating that they do act to some degree on the ovaries).

Nomenclature.—As the designation "Theelin" was not widely accepted, the Council on Pharmacy and Chemistry, on the advice of a committee of workers in this field, adopted in 1936 a system of nomenclature based on the root of "estr" (estrone for theelin, estriol for theelol, and so on), retaining the Doisy names as synonyms.

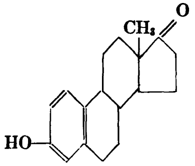
Sources.—In nonpregnant females the estrogenic substances are probably formed in the theca interna of ovarian follicles of all sizes; in pregnancy they come chiefly from the fetal portion of the placenta (review, G. W. Corner, 1938). Estrogens are produced by gonadial tissue even in echinoderms (J. K. Donahue and Jennings, 1937). Theelin is secreted in the maturation of the graafian follicles, and was first demonstrated in the follicular liquid (Doisy and associates, 1934). Its absolute concentration in the ovary is 1:10,000,000, much lower than that of other hormones in their endocrine glands (Doisy). It is ten times more abundant in the urine of pregnant women, which is the usual source of the commercial preparations; but placenta (Allen *et al.*, 1922) and amniotic fluid (Brouha and Simonnet, 1927) also give good yields. It may be prepared from male urine (Laqueur and de Jongh, 1927) and from plants (Dorn *et al.*, 1926). *Theelol* may be prepared from pregnancy urine (Doisy and Thayer, 1931) and from placenta ("emmenin," Collip, Browne and Thompson, 1930).

Chemical Structure.—The estrogenic, androgenic, progestational and adrenal cortical hormones are "*steroids,*" a group name introduced by Callow and Young, 1936, for all substances containing a cyclopentene-phenanthrene carbon skeleton (Marrian, 1939). They include other sterols, bile acids, cardiac glucosides, vitamin D and others. The estrogenic hormones are derived from a nucleus, estratriene, as follows:

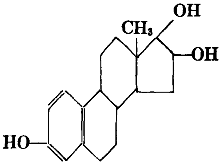


Estratriene

$C_{18}H_{24}$
$\Delta^{1,3,5}$,—estratriene



Estrone
(Theelin)
$C_{18}H_{22}O_2$
3-hydroxy 17-keto
$\Delta^{1,3,5}$,—estratriene



Estriol
(Theelol)
$C_{18}H_{24}O_3$
3, 16, 17-trihydroxy
$\Delta^{1,3,5}$,—estratriene

The structure of the estrogens is related to that of the carcinogenic hydrocarbons of tar, which have some estrogenic action, but are much less potent (J. W. Cook, Dodds and Lawson, 1936). Dodds and Lawson, 1936, also synthesized estrogenic agents without a phenanthrene nucleus. Conversely, the estrogenic hormones are feebly carcinogenic (review, Leo Loeb, 1935).

Assay and Units.—The dosage of the estrogen esters should be expressed in weight, and not as estrogen base, since their potency varies with their absorbability (Council report, 1942, J.A.M.A. *120*:921). The International Unit corresponds to the estrogenic potency of 0.1 gamma of the international standard powder, which is about a third of the amount necessary to induce estrus with vaginal cornification in ovariectomized rats of about 140 Gm. It is about a third of the Doisy unit. A milligram of theelin corresponds to 10,000 international units, when administered in oil. The test can be made more delicate by intravaginal administration, so that it can be applied directly to urine (W. R. Lyons and Templeton, 1936).

Absorption.—Estrone and estriol are soluble in oil and only slightly soluble in water. They are absorbed from the digestive tract as well as from subcutaneous injections, but the steroid estrogens and androgens are to a great extent inactivated in the liver (G. R. Biskind and Mack, 1939), largely by excretion into the bile (Cantarow *et al.*, 1945). They are therefore much less effective by mouth. Diethylstilbestrol is but little attacked by the liver and is therefore better suited for oral administration (M. I. Allen, 1941). Estrogens and androgens are absorbed very well from ointments applied to the intact skin; indeed, the effect of a given quantity is greatest by this channel, because the more gradual absorption maintains it longer in the blood (Zondek, 1935; C. R. Moore *et al.*, 1938). Full therapeutic effects may be obtained clinically by this method (U. Salmon, 1938).

Fate and Excretion.—After intravenous injection, the estrogenic hormones disappear rapidly from the blood (R. T. Frank, Goldberger and Spielman, 1932). With clinical administration, at most 20 per cent is excreted, chiefly by the urine (review, Doisy *et al.*, 1942). They are conjugated with glycuronic acid (Odell and Marrian, 1936). The conjugates are inactive physiologically, but activity may be restored by hydrolysis. Thiamine deficiency interferes with the hepatic destruction of estrone, even when no organic lesions of the liver are apparent (M. S. Biskind and Biskind, 1942). Because of the rapid elimination, the more slowly absorbed esters with fatty acids (benzoate, acetate, propionate) are relatively more efficient.

The **actions of the estrogen** consist fundamentally in stimulation of the anatomical development of the accessory female genital system: the vagina, uterus, uterine tubes (not the ovaries); and in stimulation of the excitability of the uterine muscle. These effects are associated with vasodilatation on the sex organs, demonstrated by Hechter *et al.*, 1941. By the specialized rapid growth promotion, injection of appropriate doses can bring immature female rats or mice with or without ovaries to the sexually mature condition in four or five days; so it is apparently responsible for puberty. As part of this action it induces the special *secondary female sexual characters*, such as the plumage of birds and the sexual swelling and reddening of certain monkeys. In mature females, it *induces estrus;* and as a part of this, the cornification of the *vaginal epithelium*, in a few days, which may be accurately followed by the types of cells in vaginal smears (Stockard and Papanicolau, 1917). The latter occurs also in human subjects. This is utilized for its biological recognition and assay. A slight increase of *basal metabolism* has been described (McClendon *et al.*, 1929; E. Lacqueur *et al.*, 1927); it is denied by others (M. M. Kunde *et al.*, 1931). Its continued administration causes the development of the *mammary duct system*, but extensive alveolar formation requires the anterior pituitary lactogenic hormone. The growth of the mammary ducts is due to a local action, for it is confined to one side by local application (review, W. E. Petersen, 1944). Estrogen does not stimulate the *ovaries* in any way; on the contrary, increase of estrogen tends to inhibit the production of gonadotropic hormone by the anterior pituitary gland, and long-continued administration is said to decrease their size. The *motor excitability of the uterus* is increased and it is sensitized to pitocin (Bourne and Burn, 1928; Scarborough, 1928). S. R. M. Reynolds, 1938, attributed the hyperemia of the uterine tissue and its increased motor excitability in part to liberation of acetylcholine in the uterus. The actions of estrogen and progesterone are partly antagonistic; changes in their equilibrium are largely responsible for the phenomena of the female sexual cycles.

Excessive doses of theelin (at least up to ten times the therapeutic dose) do not appear to produce directly toxic effects, according to most observers (E. Laqueur and de Jongh, 1928; J. A. Morrell *et al.*, 1930), but long-continued injections may induce hyperplastic and then metaplastic changes in the uterus, cervix and breast.

Large doses, at least 70,000 I.U., inhibit the menstrual cycle by inhibiting the gonadotropic secretion of the anterior pituitary, thereby preventing the development of the corpus luteum and the formation of progesterone. Still larger doses, more than 600,000 I.U., may cause glandular cystic hyperplasia of the uterine mucosa. With 6,000,000 I.U. administered during sixty days, functional castration resulted, by preventing the ripening of the follicles. The cervical glands were markedly enlarged and the portio developed a large papillary, but not carcinomatous, erosion. The anterior pituitary reacted with marked increase of eosinophile cells. Other endocrine glands appeared normal (Zondek, 1940). The anterior pituitary also showed histologic indications of hypersecretion on implanting stilbestrol or hexadiene into immature rats (C. L. Foster, 1942). Prolonged administration of theelin with 100,000 to 200,000 rat units in divided doses over two or three months (Mayer, Meranze and Israel, 1935) produced no appreciable change in body weight, basal metabolism, blood pressure, blood count, coagulation or bleeding time. Sometimes there was a secondary delay of menstruation, probably by inhibition of the anterior pituitary. A few showed growth of mammary glands and increased libido.

Relatively large doses in *rabbits* showed no macroscopic changes in the vital organs. The response of the ovaries to huge doses was sometimes stimulant, sometimes degenerative. Very prolonged administration (five to eight months) to female rats has an unfavorable tendency on fertility, gestation and lactation (Wade. 1934).

Carcinogenic Activity.—Several investigators have produced mammary cancer, pituitary hypertrophy, adenomas and carcinoid changes in the vagina and uterus, and sarcomas, all in mice, and cervical growths, possibly precancerous, in monkeys (Geschickter *et al.*, 1934; Witherspoon, 1935; W. U. Gardner *et al.*, 1936; review E. Allen, 1942), raising the question of the possibility of causative connection with human mammary, uterine and prostatic tumors. This enjoins caution in the clinical use, although these experimental effects require doses of estrogen enormously greater than are used clinically (Doisy, 1937). Geist and Salmon, 1941, who made biopsy studies of vaginal and endometrial changes during prolonged administration in a large group of women, found no indication of genital carcinoma even with doses that added to 53 million international units. The very large doses administered by Zondek, 1940, did not result in cancer in these women; but individual susceptibility varies greatly, even in animals.

Intersexuality.—Administration of large amounts of estrogens to pregnant rats results in intersexed or feminized male offspring (R. R. Greene, Burrill and Ivy, 1938). Similarly, androgen administration yields masculinized female offspring (Greene and Ivy, 1937).

Effects of Estrogenic Substances on Males.—Prolonged administration of theelin to *mature male* rats somewhat retards their body growth and decreases the weight of their genitalia, but the reproductive capacity remains normal (Wade, 1934). Beuthner and Fals, 1928, found no change in mature males, with their dosage, but immature males reacted with degenerative changes in the testicles, with recovery on discontinuance. Laqueur, 1932, observed more marked "antimasculine" changes, including impeded development and degeneration of the testicles and atrophy of the secondary characteristics, including the seminal vesicles; but in castrated animals, menformon promoted the development of the seminal vesicles.

Prostatic carcinoma is sometimes strikingly improved by administration of estradiol or diethylstilbestrol, as by castration or irradiation of the testicles. The extension of the tumors is slowed, and the clinical symptoms are relieved, so that life is more comfortable in half of the patients, although no cure has yet been reported (C. L. Deming, 1946). The mechanism is obscure (W. P. Herbst, 1942).

Ovipositor Reaction of Bitterling.—The injection of estrogen into this fish (Rhodeus amarus), or its addition to the water in which the fish is kept, produces marked enlargement of the ovipositor (Fleischmann and Kann, 1932). The reaction also follows administration of the urine of pregnant women (A. E. Kanter *et al.*, 1934), and of adult males. The latter is probably due to corticosterone of the adrenal cortex, which gives the same reaction. It is not produced by anterior pituitary extract (Fleischmann and Kann, 1938).

Skeleton and Blood Calcium Level.—Injection of estrogenic hormones or diethylstilbestrol into birds raises the level of serum calcium and accelerates the formation of endosteal bone. The latter is probably due to stimulation of the osteoblasts, not to the calcium increase. There is also a large rise in blood lipid phosphorus and increased excretion of phosphate released from the bones (W. U. Gardner and Pfeiffer, 1945). The oviducts also show increased growth (M. R. McDonald, Riddle and Smith, 1945). The breakdown and ossification of growing cartilage is accelerated by estrogens (M. Silberberg and Silberberg, 1939). In mice, estrogens produce hypercalcification of the skeleton, with partial or complete obliteration of the marrow cavity. This is prevented by the simultaneous administration of testosterone (W. W. Gardner and Pfeiffer, 1938).

Lipemia.—Long-continued injections of large doses of estrogenic hormones into roosters greatly increase the fat content of the blood, by the mobilization of tissue fat. Other sterols lack this action. It is not mediated through the anterior pituitary gland and does not occur in mammals (Zondek and Marx, 1939).

Anesthetic Effects of Steroid Hormones.—Intra-abdominal injection of sufficient doses of all steroid hormones and of stilbestrol derivatives produces depression and loss of consciousness, which Selye and Heard interpret as "anesthesia"; but D. B. Farson *et al.*, 1946, who produced analogous effects with intravenous injection of cholesterol suspensions, report that response to pain persists. Daily injection of the steroid hormones rapidly induces tolerance, which extends to the other derivatives. The action is stronger in vertebrates with relatively lower nervous development. Invertebrates are completely resistant (H. Selye and Heard, 1943).

Antagonism to Alcohol Narcosis.—The susceptibility of female rabbits to the acute narcotic effects of alcohol is increased by castration, and decreased by administering estrone, so that a higher blood level of alcohol is necessary (L. Goldberg and Störtebecker, 1943).

Root growth of lupine seedlings is stimulated by estrone, 1:200,000, inhibited by progesterone. Diethylstilbestrol is slightly inhibiting (D. I. Macht, 1946).

The therapeutic use of estrogens in gonorrheal vulvovaginitis of children was suggested by R. M. Lewis, 1933, to render the soft epithelium cornified and more resistant, as is the adult vaginal epithelium. Good results were reported from intramuscular injections of 200 international units, 0.1 mg. of estrone, every second or third day, or vaginal suppositories of 2000 units (Mazer and Schechter, 1939), until the smears are negative. This treatment, however, has been generally abandoned, as further experience has shown that the gonococci are not killed, and the estrogenic effects on the child (engorgement of the breasts, growth of pubic hair; J. J. Reichert *et al.*, 1937) are undesirable, although they usually return to normal promptly on cessation of the injections. Experience with monkeys indicates that the ovaries are not damaged by the treatment (Doisy, 1937, review). It is probably more useful in senile vaginitis. Up to 5 mg. (50,000 I.U.) weekly may be required. Beneficial results have been reported from injections of estrogenic hormones in *atrophic rhinitis* (Mortimer, Wright and Collip, 1937; Blaisdell, 1938); but Soskin and Bernheimer, 1939, attributed the improvement to vasodilatation by increase of acetylcholine.

Treatment of Menopause Symptoms.—Administration of estrogens generally decreases materially the phenomena of natural and surgical menopause and helps substantially to tide over the period of adjustment. The nervousness, fatigue and mental depression, the number and intensity of the vasomotor crises, the "hot flashes" and the decrease of basal metabolic rate are improved within ten days. The vaginal epithelium also returns to the natural menstrual type. When the administration is omitted, all the phenomena recur; but with long-continued administration they become gradually less (Papanicolaou and Shorr, 1936; Mayer and Israel, 1937; Collett *et al.*, 1937; Doisy, 1937, review). The dosage must be adjusted by the results; 250 to 1000 units of estrone or estriol per day generally suffice. Oral administration of either estrone or estriol gives probably as good results with equal dosage as do intramuscular injections, and the effects are more lasting. Large doses sometimes cause considerable uterine bleeding.

The basal metabolic rate of castrated women is disturbed by the administration of estrogenic hormones. Small doses, 500 to 1000 I.U. of estrone, produce a prompt and fairly large increase of the B.M.R.; larger doses, 1000 to

2000 I.U., result in less rise or in fall of B.M.R. (Collett, Reed *et al.*, 1940).

The *electro-encephalogram* in post-menopausal mental patients is not changed by stilbestrol or progesterone (Cress and Greenblatt, 1945).

The *use of estrogens in dysmenorrheas of various kinds* is generally not advisable. They would need to be adapted to the varying balance of estrogen and other sex hormones, which is not feasible (review, Novak, 1934).

Acne and hypertrichosis have been treated with estrogenic substance, but this has not been very successful and should not be used unless there is other evidence of ovarian disturbance (L. M. McCarthy and Hunter, 1937).

Termination of pregnancy may be induced in rats through estrogenic injection, by the stimulation of uterine contractions. Estrone, administered before implantation, caused hyperplasia of the mucosa and fibrosis. If it was given at various stages after implantation, the embryos were killed, without necessarily damaging the uterus (D'Amour and Gustavson, 1934).

Hemophilia.—Estrone has been tried with the assumption that the immunity of women to this condition may be due to the female sex hormone (Grant, 1904; Birch, 1931). The theoretical basis was not sound, since the immunity is supposedly a chromosome characteristic, which would not be affected by hormones. Careful trials on seven hemophilic patients were entirely unsuccessful; nor did the urines of untreated patients show any deficiency in estrogenic hormone (R. B. Stetson and associates, 1934).

L. Loewe and Lenke, 1938, failed to confirm the claim that theelin protects rats against *peripheral gangrene* induced by ergotamine.

Cutaneous administration of estrogenic hormone as ointments has about a seventh of the potency of injections; the absorption is much better from solutions in benzene, ether or alcohol (Zondek, 1938). If the ointment is applied to the breast it acts particularly at this site, but requires doses which also have systemic effects (MacBryde, 1939).

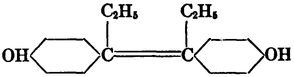
Ethinyl estradiol is effectively absorbed through the skin of rats, when applied as alcoholic solution (C. F. Morgan and Ponzio, 1944).

Preparations.—*Estradiol*, U.S.P.; alpha estradiol; dihydrotheelin; a white, crystalline powder, odorless and tasteless; stable in air; almost insoluble in water, soluble in alcohol and in aqueous solutions of fixed alkalis, sparingly soluble in oils. Average dose, 0.2 mg. *Estradiol Benzoate*, U.S.P.; almost insoluble in water, soluble in alcohol, sparingly soluble in oil. Average dose, 1 mg. intramuscularly, once or twice per week. *Estriol* (*Theelol*), N.N.R.; characters and solubility as for estrone; considerably less potent. Marketed as capsules of 0.06, 0.12 and 0.24 mg. Dose, 0.06 to 0.12 mg. once to four times daily. *Estrone* (*Theelin*), U.S.P., small white, odorless crystals, practically insoluble in water, soluble in alcohol and in oils. One mg. = 10,000 International Units. Marketed in ampuls of oil solutions, 0.1, 0.2 and 1 mg., and suppositories of 0.02 and 0.2 mg. Dose, 0.2 to 1 mg. once or twice a week. *Commercial noncrystalline preparations* from the urine of pregnant women or pregnant mares or placental extracts contain chiefly estrone (S. C. Freed, 1941). Several brands of these *Estrogenic substances* are listed in N.N.R.

DIETHYLSTILBESTROL

Diethylstilbestrol, triphenyl-ethylene and a number of other synthetic substances of relatively simple structure, not containing the phenanthrene ring, produce all the effects of the natural estrogenic substances and are clinically effective for replacement therapy in menopause, to secure cornification of vaginal epithelium (Russ and Collins, 1940), to inhibit lactation, to check obstruction and metastases in prostatic carcinoma (B. G. Clark and Viets, 1943), and for the other uses of estrogenic substances; with the advantage that stilbestrol is effective by mouth as well as by parenteral injection (with a potency ratio of 1:2 to 5). Undesirable side actions, especially nausea, vomiting and headache, occur rather frequently if the absorption is too rapid. They do no permanent damage. The toxicity is probably no greater than with the natural astrogens.

Diethylstilbestrol,



sometimes misnamed *stilbestrol*, was introduced by E. C. Dodds, Goldberg *et al.*, 1938. It is potent by mouth and parenterally, since relatively little is inactivated by the liver (M. J. Allen and Greengard, 1941; B. Zondek *et al.*, 1943). It is about two and a half times more potent than estrone by injection in animals. Clinically it is less active than estradiol benzoate parenterally, but surpasses it by mouth, losing about half of its activity by this method (review, Council on Pharmacy and Chemistry, 1939; J.A.M.A., *113*:2312). In ten days following a single oral dose of 10 to 15 mg., 10 to 30 per cent is *excreted* by the urine and feces (von Haam *et al.*, 1940).

Numerous derivatives have been examined for correlation of action and *chemical structure*. The most potent have two rings, at least one benzenic; and two OH groups at opposite poles of the molecule (G. Masson, 1945).

Clinical Effect on Lactation.—Diethylstilbestrol effectively prevents or minimizes breast pain and engorgement, if 15 mg. are administered by mouth, promptly for three to ten days after parturition. Lactation is delayed and decreased, but not permanently suppressed even by very large doses (H. F. Connaly *et al.*, 1940; Abarbanel and Goodfriend, 1940). However, estrogenic hormones are now rarely used for this purpose. Prolonged administration of 5 mg. daily *to males* may produce marked mammary enlargement and diminution of sexual function, without other toxic effects, probably by depressing the pituitary gonadotropic secretion (C. W. Dunn, 1940).

The clinical toxicity is not materially greater than with natural estrogens. Indeed, massive and prolonged administration to pregnant or nonpregnant women does not produce serious toxic effects (K. J. Karnaky, 1945). Ten to 20 per cent of patients have minor untoward symptoms, corresponding closely to those of the nausea of pregnancy, and occurring especially with the larger doses and in women who were much nauseated when pregnant (J. W. Finch, 1942): nausea, vomiting, headache, abdominal distress, anorexia, diarrhea, lassitude, paresthesias, vertigo, thirst, acute psychotic reactions, cutaneous rashes, angioneurotic edema (W. Saphir and Weinglass, 1942). They occur on parenteral as well as oral administration. They are attributable to rapid absorption and individual susceptibility (S. C. Freed, 1941). Patients can usually be quickly desensitized by reducing the doses to 0.1 mg. per day and increasing by 0.1 mg. every five or six days until the therapeutic level is reached (Finch, 1942). Abnormal uterine bleeding is rather frequent when diethylstilbestrol is administered at menopause, and it is advisable to use it only when really needed (E. Novak, 1944).

Large doses (330 mg. by mouth in seven days) do not appear to interfere with the progress of human pregnancy, although they may do so in animals by eliminating the action of the pituitary gonadotropic hormone on the corpus luteum (Zondek and Bromberg, 1942). No tissue, liver or blood damage has been demonstrated clinically, even with prolonged administration (von Haam, Hammel *et al.*, 1940), and with large doses (10 mg. daily) to women who had previously some liver dysfunction (S. C. Freed, Rosenbaum and Soskin, 1940). It appears inadvisable to administer extensive courses to patients with a cancerous family history (Buxton and Engle, 1939).

Toxic Effects on Animals.—Dogs (O. Arnold and Hamperl, 1939), rats and rabbits may show blood and organ changes, cloudy swelling, congestion and necrosis of the kidneys, liver and adrenals. Mice die in ten to sixteen days after administration of 0.1 to 1 mg. per Gm.; rats die in an hour after 1.5 to 5 mg. per Gm. (Krietmair and Sieckmann, 1939). Rats have decreased appetite; nasal, vaginal and intestinal hemorrhages; fatty degeneration of the liver with subsequent necrosis; and other lesions (A. Loeser, 1939). Disturbances of the myelogenic system, with granulocytopenia and anemia, have been reported in dogs (R. Tislowitz, 1939). Intravenous injection of 10 to 20 mg. into dogs produces prompt increase of capillary fragility and purpura. This is cured by alpha tocopherol (F. Skinner *et al.*, 1946).

Secretory exhaustion of the anterior pituitary with cytoplasmic vacuolization has been described for immature rats (C. L. Foster, 1942). No carcinomas were observed after implantation of large doses in rats (C. R. Page *et al.*, 1941). Male mice showed retarded growth, atrophy of the viscera, especially the spleen; decreased spermatogenesis, and mammary cancers (Shimkin and Grady, 1941).

Intramuscular injections for twenty-four days did not induce hypertension in rats (H. C. Hill, 1946).

Diabetes is produced in rats by the administration of the stilbestrols in large doses. The hepatic glycogen is markedly increased (R. S. Teague, 1942), as is also the insulin content of the pancreas in rabbits (M. Griffiths, 1942). It is mediated partly but not altogether through the adrenals and anterior pituitary. It occurs after partial pancreatectomy (D. J. Ingle, 1944).

PREPARATIONS.—**Diethylstilbestrol**, U.S.P., a white, crystalline powder, slightly soluble in water and dilute mineral acids, soluble in dilute alkalis, alcohol and fat solvents. Dosage, 0.2 mg. (1/300 grain), increased to 0.5 to 1 mg. daily by mouth; or similar doses one or more times weekly by intramuscular injection. Administered orally as *Diethylstilbestrol Capsules* and *Tablets*, U.S.P., usually available as 0.1, 0.5 and 1 mg.; intramuscularly as *Diethylstilbestrol Injection*, U.S.P., a sterile solution in oil or other suitable solvent, usually available in ampuls of 0.5 mg. and 1 mg. in 1 cc. *Vaginal suppositories* (0.1 and 0.5 mg.) may be used in vaginal conditions. *Subcutaneous implantation* of a cylindrical pellet of 50 mg. of crystalline diethylstilbestrol yields a constant daily absorption of 0.35 to 0.45 mg. for about a hundred days. Two or three such pellets are implanted for palliation of prostatic carcinoma (Shimkin and Zon, 1943).

Diethylstilbestrol esters are more slowly absorbed, securing the advantage of more prolonged and less intensive action. The *dipalmitate* is superior to the dipropionate in this respect (S. C. Freed *et al.*, 1942). *Monomethyl ether* (*Monomestrol*, N.N.R., *Mestibol*) has also been proposed (Geschickter and Byrnes, 1942).

Hexestrol, dihydro diethylstilbestrol, $(C_6H_4OH)_2$-$(CHC_2H_5)_2$, has the same action as diethylstilbestrol with the doubtful claim of lower incidence of toxic symptoms (Bieren and Compton, 1942).

Benzestrol, N.N.R., *Octofollin*, $(C_6H_4OH)_2.(C.H.C_2H_5)_2$-$(CH.CH_3)$, a dihydromethyldiethylstilbestrol, also has the actions of diethylstilbestrol with the claim of fewer untoward actions (H. K. Roberts *et al.*, 1943; E. W. Blanchard *et al.*, 1943). Dosage, 2 to 5 mg. daily by mouth, as tablets (available as 0.5, 1, 2 and 5 mg.); or an injection (available as 5 mg. in 10 cc.).

Triphenylethylene and **Triphenylchlorethylene** are also estrogenic (J. M. Rolson and Schönberg, 1937; A. E. S. Macpherson and Robertson, 1939).

ANDROGENIC HORMONES

A number of steroids closely related chemically to the estrogenic hormones are masculinizing, inducing growth and development of the genital organs of the male, including the secondary sexual characteristics. They counteract the effects of castration in the male, the atrophy of the seminal vesicles, prostate and penis and the diminished libido. In capons they induce growth of the comb and the characteristic male plumage (review, F. C. Koch, 1937). They circulate in the blood of males, and in lower concentration in that of females, but the human male does not show hormone cycles. Their administration constitutes adequate replacement therapy in true testicular deficiency (eunuchism), but their practical applicability has not been determined. This applies also to their use in cryptorchidism. Their influence on prostatic enlargement is questionable. They have little or no effect on senile or psychic impotence, or as aphrodisiac.

Chemistry.—The most important of the androgenic hormones is *testosterone*, a steroid secreted presumably by the interstitial cells of the testes, now generally prepared synthetically as *testosterone propionate*, since the fatty esters are more slowly absorbed from the site of injection and therefore produce a more continuous action. This is also effective on percutaneous application (report, Council on Pharmacy and Chemistry, 1939, J.A.M.A., *112:* 1949).

The *androgenic hormones of male urine* consist chiefly of *androsterone* and dehydroandrosterone, which have relatively little action on mammalian sex tissues. They are excreted as glycuronides which are much less potent and from which they can be easily liberated by acid hydrolysis (review, F. C. Koch, 1938). The urinary androgenic hormones are probably derived from testosterone, which is not found in the urine. When it is injected, it is excreted chiefly as androsterone (Dorfman *et al.*, 1939). *Dehydro-androsterone* is isomeric with testosterone. The chemical structure of androsterone differs from that of estrone only by the addition of a methyl group. It was isolated as pure crystals from human male urine by Butenandt and Tschorning, 1931, and synthesized from cholesterol by Ruzicka, Goldberg *et al.*, 1934. The androgenic hormones of the urine of women have not been isolated sufficiently pure for identification. *Other androgenic hormones* have been found in abnormal conditions, such as hirsutism, and are perhaps formed in the adrenal cortex. Androgenic actions have been demonstrated in some fifty natural and synthetic substances. *Quantitative differences of androgenic* potency exist in normal and abnormal urines of men and women, but are not so great as might be expected (F. C. Koch, 1938).

Effects on Males.—Administration of the androgenic hormones to castrated males prevents and repairs the castration effects. These hormones are recognized and assayed by increasing the *comb growth* in capons (also in hens), restoring the male *plumage pattern*, and the aggressiveness. The effect on the comb is also secured by local application (0.5 gamma of androsterone daily, S. R. Hall and Dryden, 1939). It is antagonized by the local application or injection of estrogen and progesterone; diethylstilbestrol inhibits only on injection (Mühlbock, 1939). Conversely, testosterone, androsterone and progesterone (but not desoxycorticosterone) inhibit the atrophy of male organs by chronic estriol treatment. This action does not parallel the effect on castrates (Albert and Selye, 1942). The androgenic hormones prolong the life and motility of the *spermatozoa* in the seminal vesicles of castrates. In guinea pigs they cause general *muscular hypertrophy*, especially of the temporal muscles (which are normally more developed in males; Papanicolaou and Falk, 1938). They do not stimulate *spermatogenesis*, but rather diminish it by inhibiting the *gonadotropic* function of the *anterior pituitary gland* (review, P. R. Moore, 1934). Injections of testosterone propionate or acetate produce partial or complete regression of *breast hypertrophy* in males (W. J. Hoffman, 1939). They slowly darken the *color of the skin and hair* in castrated men and ovarectomized women (J. B. Hamilton and Hubert, 1939). They tend to produce *descent of the testicles* in cryptorchidism, but are less effective than the gonadotropin of pregnancy urine; they cause frequent erections, growth of the penis, scrotum and pubic hairs (Zeithaml, 1938); and may damage spermatogenesis (C. R. Moore, 1935; W. O. Thompson and Heckel, 1939). Favorable results in "male climacteric" were reported by A. A. Werner, 1939. Vest and Howard, 1939, claimed good results from implantation of testosterone crystals in hypogonadism.

Prostate.—Androgens increase the prostatic secretory epithelium (E. Z. Burkhart, 1939), and excessive doses produce hyperplasia. Estrogens have the opposite effect. This is the basis of the treatment of prostatic cancer by castration and estrogens. Nearly all patients show improvement, often prolonged (C. Huggins, 1943).

The effects of testosterone and estradiol esters on the *resistance to barbiturates* has been studied in rats by H. G. O. Holck *et al.*, 1942.

Effects on Females.—Moderate doses act like estrogenic hormones, but are much less potent. They accelerate the growth and development of the uterus in immature rabbits and cornify the vaginal epithelium in spayed rats (Deanesley and Parkes, 1937). On the other hand, testosterone acts like weak progesterone in that it inhibits contractions of the uterus and renders it irresponsive to pitocin (Leonard, Lager and Hamilton, 1937); it inhibits the onset of menstruation in monkeys (Hartman, 1937), and causes some progestational proliferation, but much less than progesterone (J. Robson, 1937). It produces development of mammary acini in virgin rats (G. L. Laquer, 1943). It tends to suppress estrus by inhibiting the gonadotropic function of the anterior pituitary gland. The administration of large doses to pregnant rats results in intersexed female offspring; *i.e.*, considerable development of the male sex organs and defects in the female organs (R. R. Greene and Burrill, 1938).

Clinically, testosterone propionate has no effect in doses of 200 mg. per month; but with 500 mg. or more per month, it causes temporary suppression of the menstrual cycle, hypoplasia of the endometrium and evidence of estrogen deficiency in the vaginal epithelium. Recovery ensues if the administration is discontinued. Larger doses produce hoarseness, hirsutism, enlargement of the clitoris, acne and increase of weight; these also regress in almost all cases with cessation of the administration (Geist, Salmon *et al.*, 1940). It has been administered to suppress abnormal uterine bleeding in doses of 400 to 2000 mg. per month (J. P. Greenhill and Freed, 1939). It *inhibits lactation* during early puerperium, without the usual pain and discomfort and without undesirable after-effects (Kurzrock and O'Connell, 1938). Hypodermic injections of 25 mg. daily for two or three days suffice if started with the beginning of lactation (not before nor after this time); 5 to 10 mg. relieve the pain of engorged breasts without diminishing secretion (P. V. Duffy and Corsaro, 1941).

PREPARATIONS.—*Testosterone Propionate*, U.S.P. ("perandren"), is the most effective androgenic hormone available for clinical use (S. C. Freed, 1941). It is prepared from bull testes, or synthetically from cholesterol. It is insoluble in water, soluble in alcohol and in oils. One mg. equals 50 International Capon Units. Dosage, 5 to 50 mg., intramuscularly in oil, twice to six times per week. Priapism indicates excessive dosage. Marketed in ampuls of 5, 10 or 25 mg., as oil solution. *Methyltestosterone*, U.S.P., is more potent for oral or sublingual administration (50 to 100 mg. daily; editorial, J.A.M.A., *117*:622, 1941). It is a white crystalline powder, insoluble in water, sparingly soluble in vegetable oils. *Methyltestosterone Tablets,* U.S.P.; usual sizes, 5 and 10 mg.

PROGESTERONE

This, the characteristic hormone of the corpus luteum, produces the extensive development and the secretory activity of the uterine mucosa which are necessary for the implantation of the ovum. Its suppression by excision of the corpus luteum during early pregnancy prevents nidation of the fertilized ovum; or if already implanted, the pregnancy does not proceed to conclusion. Its injection is effective after ovariectomy in producing the endometrial changes of the premenstrual period in women and monkeys, and the pregnancy changes in rabbits and guinea pigs. Progesterone also quiets the spontaneous movements of the uterus (Reynolds and Allen, 1932) and inhibits the response of the uterus (rabbit's excised) to posterior pituitary stimulation (Knauss, 1933). This is probably essential to the continuation of pregnancy, especially to overcome the estrogen which stimulates the uterine motor activity. Small doses administered intravenously during labor decrease uterine activity, but large doses increase the strength and frequency of the contractions (H. Winzeler, 1944). It activates the growth of the mammary alveolar tissue. Its formation in the ovary begins soon after the discharge of the ovum and continues through the first three months of gestation; after this time it is formed by the placenta. It is not established how far progesterone is concerned in other relations of the corpus luteum to sexual functions.

Therapeutic indications for progesterone are not well established. It has been administered in menstrual disorders, amenorrhea (B. Zondek, 1942), habitual functional abortion and menstrual nasal congestion (Willson-Pepper and Royle, 1939).

Progesterone prevents copper-induced *ovulation* in rabbits (M. H. Friedman, 1941). It has no effect on the emptying time of the *stomach* in normal man (Sleeth and Van Liere, 1940).

Chemical Nature.—The characteristic effects were shown on crude extracts by Hisaw, Meyer and Weichert, 1928. Progesterone was isolated in pure crystalline form independently, about 1934, by W. M. Allen, by Butenandt and by Slotta. These and Corner, who was instrumental in its discovery, all agree upon the title "Progesterone" to displace the older titles of corporin, progestin and luteosterone. It is also a steroid, which differs chemically from androsterone only by the addition of a third methyl and a second ketone oxygen in place of a carboxyl (W. M. Allen and Wintersteiner, 1934). It has been synthesized by Butenandt, starting from stigmasterol, a wax obtained from soy beans and from the "pregnandiol" fraction of pregnancy urines. It occurs in two forms differing by a few degrees in melting point. Both forms produce all the typical progesterone actions (W. M. Allen and Reynolds, 1935).

Progesterone is not *excreted* as such, but as a reduction product, pregnandiol, conjugated with glycuronic acid, which is found in the urine of pregnancy and during the corpus luteum phase of the cycle (Marrian, 1939). It increases the urine output of cats (Selye and Bassett, 1940).

Pure *synthetic progesterone* is commercially available. It is not well absorbed from the digestive tract, and is partly destroyed by the liver (G. Masson and Hoffman, 1945), so that it is not very effective by mouth. It is administered hypodermically, generally in oil solution. *Anhydrohydroxyprogesterone* is effective by mouth.

Progesterone, U.S.P.; practically insoluble in water, sparingly in vegetable oils, soluble in alcohol. Average dose, 5 mg. intramuscularly. *Anhydrohydroxyprogesterone,* U.S.P.; average dose, 10 mg.; *Tablets,* U.S.P.; usual sizes, 5 and 10 mg.

◆

HORMONES OF THE ADRENAL CORTEX

The adrenal cortex is a distinct organ with endocrine functions, elaborating a group of steroids closely related to the sex hormones in structure and, to some degree, in action. Degeneration of the adrenal cortex results in the clinical syndrome of Addison's disease. Its complete removal, in animals in which this may be accomplished, produces no perceptible symptoms for about a week; then the animals rather suddenly develop anorexia, lethargy, muscular weakness, hemorrhagic gastro-enteritis, shock, anhydremia, hypoglycemia, hypercalcemia, and die in one to three days after the onset of the symptoms.

These effects are prevented or checked by the administration of the adrenocortical hormones.

The *time of survival after excision of both suprarenal glands* varies with different animals. With the best operative technic, dogs usually live longer than a week, many survive for ten to twelve days, a few to fourteen days, but practically none longer. Cats generally live one to two weeks, a few three weeks. Guinea pigs die in about a week. Rats vary, but more than half survive indefinitely, presumably by having accessory "interrenal" tissue in other situations (G. N. Stewart, 1926). The *salt content of the diet* has important effects on the survival time. *Pregnancy* prolongs survival, as does also the administration of *anterior pituitary extract* and *progesterone.* Estrogen shortens life. *Partial adrenal deficiency* has been produced in cats and dogs by subtotal ligation of the blood supply. The animals survive four to six months, with acute phenomena and exacerbations, similar to those of

Addison's disease (Rogoff, 1933). *Addison's disease* is a clinical syndrome accompanying degeneration of the adrenal glands. Aside from progressive melanin pigmentation of the skin and buccal mucosa, its phenomena are subacute manifestations of those described for removal of the adrenals: loss of appetite, muscular asthenia and, toward the end, vomiting, diarrhea, cardiac weakness, fall of blood pressure and various neurologic symptoms. It is markedly subject to occasional spontaneous remissions and exacerbations.

Active Constituents.—Five closely related steroid compounds important to life have been isolated from the adrenal cortex. The most important are corticosterone and desoxycorticosterone, the latter being closest to progesterone. The amorphous fraction is also potent. The sex hormones are present in small amounts; also a thyrotropic hormone, and a considerable amount of ascorbic acid (Györgi, 1929). Epinephrine is absent. *Desoxycorticosterone* is the most potent contituent in maintaining life after excision of the adrenal gland, and in its effects on the electrolyte and water balance; but only minute quantities are present in the adrenals, so that it may not play the most important role.

Removal of the Experimental Deficiency Phenomena by Extracts of Suprarenal Cortex.—G. N. Stewart and Rogoff, 1925, were the first to prove that injection of saline extracts of suprarenal cortex secures the survival of animals after complete removal of both suprarenal glands. They designated the (unisolated) hormone as "*interrenalin.*" F. A. Hartman, 1927, called his saline extract "*cortin.*" J. J. Pfiffner and Swingle, 1929, used organic solvents for the extraction; and further improvements have resulted in considerable purification and concentration (Ehrenstein and Britton, 1937; G. Hunter and Cantor, 1937). The extracts may be standardized by bio-assay and are administered hypodermically. *Commercial extracts* are marketed under several names ("*eschatin,*" and so forth). They are sometimes quite ineffective (Rogoff, 1934).

Oral administration of cortical extracts is probably effective, but requires considerably (six to twelve times) greater doses; but in rats oral administration gives better results (Grollman and Firor, 1936). It is probably not advisable clinically, even to supplement the injections, for unless the medulla is removed from the gland immediately after death, the material is highly toxic and therapeutically ineffective. (A. Grollman and Firor, 1934).

Desoxycorticosterone is the most potent of the isolated constituents for maintaining life after adrenalectomy, but the amorphous fraction is almost equally potent. Corticosterone requires larger amounts.

The *cortical hormone concentration of the various animals* shows curious differences. Vars, Taylor and Pfiffner, 1934, reported the following "dog-units" per kilogram of gland: Mare, less than 165; horse, 1500; ox and dog, 2500; sheep and hog, 3500.

Clinical Efficiency in Addison's Disease.—Intramuscular injections of purified cortical extracts produce marked symptomatic improvement, especially in the early cases, although generally not so striking as in the acute deficiency of animals. Supplemented by sodium chloride administration, they are valuable for temporary alleviation of the crises. Their cost practically prohibits adequate continuous use, but it is doubtful whether they would postpone the final fatality indefinitely.

The effects of the injections are usually apparent within twenty-four to seventy-two hours and extend five to seven days after stopping the treatment. They are successively: (1) relief of the anorexia, nausea and vomiting; (2) reappearance of appetite and hunger sensation; (3) gain of weight, relief of fatigue, increase of strength and endurance; (4) apparent decrease of pigmentation (due to stretching of skin by dehydration, not to disappearance); (5) increased resistance to infection and to surgical procedures (Rowntree, Greene *et al.*, 1931; Harrop, Weinstein and Marlow, 1932). Hypertrophy of the breasts has been reported in the male patient during treatment with a cortex extract (R. A. Edwards *et al.*, 1938). This was presumably due to other hormones. *Adrenalectomy decreases the resistance of animals* to infections, toxins and many other poisons, excessive heat or cold, reduced barometric pressure, traumatic shock and, especially, severe burns. Injection of the extracts restores the resistance to morphine and histamine (Houssay and Marenzi, 1931) and tends to restore the other conditions toward normal; but effects on normal animals are doubtful (review, Swingle and Remington, 1944). The *gamma globulin* of the blood, the presumptive mother substance of the antibodies, is increased by administration of adrenotropic pituitary hormone or of the adrenal steroids (A. White and Daugherty, 1945). *Corticosterone* seems concerned especially with carbohydrate and other organic metabolism (review, Swingle and Remington, 1944).

Desoxycorticosterone.—It was isolated and synthesized by T. Reichstein *et al.*, 1937, and is used as the ester, *desoxycorticosterone acetate.* Daily hypodermic injection prolongs the life of adrenalectomized dogs, even with low NCl income; its omission precipitates the deficiency symptoms, which disappear when it is resumed (Thorn and Eisenberg, 1939). Its administration to patients with Addison's disease, on constant fluid and mineral intake, increases the plasma volume and the total Na and Cl of the plasma, and lowers the potassium level if this was high (Thorn and Howard, 1939). It has no significant effect on the *carbohydrate metabolism* in adrenal insufficiency (Britton and Corey, 1940). The cortical steroids act somewhat on the *sex organs.* This may be important in early life and is probably responsible for virilism, feminism and precocious puberty in patients with adrenal cortical tumors. Conversely, all the *sex hormones*, estrogenic, androgenic and progestational, cause some degree of Na and Cl retention; but only progesterone prolonged the life of male dogs after excision of the adrenals (Thorn *et al.*, 1937, 1938).

Electrolyte and Water Balance.—The phenomena of cortical deficiency depend largely, but not exclusively, on changes in the sodium metabolism. The principle disturbance is inability of the tubular epithelium to reabsorb sodium from the glomerular filtrate (H. E. Harrison and Darrow, 1939), resulting in large loss of this element by the urine, and decrease of the concentration of NaCl and $NaHCO_3$ in the blood serum. The excretion of water is increased, though not to the same degree as that of sodium. The depletion of this fluid from the blood and tissue spaces produces dehydration shock and oliguria. This is precipitated in Addison's disease patients and in adrenalectomized animals by salt restriction, and relieved by salt administration (review, R. F. Loeb, 1936). In compensation for the sodium loss, the urinary excretion of *potassium* is diminished in adrenocortical deficiency, and its concentration in the blood tends to rise (W. D. Allers, 1935). The rise in the K:Na ratio may be partly responsible for the deficiency symptoms (Zwemer and Truszkowski, 1936). Such individuals are hypersusceptible to potassium administration (E. C. Kendall and Ingle, 1937). *Administration of cortical extract to patients with Addison's disease*, or to adrenalectomized animals, promptly diminishes the excretion of sodium and of chloride and increases that of potassium, much more than in normal individuals. These effects are also produced by the isolated principles, especially by desoxycorticosterone; and by estrogens, progesterone and testosterone (F. A. Hartman, Thorn *et al.*, 1937; review, Swingle and Remington, 1944; J. P. Peters, 1944).

Impaired kidney function after removal of the adrenal cortex and in severe Addison's disease entails various other complex changes, including rise in blood urea, decreased phenolsulfonephthalein output, and in later stages retention of sulfate, phosphate and creatinine. The urea retention may occur before any clinical symptoms and while the urine volume is not decreased. Adrenalectomized animals are highly susceptible to *water intoxication* (Swingle, Parkins *et al.*, 1937), probably through inadequate urinary excretion, the ingested water being retained as extracellular tissue fluid (R. A. Shipley, 1945). In the later stages, dehydration is largely responsible for impairment of kidney function (E. K. Marshall and Davis, 1916). Support of diuresis by injection of isotonic *dextrose or glycerin solutions* somewhat defers death after adrenalectomy; but it is not comparable to sodium chloride (Marine and Baumann, 1927). Excision of the adrenals often lowers the *blood sugar level*, and the liver and muscle glycogen, especially when the food intake is poor. This is prevented by administering sodium chloride (C. N. Long *et al.*, 1940). It is probably due to deranged protein catabolism. The *oxidation of dextrose* is also disturbed, accounting partly for the muscular weakness. Adrenalectomy prevents the development of *fatty liver* after pancreatectomy, fasting or phlorhizin poisoning (Verzár *et al.*, 1938).

The electrolyte and water balance of normal animals is affected in the same direction, but not so potently, by *desoxycorticosterone*. This protects also against the effects of excessive water ingestion (R. O. Gaunt, 1943). Excessive doses are deleterious, even in adrenal deficiency, by retention of sodium and water and by loss of potassium, especially from muscle cells, leading to degeneration of cardiac muscle and electrocardiogram changes (W. Raab, 1942). Adrenal cortical extract and corticosterone have little effect on the normal balance (D. C. Darrow and Miller, 1942). Administration of desoxycorticosterone does not influence the course of *potassium auto-intoxication* by ureteral ligation (A. W. Winkler *et al.*, 1942).

Overdosage with desoxycorticosterone, especially if long continued, leads to increase of plasma volume, without tissue edema (Selye and Hall, 1943), but with polydipsia and polyuria, simulating *diabetes insipidus*, except that pituitrin is not fully effective (C. A. Winter and Ingram, 1943). Hypertension occurs clinically, generally returning to normal within two weeks after discontinuance (Perera *et al.*, 1944). Animals develop renal tubular hypertrophy and glomerular sclerosis (Selye and Hall, 1943). If de soxycorticosterone is given with sodium chloride, severe *motor disturbances* arise and progress to complete paralysis and death. They disappear on salt withdrawal, although the sterone is continued (Selye and Hall, 1943). Under certain conditions, rats develop polyarthritis resembling acute rheumatic fever, Aschoff bodies in the heart, and sometimes periarthritis nodosa (Selye, Sylvester *et al.*, 1944). Changes in the thymus and spleen are described by Selye, 1941. The *adrenal cortex* undergoes marked involution in male cats, but not in females (E. L. Sarasan, 1943); large doses of progesterone induce cortical involution in females, not in males; androgens much more readily in females. Estradiol produces marked hypertrophy, much more in males, inhibited by desoxycorticosterone, progesterone and testosterone (Selye, 1940). Desoxycorticosterone has *no carcinogenic action* in mice (Shimkin and Grady, 1941).

Pituitary adrenotropin controls the adrenal cortex as regards sugar, fat and protein metabolism, and to some extent its protective function against toxic substances, and probably its effects on muscle metabolism. It has apparently little effect on the electrolyte and water balance (H. G. Swann, 1940).

Lactation is completely inhibited by ablation of the adrenals and restored by cortical extract (J. L. Carr, 1931), but not by desoxycorticosterone (R. Gaunt, 1941).

Sodium chloride therapy of adrenocortical deficiency prolongs life after total excision of the adrenals (Stewart and Rogoff, 1925;

Marine and Baumann, 1927) and mitigates the nausea, fatigue and the other symptoms of Addison's disease, except the pigmentation. While it does not take the place of the hormone completely, it diminishes the requirements, possibly to the amount that the diseased gland can still manufacture. Usually some cortical extract must be given in addition to the salt. The latter should be administered in the dosage of 7 to 10 Gm. per day, in addition to what is normally taken in food (R. F. Loeb, Atchley and Stahl, 1935). Reduction of salt is likely to bring on a critical exacerbation. Potassium should be avoided.

Adrenalectomized rats develop a salt appetite, and this prolongs their survival time (C. P. Richter, 1936). Adrenalectomized dogs maintained by salt administration without hormone are hypersensitive to many substances not ordinarily toxic, and of course especially to potassium; so that 0.5 Gm. produces severe prostration. If the potassium income is increased gradually, considerable tolerance is established (Kendall and Ingle, 1937).

Mechanism of the Deficiency Symptoms.—The anhydremia and the change in the K:Na ratio are not an adequate explanation; for while the symptoms are in many respects analogous and are relieved by salt administration, nevertheless, the adynamia, hypotension, hypoglycemia, pigmentation, gastro-intestinal symptoms and neurologic disturbances are seen in Addison's disease patients when the sodium concentration of the blood is normal; and administration of cortical extracts to adrenalectomized dogs improves the symptoms strikingly before obvious changes occur in the urea, sodium or water content of the blood serum (Loeb and Atchley, 1937). Cortin maintains the life of adrenalectomized animals in the absence of the sodium-retaining hormone, in spite of the low plasma sodium (Hartman, Spoor and Lewis, 1939).

Capillary permeability, judged by Menkin's leukotoxin method, is inhibited by corticosterone, not by desoxycorticosterone; it is increased by estrone, diethylstilbestrol and progesterone (S. C. Freed and Lindner, 1941).

Therapeutic Use.—Extracts of adrenal cortex are used in the treatment of adrenal deficiency, 100 to 500 dog units per day for maintenance, 2500 to 5000 units in the crises, hypodermically, intramuscularly or intravenously. Oral administration is effective, but wasteful. The potency is assayed by survival of adrenalectomized dogs or rats (Cartland Kuizenga, 1936). Synthetic *desoxycorticosterone acetate* may be used as a reference standard (Grollman, 1939). This may also be employed clinically and is considerably cheaper than the extracts, especially if pellets are implanted under the skin (Thorn and Firor, 1940); a single implantation supplies the hormone for eight to twelve months. The supplementary sodium chloride income must be carefully regulated, as excess of this or of the hormone produces edema. *Histamine shock* in mice and rats may be prevented most effectively by desoxycorticosterone acetate together with parenteral injection of saline solution; treatment of established shock is much less successful (Perla *et al.*, 1940). *Traumatic and hemorrhagic shock*, however, is neither prevented nor mitigated by adrenal cortical preparations (K. A. Huizenga. Brofman and Wiggers, 1943; Swingle *et al.*, 1943). Venous limb occlusion shock is reported to give better survival with desoxycorticosterone acetate than with cortical extracts (I. H. Shleser and Asher, 1942).

Desoxycorticosterone acetate, U.S.P., is a white crystalline powder, practically insoluble in water, slightly in vegetable oils, sparingly in alcohol.

RENAL HYPERTENSIVE SUBSTANCE

The frequent clinical coincidence of renal vascular disease and hypertension suggests a causal relation, and Harry Goldblatt confirmed experimentally that continued restriction of the blood flow of a kidney results in persistent high blood pressure. It occurs with denervated kidneys and is therefore not nervous but humoral. It does not occur if a kidney is excised, so that the substanec must be formed in the kidney, probably by excessive production of the *renin* of Tigerstedt and Bergmann, 1898, (not to be confused with rennin!), which is found in saline extracts of kidneys, normal as well as ischemic. This is a proteolytic enzyme, which is not itself hypertensive, but reacts with a blood globulin, "hypertensinogen," to form a thermostable pressor substance *hypertensin* (Fasciolo), or *angiotonin* (Page), which acts directly on blood vessels. This is continuously destroyed in the blood, in the body and *in vitro*, by an enzyme, *hypertensinase* or *angiotonin inhibitor* (review, H. A. Lewis and Goldblatt, 1942; I. H. Page, 1940; Fasciolo *et al.*, 1940; terminology, E. Braun-Menendez *et al.*, 1943).

Renin, as contained in saline extracts of normal kidneys, produces a prolonged rise of blood pressure when it is injected intravenously (Tigerstedt and Bergmann). It is not constrictive in perfusion of excised organs unless blood plasma has been added (B. Friedman *et al.*, 1938). Only a small amount of renin is needed in ratio to the plasma substrate. It is nondialyzable and is destroyed by heat. It may be replaced by pepsin. It is present in the kidneys of all warm-blooded animals, but not in cold-blooded. Human renin appears somewhat specific (Braun-Menendez *et al.*, 1943).

The *plasma substrate* (*prehypertensin, preangiotonin, precursor, activator*), which is proteolyzed by renin to form the active substance, is probably a pseudoglobulin, probably formed in the liver. It disappears gradually in adrenalectomized dogs and is restored by administration of adrenal cortical hormones.

The *pressor substance* itself ("*hypertensin*" of Braun-Menendez, "*angiotonin*" of Page) is formed *in vitro* as well as *in vivo* by the digestion of blood plasma with renin. It is a thermostable, dialyzable substance, which has been isolated as a crystalline picrate. It constricts blood vessels directly. Its effects appear identical with those of experimental renal ischemic hypertension and of clinical "essential" hypertension, but it has not been shown that it is increased in the blood of hypertensive patients (Braun-Menendez). It is *destroyed* within a few minutes after injection, and also *in vitro*, by an enzyme, *hypertensinase* (angiotoninase, antiangiotonin, angiotonin inhibitor).

Repeated intravenous injection develops refractoriness (tachyphylaxis; Tigerstedt and Bergmann, 1898) partly by exhausting the store of globulin precursor, but perhaps also by developing an inhibiting substance (Page and Helmer, 1939).

Response to Drugs.—The blood pressure of dogs rendered hypertensive by the application of the Goldblatt clamp for one to two and a half months, could not be kept down by administration of estrone, testosterone, extracts of liver, pancreatic or adrenal cortex, pituitrin, tyrosinase, mannitol hexanitrate, thiocyanate, bromide, veratrum viride, acetylcholine, nicotinic acid, mistletoe, garlic or parsley. Intravenous injection of kidney extract produced about the same rise as in nonhypertensive controls (Wakerlin and Gaines, 1940; H. Goldblatt, Kahn and Lewis, 1942).

Urinary Hypotensive Substances.—Intravenous injection of many urines produces an acute fall of blood pressure resembling that of histamine. Several active extracts have been described, differing quantitatively in the susceptibility of various animals, in heat stability, and so on (review, R. R. Rigler, 1938).

Kallikrein is a hypotensive, noncrystallizable, nondialyzable, organic constituent of human and especially dog's urine, of unknown composition, destroyed by boiling and by strong acids and alkalis and oxidizing agents. It occurs also in pancreatic juice, saliva and blood.

Depressan is a heat-stable hypotensive substance obtained from boiled human urine (Wollheim and Lange, 1932).

◆

NITRITES, NITROGLYCERIN AND OTHER ALKYL NITRATES

Nitrites, nitrous esters and organic nitrates which are reduced to nitrites in the body, lower the tonus of arterial muscle, producing prompt fall of blood pressure. The action is directly on smooth muscle, and is mutually antagonistic with epinephrine. These drugs are used for relief of arterial spasm and other conditions of high blood pressure. They form methemoglobin in the body and *in vitro*.

Members.—The group comprises the inorganic nitrites ($NaNO_2$), the nitrous esters (amyl nitrite, ethyl nitrite, "Sweet Spirits of Niter"), and substances which liberate the nitrite ion within the body. Most important among the latter is glyceryl trinitrate (nitroglycerin or glonoin), which is easily broken up by alkalis into a mixture of nitrates and nitrites; a similar change occurs in the body. Erythrol tetranitrate and mannitol hexanitrate undergo analogous decompositions, but much more slowly. Even inorganic nitrates are reduced to a slight extent (Binz, 1901), especially by the putrefactive bacteria of the colon, and may then give rise to the phenomena of nitrite poisoning; but this requires large doses such as the quantities of bismuth subnitrate used in roentgen diagnosis.

Reduction of Nitrates to Nitrites.—It is generally assumed that the organic nitrates act only after being reduced to nitrites; but excised vessels react promptly to these nitrates so that they may perhaps act directly. It is also remarkable that the effective dose of glyceryl trinitrate is but a hundredth of that of sodium nitrite. On the basis of available nitrite ion, the fatal dose of sodium nitrite for rabbits with intravenous injection is at least twice that of the glyceryl trinitrate (Olman and Crandall, 1931). Presumably the organic esters penetrate more readily into the cells, and perhaps the reduction occurs only after their penetration, for they may depress blood pressure without increasing the nitrite concentration of the blood (Rath and Krantz, 1942; C. R. Marshall, 1945).

Composition and Action.—The nitrates of monohydric alcohols are less effective than the polyhydric. Nitroglycerin and erythrol tetranitrate act quantitatively alike when equimolecular doses are injected into a vein; by mouth the action of the erythrol ester is weaker and more prolonged, because it is much less soluble and therefore more slowly absorbed (Marshall, 1913). Krantz, Carr *et al.*, 1939, investigated the *nitrates of a series of sugar alcohols* for vasodepressor action on dogs. Ether linkage was found to diminish the potency but to prolong the action. *Isomannide dinitrate* resists hydrolysis and has the advantage that it dilates the coronary vessels (beef, rabbit and dog) without producing methemoglobin.

The relation of action to the constitution of aliphatic nitric and nitrous esters is reviewed by W. F. von Oettingen, 1946.

The nitrites fall into two groups according to the relative dominance of the two chief actions: The *vasodilatation* predominates with alkyl nitrites and alkyl nitro-substitution products. The introduction of OH and CO_2H groups into organic nitrates diminishes their vasodilator action (C. R. Marshall, 1912). *Methemoglobin formation* predominates with amido compounds and with aromatic nitro-substitution products.

Aromatic Nitro-Substitution Products.—The introduction of NO or NO_2 into the ring or side chain of cyclic hydrocarbons increases the toxicity. The reduction of the NO_2 of nitrobenzene to NH_2 (aniline) diminishes the toxicity; this is further decreased by introducing alkyl into the amido group. Stimulation and then paralysis of the central nervous system are marked with the nitro compounds, less with the amido compounds.

Actions on the Circulation.—The most important effect of the nitrites is a prompt fall of blood pressure, due to vasodilatation by direct action on the blood vessels.

Vasodilator Action.—This is first noticed in the skin of the face, in an area similar to that involved in blushing, but which may extend over the entire trunk to the ilium.

The *meningeal vessels* undergo dilatation at the same time. There is consequently redness of the face, heat and throbbing in the head, and headache. The flushing of the skin is brief, although it may considerably outlast the return of blood pressure. The headache is likely to persist, especially with erythrol tetranitrate.

The dilatation does not, however, remain confined to the skin, but spreads to other vessels, and relaxation of the splanchnic area in particular causes a speedy *fall of blood pressure* and a dicrotic pulse. The fall of blood pressure is due entirely to the extensive vasodilatation produced by the direct action of the nitrite on the arterioles and venules. The vasomotor center is not inhibited, but rather stimulated by the cerebral anemia (Pilcher and Sollmann, 1914). The total return flow of blood to the heart, and the auricular pressure, are not altered (C. J. Wiggers, 1918).

With inhalation of amyl nitrite, the effects are complicated by reflexes from its stifling odor and by central narcotic actions (Dautrebande, 1932). There is generally at first some reflex (vagal) slowing of the heart; but soon the *heart is greatly quickened,* so that a rise of blood pressure is frequently observed at the start (Hewlett, 1906), the dilatation being more than overcome by the quickened beat.

Evidences of Vasodilatation.—The vasodilatation can be demonstrated directly by inspection (the blushing); by plethysmographic measurements (Dossin, 1911) and by increased rate of vein flow. The fall of pressure occurs equally well when the cardiac changes are excluded by atropine.

Effects on Vein Flow and Vein Pressure.—In man, Hewlett, 1913, found increase of the volume, but scarcely of the blood flow, of the arm. Stewart, 1915, showed increase of the blood flow of the hand. There are also definite changes in the "pulse flow" (the flow during the cardiac cycle.). These occur when therapeutic doses are given in arterial tension, even when the blood pressure readings are not reduced (Hewlett, 1917). Burton-Opitz and Wolf, 1910, on injecting nitrite into the femoral artery of dogs, found the vein flow and vein pressure increased in the corresponding leg, while the general arterial pressure was practically unchanged. If amyl nitrite was inhaled, the vein flow in the leg decreased with the blood pressure, because of the withdrawal of the blood into the more powerfully dilated splanchnic vessels. Capps, 1911–1913, also found a fall of vein pressure.

Circulatory collapse occurs when the subject is in an upright position, from doses of sodium nitrite which have practically no effect in a recumbent position. The collapse is pronounced when the maximal blood flow through the hand has fallen to 20–40 per cent of the normal value. This is accompnaied by marked fall of vein pressure (S. Weiss *et al.*, 1937). The primary action appears to be on the venous side of the circulation, and raising the vein pressure increases the organ volume more than in normal subjects (Wilkins *et al.*, 1937).

Site of the Dilator Action.—Vasodilatation occurs after ligation of the blood vessels of the brain (Mayer and Friedrich, 1875); after destruction of the spinal cord (Lauder Brunton, 1869); in excised organs (Atkinson, 1888; Marshall, 1898, and later); and in excised arterial segments (Cow, 1911). The perfusion method shows that the vasomotor center is more commonly stimulated. The dilator action is therefore peripheral. Nitrites also relax other smooth muscle, without reference to their innervation. The action is therefore presumably directly on the contractile substance.

Antagonisms.—Nitrites are mutually antagonistic with most vascular constrictors: splanchnic stimulation (Bernheim, 1874), epinephrine, strophanthin, and others, raise the blood pressure during the nitrite fall; and conversely, nitrites lessen the rise of these constrictor agencies. The result is essentially an algebraic addition of the two opposed actions.

The antagonism is quantitative; *f. i.*, sciatic stimulation gives the same millimeter rise during as before the nitrites; and nitrites give the same millimeter fall during as before strophanthin, hydrastinine, pituitary, strychnine or ergot. This suggests that the point of attack of the nitrites is different from that of the pressor agencies (Pilcher and Sollmann, 1915). Cameron, 1906, proposed to utilize the antagonism for the bio-assay of epinephrine. He states that 0.6 mg. of nitroglycerin exactly neutralizes the pressor effect of 0.0075 mg. of epinephrine.

Lactate.—Perfusion of cat leg with sodium nitrite and also with acetylcholine often fails to produce vasodilatation until lactate is added (Densham, 1927).

The *capillaries* are dilated (microscopic observation) by the direct injection of undiluted amyl nitrite into the human skin (Carrier, 1922), but this may be due to local irritation.

The *vasomotor center* is not depressed, but rather is stimulated by its anemia; the stimulation, however, can not overcome the peripheral depression. This is shown by the perfusion experiments of Pilcher and Sollmann, 1915. Similarly, the blood pressure does not fall if a nitrite is introduced into the cerebral circulation, but prevented from reaching the systemic vessels. (Filehne, 1874, had concluded that the vasomotor center is depressed.)

The **heart** may be quickened during the fall of pressure, preceded by slowing in the event of amyl nitrite inhalation. Both effects are reflexes from the carotid sinus, but large doses also stimulate the cardio-inhibitory center directly (Heymans, Bouckaert and Regnier, 1933). The cardiac muscle is not affected directly to an important degree, but the coronary blood flow is increased by dilatation of the coronary vessels, and this together with the lowered resistance may improve the contractions of the weakened heart (review, H. D. Green, 1940). Generally the cardiac excursions are smaller because of the quickened rate. The size of the heart is markedly reduced (roentgenoscopy, Katzilambros, 1933). The blood pressure waves appear particularly low, because the pressure wave is more readily dissipated, on account of the dilatation. The pulse, on the other hand, may be bounding and dicrotic, because the arteries are emptied more completely during diastole.

The *tachycardia* is due mainly to reflex depression of the vagus center, for after section of the vagi, or after atropine, nitrites cause but little further acceleration (Mayer and Friedrich, 1875). The slight remaining quickening is abolished by dividing the accelerators (Dossin, 1911). The rate of the excised heart is not changed by nitrites (Plumier, 1905). The excitability of the vagus trunk to direct electric stimulation persists.

The depression of the vagus center is due to the fall of blood pressure, and not to a direct action of the nitrite, for no quickening occurs if the pressure is kept level by partial compression of the aorta (Filehne, 1879). The vagus center may still respond to strong reflex stimulation (Mayer and Friedrich).

Diagnostic Significance of the Heart Rate.—In normal man, the acceleration on inhaling amyl nitrite may be considerable, often to double. Practically all irregularities of impulse formation or conduction are either improved or exaggerated (D. Scherf, 1927). With complete heart block, the auricular rate is accelerated during the amyl nitrite fall of pressure; but the ventricular rate sometimes very little, or sometimes two or three times as much as the auricles (A. R. Gilchrist, 1934). In experimental partial heart block, the rate is still quickened by amyl nitrite (Fredericq, 1916).

Electrocardiograms.—When amyl nitrite is inhaled by intact dogs, there is at first a marked reflex increase of vagus tone, shown by slowing of the sinus rate, exaggerated sinus arrhythmia, lengthened A-V time or A-V block, and a negative tendency of the P and T waves. As the blood pressure falls, these changes are reversed. The vagus tone becomes depressed, the sinus rate is quickened, the arrhythmia and block disappear, and A-V time is shortened; the P and T waves become more positive. These phenomena are not affected by previous digitalization; however, large doses of nitrite abolish the ectopic beats due to digitalis (Halsey, 1917). The *excised mammalian heart* is scarcely affected by moderate doses, perhaps slightly stimulated, then depressed (Loeb, 1903; Plumier, 1905; Dossin, 1911). The *excised frog's heart* may be quickened by low concentrations (1:10,000); higher concentrations weaken (1:5000), or stop (1:1000) the contraction.

Coronary Vessels.—Increased outflow has been demonstrated in intact animals (F. Meyer, 1912; N. H. Boyer and Green, 1941); in Starling heart-lung preparations (Bodo, 1928); and in excised mammalian hearts (O. Loeb, 1903; L. N. Katz and Lindner, 1939). The coronary vessels are therefore dilated (also excised arterial rings; Voegtlin and Macht, 1913), and the coronary circulation is improved. This explains the beneficial action in angina pectoris.

Angina Pectoris.—The inhalation of amyl nitrite was introduced by Lauder Brunton in 1867. In *coronary spasm and sclerosis,* nitrites promptly give marked or complete relief of the pain and anxiety, and under their influence greater exertion may be undertaken before bringing on an attack. One to 3 drops of the promptly acting amyl nitrite are inhaled. It may be carried in thin glass capsules, "pearls," one of which is crushed in a handkerchief, as needed, or a tablet of glyceryl trinitrate (0.6 mg., 1/100 grain) may be dissolved under the tongue. This generally acts in one to three minutes and may be repeated every four minutes until relieved.

In coronary thrombosis and infarction, nitrites do not relieve the pain; indeed, they may aggravate it by the fall of pressure (Wearn, 1923; Prodger and Ayman, 1932; Wiggers and Green, 1936).

S. M. Smith, 1921, reported beneficial results from glyceryl trinitrate after closure of a coronary branch in dogs. The distal cyanosis tended to fade, and the blood flow from the distal end of the severed coronary arteries tended to increase.

Cardiac Insufficiency.—The relief of the heart from excessive resistance may render nitrites useful in these conditions. Glyceryl trinitrate (1 mg.) is used, generally in combination with digitalis.

Use against Arterial Hypertension.—The vasodilating action of the nitrites tends to relieve the headache and other symptoms, and the relief lasts somewhat longer than the fall of blood pressure; but nitrites fail to lower the pressure in arterial sclerosis, and also often in severe essential hypertension, perhaps because the dilator action is automatically compensated by increased central tone. In any case they usually lose their efficiency after a short time. Increasing the dose produces unpleasant symptoms—headache, restlessness, sometimes dyspnea. They must therefore generally be alternated with venesection, sweating, nauseants, and the like. The effect of these is usually less marked, but more lasting (J. L. Miller, 1910; C. H. Lawrence, 1912). Glyceryl trinitrate appears to be the most useful; amyl nitrite may lower the pressure when glyceryl trinitrate fails, but it causes more headache. Erythrol tetranitrate often causes intense headache. Sodium nitrite is said to give least headache (Hewlett, 1912), but is liable to upset digestion. Mannitol hexanitrate is not successful in maintaining normal blood pressure in animals with experimental renal ischemia (H. Goldblatt *et al.*, 1942).

Some tolerance usually develops if the administration of glyceryl trinitrate is continued, often in two or three days. The dosage must then be increased or the response disappears. Suspension of the administration for a few days may restore the susceptibility (also with rabbits; Myers and Austin, 1929). Matthew claims that the tolerance is not acquired with sodium nitrite or erythrol tetranitrate.

Rapidity and Duration of Action.—This constitutes the principal difference between the members of the group and varies greatly with individuals. The differences are due chiefly to absorption, for all act essentially alike when injected by vein (J. H. Wills *et al.*, 1944). Amyl nitrite, when inhaled, acts in ten to fifteen seconds, the action disappearing again within seven minutes. For the others, with the usual oral clinical doses, the onset and duration average respectively: glyceryl trinitrate, two and twenty minutes; sodium nitrite, seven and sixty-two minutes; erythrol tetranitrate, thirty-five and 260 minutes; mannitol hexanitrate, fifty-five and 252 minutes (J. C. Weaver *et al.*, 1944).

The extent of the fall increases with the dosage, the increase becoming progressively smaller. The duration of the action is not so much influenced by the dosage. The fall of systolic pressure in hypertensive patients averages: glyceryl trinitrate, 6 mg., 16 mm.; sodium nitrite, 130 mg., 21 mm.; erythrol tetranitrate, 16 mg., 14 mm.; mannitol hexanitrate, 32 mg., 12 mm. The diastolic fall is half or less. Normal individuals show generally less effect. The reliability of therapeutic response depends rather more on the rapidity of action than on the average fall (J. H. Wills *et al.*, 1944).

Administration.—The dosage of the nitrites should be kept as low as possible, to prevent the rapid development of tolerance. It is best to give just enough to cause a slight quickening of the pulse and feeling of fulness in the head; or a fall of systolic pressure of not more than 30 mm. This dose may be given four times a day. The initial dose may be 0.5 mg. ($\frac{1}{100}$ grain) of glyceryl trinitrate, increasing gradually. The equivalent doses of the other nitrites are shown in the preceding paragraph. The treatment may be intermitted for a few days in every two or three weeks, starting again with a smaller dose. Hypodermic injections are rarely needed, the drugs being readily absorbed. Glyceryl trinitrate is materially more potent when it is absorbed from the tongue than when it is swallowed. In the latter case it is absorbed into the portal circulation and destroyed by the liver. (For this reason, about twenty times as much is required to lower the blood pressure when it is injected by a vein that empties into the portal system, such as the splenic, than by a vein which avoids the portal circulation, such as the femoral.)

Bismuth Subnitrate as a Conveyor of Nitrite Action.—This was advocated by E. J. Stieglitz, 1930, in hypertension (0.65 Gm. three times daily), to furnish a continuous supply of nitrite by its reduction in the colon. Bruen, 1934, however, could not demonstrate any effect on the blood pressure and other symptoms, with the largest practicable therapeutic doses. The small quantities ordinarily absorbed are probably bound by the liver. Serious poisoning sometimes occurred from the large doses formerly used in roentgenoscopy.

Nitrite Headache, Meningeal Congestion, Cerebrospinal Fluid Pressure, Brain Volume.—The headache produced by nitrites is due primarily to meningeal congestion. The pia vessels dilate (confirmed by microscopic observation through trephine opening; H. G. Wolff, 1929), by the direct action of the nitrite upon them, notwithstanding the fall of arterial pressure. The brain volume increases (observed in man through trephine opening; Raphael and Stanton, 1919). The pressure of the cerebrospinal fluid rises (W. D. Paul and Greene, 1936). On the other hand, *migraine* sometimes yields to nitrite, presumably when it was connected with arterial spasm. Occasional benefit has also been reported in *epilepsy*.

Intra-ocular tension is raised by amyl nitrite, even when the general blood pressure is lowered (Wessely, 1915). This enjoins caution when using nitrites in *glaucoma*. The *retinal vessels* are also dilated (Hirschfelder, 1915). Amyl nitrite may produce the appearance of *yellow spots* in the visual field. The mechanism is not clear.

Hemostasis.—Nitrites have been tried against *internal hemorrhage*, on the assumption that the lowered blood pressure would tend to arrest bleeding and permit the formation of a clot; but the bleeding would be favored by the direct dilator action. The resultant of these opposite tendencies is difficult to foresee, and probably varies with different conditions. Nitrites would therefore be unreliable remedies. Experimentally, Frey, 1909, found a slight increase of pulmonary hemorrhage; Lisin, 1907, claimed diminution of intestinal hemorrhage. *Capillary hemorrhage from superficial wounds* is increased by the systemic administration of nitrites, notwithstanding the fall of pressure (Hanzlik, 1918).

Respiration is accelerated (Mayer and Friedrich), probably by the changes in the blood and circulation. The *bronchial muscles* are relaxed by nitrites (Doyon, 1906; excised, Titone, 1913; surviving lungs, Baehr and Pick, 1913). This may explain their *use in asthma;* but the action is not sufficient to combat anaphylactic bronchial spasm in guinea pigs (Barlow and Beams). The smoke of the "Charta Potassii Nitratis" (paper impregnated with saltpeter) probably owes a part of its effect to nitrite compounds. The *pulmonary vessels* are not markedly dilated; indeed, Macht, 1914, found constriction in excised pulmonary arteries. The pressure in the pulmonary artery is generally slightly increased (literature in Wiggers, 1911). The rise is probably due partly to the engorgement of the large veins. The *nasal mucosa* becomes congested when glyceryl trinitrate is administered, even before the blood pressure falls (Walton and Kehr, 1928). Amyl nitrite inhalation in dogs may give either slight dilatation or considerable constriction (D. E. Jackson, 1927).

Gastro-Intestinal Tract.—Amyl nitrite inhalation promptly inhibits *gastric peristalsis* and tonus, the effect being greatest when the cutaneous flush is felt in the face. The peristalsis returns to its previous activity with equal promptness, in about three minutes after the inhalation is stopped (Todd, 1930). This is used in roentgenology for relaxing pyloric spasm (G. W. Holmes and Dresser, 1928; Beans, 1931), and for the relief of colic pain, for it has a similar effect on the intestines. Hirschfelder, 1915, reported that the systemic administration of nitrites relaxes the intestinal constriction produced by lead salts. It has been used clinically in lead colic, but with limited success. Sodium nitrite, 0.064 Gm., delays the emptying time of the stomach by an average of 24 per cent, but with marked individual variations (Sleeth and Van Liere, 1941). It may also cause some gastric irritation by the liberation of nitrous acid, but generally not sufficient to interfere with its therapeutic use. There is also some slight interference with the digestive ferments (Hale, 1910). A. Bergman, 1929, reported increased volume of gastric juice during the first hour after its injection, with diminished total and free acidity.

Other smooth muscle is generally relaxed in excised organs, by sufficiently high concentrations; for instance, the *ureter* (Macht, 1917) and the *gallbladder* (Lieb and McWhorter, 1915); but the relaxant action is not sufficiently powerful to be effective against the colics caused by obstruction of the bile ducts, ureters or urethra.

Urine.—The variations produced in the secretion of urine appear to be purely secondary, and depend upon whether the renal arterioles or those of the general circulation are relatively more dilated; the former cause an increase, the latter a diminution, of urine.

In patients with excessively high blood pressure, the nitrites generally increase, some times considerably, the excretion of urine, nitrogen, total solids and phenosulfonphthalein (Lawrence, 1912).

Metabolism.—The effects were studied by Surveyor, 1906.

Temperature.—The dilatation of the skin vessels increases the surface temperature (as much as 3° C. in the blush area; Lahnstein). There is a corresponding increase of heat loss, but this is compensated in normal individuals, at least for small doses, so that the normal temperature is not affected. In fever, however, there is a distinct antipyretic effect (Jacobj, 1913; Krauss, 1913). Ethyl Nitrite, as "Sweet Spirits of Niter," has been used popularly as a diaphoretic and diuretic. Its action is not very energetic. Large doses of nitrites also lower the normal temperature by depressing the circulation.

Methemoglobinemia.—Excessive doses of nitrites form methemoglobin (Gamgee, 1868), which causes cyanosis and asphyxia. The animals generally recover since the blood corpuscles are not destroyed. It is significant as a factor in nitrite poisoning. It is utilized in the treatment of cyanide poisoning, to form the nontoxic cyanhemoglobin.

One molecule of nitrite reacts with two of hemoglobin to form two of methemoglobin, *in vitro* and presumably *in vivo* (L. A. Greenberg *et al.*, 1943). The change to methemoglobin is preceded by a short induction period, followed by a rapid reaction. With excess of nitrite, part of the methemoglobin forms nitric oxide hemoglobin (W. Marshall and Marshall, 1945). If sodium nitrite is administered by vein to dogs, the methemoglobin reaches its maximum in five minutes to an hour, and disappears again completely in a few hours. The amount formed is *proportional to the dose.* Death occurs from this cause with 50 mg. per Kg. of body weight (Hug, 1933).

The methemoglobinemia can be removed by intravenous injection of *methylene blue,* 1 to 2 mg. per Kg., or orally every four hours, clinically (A. F. Hartmann, Perley and Barnett, 1938) and in animals (A. P. Richardson, 1939).

Red blood corpuscles absorb nitrite ions, with removal of chloride ions. The entrance of the nitrite ions is retarded by certain anions (Rohonyi, 1916).

The *red color of corned beef*, produced by pickling with saltpeter (potassium or sodium nitrate), is due to formation of nitrite and its combination with the myohemoglobin (R. H. Kerr *et al.*).

Fate.—Nitrite leaves the blood stream rapidly, even before the recovery of the blood pressure (Crandall, Leake *et al.*, 1929). Some 60 to 70 per cent disappears in the body, partly by oxidation. The fate of the remainder is not known. A small amount (1:100,000,000) is reported to be normally present in the blood, saliva and sweat, but not in the cerebrospinal fluid or urine (E. J. Stieglitz and Palmer, 1937).

Toxicology.—Mild nitrite poisoning may occur from therapeutic overdosage or *hypersusceptibility*. Nervous and anxious patients may react with rise of pressure and tachycardia (G. Richard, 1921), presumably due mainly to excitement. Others may react by marked cardiac slowing and alarming syncope, even after small doses. The severity of the headache is variable. Other side actions which may occur are localized edema, excessive sweating, and visual disturbances (Cornwall, 1913). On the other hand, tolerance is sometimes quite marked. More serious poisoning has occurred accidentally, in the roentgenologic use of bismuth subnitrate and industrially with nitroglycerin. The *treatment of nitrite poisoning* is directed chiefly against the methemoglobin asphyxia, and the low blood pressure. The patient should be kept recumbent, with the head lowered. Epinephrine should be injected, to raise the blood pressure and to mobilize unpoisoned blood compounds from the spleen. Oxygen should be inhaled. Transfusion of blood may be life saving.

Toxic Symptoms from Sodium Nitrite.—Rüegg, 1935, reported three severe cases, when nitrite was taken in mistake for salt. Another outbreak, with a fatality, is reported by M. Greenberg *et al.*, 1945. The symptoms are prompt nausea, vomiting, cyanosis (methemoglobin), collapse, loss of consciousness for several hours, usually with recovery. The symptoms in animals are similar to those from nitroglycerin (Dossin, 1911). The *toxic effects of amyl nitrite* are also similar (Rosen, 1888).

Toxic Effects of Nitroglycerin.—Its extensive use as an explosive makes these especially important. Overdoses produce nausea, vomiting, colic, and sometimes bloody diarrhea. The skin is flushed and perspiring. There is vertigo and persistent throbbing headache; rarely blindness and delirium. The respiration is first hyperpneic, then dyspneic and slowed. The surface becomes cold and cyanotic; the pulse is gradually slowed, dicrotic and intermittent. Paralysis sets in, and is followed by clonic convulsions. The reflexes are lost. Death occurs by failure of respiration, after four to seven hours. The *fatal dose* varies greatly. D. D. Stewart, 1905, reported a patient in whom 20 grains of absolute nitroglycerin produced only slight effects. Nitroglycerin is readily absorbed, even from the intact skin, and persons engaged in its manufacture suffer severely from headache during the first few days. After this, however, they appear to be quite unaffected, unless they leave work for several weeks and then resume the occupation. The work is said to be not unhealthful. The *local action* on the hands may result in skin eruptions and ulcerations.

Smokeless gunpowders (nitroglycerin, nitrocellulose, and the like), when exploded, liberate gases which produce the combined effects of nitrites, asphyxia and pulmonary edema. The principal products are NO_2 (nitrogen peroxide) and CO (Kiefer, 1905). The vasodilatation and tachycardia are followed by persistent headache ("powder headache"), which does not yield to acetanilid, and so on, but is best treated by strong coffee, and poultices applied to the back of the neck.

Sodium nitroprusside, sodium nitroferricyanide, $Na_2Fe(NO)CN_5.2H_2O$, acts chiefly as the nitrites, small doses causing prolonged fall of blood pressure, without producing methemoglobin. Very large doses may possibly form cyanide (L. Hermann), and as this might imaginably occur with moderate doses (although it has not been demonstrated), its therapeutic use does not appear advisable. It is used as a reagent and occurs in dark red crystals, freely soluble in water. Alkalis decompose it into ferric hydroxide, sodium nitrite and sodium ferrous cyanide. The fall of pressure occurs promptly after oral administration of 5 mg. per Kg., hypodermically with 0.05 mg. per Kg., and intravenously with 0.001 mg. The heart is accelerated by the fall of blood pressure. The symptoms in fatal poisoning are vomiting, rapid respiration and rapid pulse (with arterial color of the blood); excitement, tremors, muscle twitching, convulsions of medullary type; dyspnea, cyanosis, mydriasis, collapse, cardiac arrest. The symptoms are probably due largely to cerebral anemia from the low blood pressure. Artificial respiration postpones death (Johnson, 1929).

Hydroxylamine (NH_2OH) is decomposed in the body into nitrite and ammonium. It produces the effects of both these substances (methemoglobin formation, convulsions, central paralysis, Lewin, 1889).

PREPARATIONS.—***Amyl Nitrite, U.S.P** (Amylis Nitris), a clear, yellowish liquid, containing not less than 80 per cent $C_5H_{11}NO_2$ (chiefly iso-amyl nitrite); peculiar, ethereal fruity odor and pungent, aromatic taste; is almost insol. in water, miscible with alc. or ether, very volatile, even at low temperatures, and inflammable. Dose, by inhalation, 0.2 cc., 3 minims. It may be carried in thin glass capsules, "pearls," one of which is crushed in the handkerchief as needed.

Sodium Nitrite, U.S.P., is freely sol. in water. Dose, 0.03 to 0.12 Gm., $\frac{1}{2}$ to 2 grains. *Sodium Nitrite Tablets*, U.S.P.; usual sizes, 30 and 60 mg., $\frac{1}{2}$ and 1 grain.

***Glyceryl Trinitrate Tablets,** U.S.P. (Nitroglycerin, Trinitrin or Glonoin); the usual sizes contain 0.3, 0.4, 0.6 and 1.2 mg. ($1/200$, $1/140$, $1/100$ and $1/50$ grain). Average dose, 0.4 mg. The drug is not volatile and the tablets do not deteriorate rapidly (Rippetoe and Smith, 1914). E. L. Sagall *et al.*, 1946, found no recognizable difference in clinical effectiveness between fresh tablets and those eleven years old, unless they were exposed to excessive heat (37° C.). *Spirit of Glyceryl Trinitrate* (Liquor, B.P.) is an alcoholic 1 per cent solution. Miscible with water and alc. Explosive when allowed to dry. (If any considerable quantity is spilled, a solution of sodium or potassium hydroxide should be poured over it immediately.) Dose. 0.03 to 0.12 cc., ½ to 2 minims. *Erythrityl Tetranitrate Tablets* (Erythrol Tetranitrate, Tetranitrol) contain 0.015 or 0.03 Gm., ¼ or ½ grain, of $C_4H_6(NO_3)_4$ each.

(*Pentaerthrityl Tetranitrate,* "PETN," used in munitions, produces nitrite effects, with relatively low toxicity; von Oettingen *et al.*, 1944.)

Mannitol hexanitrate, N.N.R.; $H(CHONO_2)_6H$, mixed with carbohydrate substances to render it practically nonexplosive. Dose, 16 to 32 mg. at intervals of four to six hours. Absorption is incomplete (L. A. Heppel, 1941). *Tablets,* 16 and 32 mg.

Ethyl Nitrite Spirit, N.F. (Spirit of Nitrous Ether, Sweet Spirit of Niter), is a pale yellowish alcoholic solution of about 4 per cent ethyl nitrite ($C_2H_5NO_2$). Deteriorates readily, unless stored in filled amber-colored bottles. Incompatible with antipyrine, morphine and iodides. The addition of water throws ethyl nitrite out of solution; it then evaporates rapidly, lowering the strength (E. R. Squibb, 1889). Dilution should be made shortly before administration (Marshall and Gilchrist, 1915). Dose, 2 cc., 30 minims, as diaphoretic.

DIGITALIS GROUP

Digitalis, Strophanthus, Squill, Apocynum, Barium and a number of other drugs increase the tonus, excitability and contractility, and the refractory phase of the cardiac muscle, stimulate the vagus center and slow the conduction through the His bundle. With therapeutic doses, these actions result in slower but more powerful beats of the heart, which bring about compensation in valvular cardiac lesions and thus relieve the symptoms—the irregularities, edemas, congestions, dyspnea, and so forth. Under these conditions, there is often marked diuresis. The blood pressure is generally unchanged in man, usually increased in animals. The vagus center may also be stimulated, especially by toxic doses, partly directly, partly through the rise of blood pressure. The tone of the arterial muscle is increased. The effects set in slowly on oral administration; almost immediately on intravenous injection. They tend to be fcumulave, and to outlast the administration or a considerable time. Toxic doses produce vomiting, cardiac irregularity and sudde heart failure. The recognition of these toxic effects is important, since they often arise from the cumulative action. The members of the group are local irritants. Their hypodermic injection is painful. Their absorption from the gastro-intestinal canal is slow and often uncertain. The active principles are generally neutral glucosides, and therefore rather unstable, especially in acid, aqueous solutions. Digitalis contains several distinct glycosides with similar actions. The various "strophanthins" are derived from several related plants. They differ in activity and toxicity according to their origin. All the characteristic digitalis effects are produced by all the members of the group, so that a single description will suffice. The differences between them are only quantitative. So far as they are known, they will be pointed out as occasion arises.

Drugs Producing Digitalis Effects.—A considerable number of drugs containing glycosides with "digitalis" action are used in medical practice, such as Digitalis, Strophanthus, Squill and Apocynum. Of less practical importance are Helleborus, Adonis, Convallaria, Thevetia, Oleander, Cheiranthus, Uzaria, Antiaris toxicaria (the Upas tree of Java; Chopra and De, 1934). Several *arrow poisons,* chiefly African, contain digitaloid glycosides: strophanthin, ouabain, antiarin, acocantherin, and so on (Trendelenburg, 1909). The toxic principles found in the skin and blood of the common *toad* and other toad species, bufotoxin, bufagin and bufotalin, are closely related to the digitalis glycosides in structure and action. *Erythrophleine,* a glycosidal alkaloid, can be counted in the group. Other alkaloids—veratrine, caffeine, curine, epinephrine—remind somewhat of digitalis, but are not typical. Barium salts, calcium ions, alkaline hydrates and even normal saline solutions produce cardiac actions which resemble those of digitalis, but the resemblance may only be superficial.

The **cardiac glycosides** consist of a sugar molecule, of unique structure in some cases and an "aglycone" or "genin," closely related in the different principles of the variousplants, composed of a cholanic (cyclopentane phenanthrenic) nucleus with seventeen carbons and an unsaturated lactone side chain with four or five carbons, which is essential to the action. The sterols, including the sexual hormones, also have a cholanic nucleus, but lack the lactone and the digitalis action (reviews, W. A. Jacobs, 1933; Tiffeneau, 1937). The genins (digigenin, and others) are responsible for the digitalis actions. The sugars influence the penetration. The aglycones are generally less potent on the heart than are the corresponding glycosides, and their action is shorter

(Chen, Robbins and Worth, 1938). The glycosides are distinguished by a latent period before they act, and by long persistence in cells (Straub). They are difficult to isolate, and are usually distinguished mainly by their solubility, stability and absorbability. These vary, however, with conditions, with the methods of extraction and with different specimens of the drug (E. Meyer, 1917). This has been responsible for much confusion.

Active Principles of Digitalis Leaf.—Three cardiac glycosides, the (crystalline) *digitoxin*, and the (amorphous) *gitalin* and *gitoxin*, have been isolated chemically pure from the dried leaves of the official Digitalis purpurea (review, A. Stoll, 1937). They total about 1 per cent of the leaf. The other cardiac principles which have been claimed for the official leaf are probably impure mixtures of the above. Digitalis, however, also contains saponins (*digitonin*, *digitsaponin* and *gitonin*), which do not produce the typical cardiac effects, but probably modify the solubility of the other principles. The cardiac glycosides have identical actions, and differ biologically only in the intensity and duration of their effects, and physically in their solubility in different solvents, and this is modified by conditions. Although pure digitoxin is but slightly soluble in water, hot or cold water extracts practically the entire glycosides from the leaves, probably with the aid of the saponin.

Digitoxin is the best characterized and probably the most important of the principles of digitalis leaf, in activity and in quantity (0.22 to 0.4 per cent). It does not occur in digitalis seed. It was isolated by Nativelle, 1869, and called "Digitaline cristallisée." Its analytical investigation was completed by A. Windaus and Stein, 1928. It occurs as crystals, soluble in alcohol and in chloroform, but difficultly soluble in water (when pure) and in ether. In the presence of other substances, even of water, the solubility characters of digitoxin are considerably modified, perhaps by converting it into colloidal forms. It is quite conceivable that some of the principles of the other groups may be physical modifications or compounds of digitoxin. *Digitophyllin*, Kiliani, is perhaps a similar crystalline principle of the leaves. *Anhydrogitalin*, Kraft, is also a closely related constituent of digitalis infusions.

Gitalin was isolated by Cloetta and investigated by Windaus. It is amorphous, soluble in water and more so in chloroform; and is the constituent extracted from the cold aqueous solutions by chloroform.

Kiliani, 1914, found that the gitalin of Kraft, 1912, is a mixture. S. Weiss and Hatcher, 1923, found that the ether-soluble portion of gitalin contains a fraction which gives the reactions of digitoxin, and is so rapidly absorbed that the clinical effect occurs promptly on oral administration (Eggleston, 1920); but it is also excreted so rapidly that the effective dosage is relatively high.

Gitoxin was isolated by Cloetta and by Kraft, and the formula established by Windaus. *Digitalein* of Schmiedeberg and of Kiliani (1913 and 1914) are probably mixtures containing chiefly gitalin. They are soluble in water, but relatively insoluble in chloroform. Most of the commercial products intended for intravenous injection, such as *Digalen*, *Digipan*, *Digipuratum*, *Digitalysatum*, *Verogen* are of this type (Straub; Krehl, 1919).

The *digitalis saponins* are readily soluble in water, slightly soluble in alcohol and lipoid solvents. The *crystalline Digitonin* Kil. was considered a definite substance, which can be split into a hexose and digitogenin; but Windaus and Schneckenberger, 1913, considered it a mixture, from which they isolated *Gitonin*. The *amorphous Digitonin* Schm. (*Digitsaponin*, Kraft) is probably a mixture of the crystalline with several amorphous saponins (Kraft). The digitonins produce, not the digitalis effects, but the irritant and hemolytic properties of the saponin group. The digitsaponins of the leaves are not hemolytic (Kobert, 1912). Digitonin and its decomposition products are discussed by Windaus and Weil, 1922.

Inactive Principles.—A number of these have been isolated, such as the crystalline glycoside *gitin* and *digin*, Kraft, 1912, from the leaves.

The name *Digitalin* has been applied to a number of dissimilar products. The resulting confusion is so dangerous that the term is not employed by modern workers; it must never be used without designating the kind of digitalin that is meant.

The original *Digitalinum Verum* of Schmiedeberg and Kiliani consisted of those amorphous glycosides of the seeds that are soluble in alcohol, but little soluble in water, chloroform and ether.

Commercial digitalins are impure, often variable, mixtures of digitalis principles. *Digitalin "Amorphous"*; generally means French or Belgian digitalin (digitalin chloroformique); uncertain composition; insoluble in water (perhaps mainly Digitalin, Schm.). *Digitalin "Crystallized"*; objectionable synonym for Digitonin; for Nativelle (French); and for Digitoxin. *Digitalin "Homolle"*; mixture of glycosides; mainly true Digitalin; practically insoluble in water. *Digitalin "Nativelle"*; crystalline, probably mainly Digitoxin. *Digitalin "German"*; amorphous mixture from seed; contains principally Digitonin (50 to 60 per cent) and some Digitalinum verum (5 to 6 per cent), and Digitalein. Soluble in water or alcohol.

Digitalis seeds contain different but related glycosides, among them the *Digitalinum verum* of Schmiedeberg and of Kiliani This is usually amorphous, but may be obtained as crystals. It is sparingly soluble in water, but is dissolved by the saponins.

Digitalis lanata, another species of the plant, indigenous in the Balkans, yields gitoxin and a new glycoside, *digoxin* (Sidney Smith, 1930), and perhaps others.

Native Digitalis Glycosides.—Stoll and Kress, 1933 (review, Stoll, 1937), find that the glycosides of dried digitalis are themselves cleavage products of glycosides, "digilanids," which may be isolated by special precautions from the fresh leaves of D. purpurea, but especially of lanata, where they exist as tannoids. The crystallized glycosides can be separated by immiscible solvents into three fractions. Enzymes contained in the digitalis leaves split off glucose and thus yield the ordinary glycosides, digitoxin from digilanid A, gitoxin from B, and digoxin from C, which is absent from purpurea. A and B differ from C by the absence of an acetyl group (hence, desacetyl digilanids).

Cleavage Products (Aglycones and Sugars) of the Digitaloids.—The close relationship is illustrated by the following tabulation (adapted from Straub). All the *genins,* except Scillaridin, have twenty-three carbons, thirty-two to thirty-six hydrogens, and three to six oxygens. All but bufagen, convallamarin and scillarin have unsaturated lactone groups, which explains their tendency to decompose spontaneously. The *sugars* are chiefly dextrose, rhamnose and four alpha-deoxy sugars, digitoxose, cymarose, digitalose and sarmentose, which have so far been found only in the cardiac glycosides. They render the glycoside more readily oxidizable (Jacobs and Bigelow, 1932). Digitoxose is responsible for the Keller-Kiliani color test.

IMPORTANT CARDIAC GLYCOSIDES AND THEIR CLEAVAGE PRODUCTS

Digitaloid			*Aglycone (Genin)*			*Sugar*	
Digilanid A	$C_{47}H_{74}O_{18} + H_2O$	=	Digitoxin	$C_{41}H_{64}O_{13}$	+	Dextrose	$C_6H_{12}O_6$
Digitoxin	$C_{41}H_{64}O_{13} + 3H_2O$	=	Digitoxigenin	$C_{23}H_{34}O_4$		3 Digitoxose	$3(C_6H_{12}O_4)$
Gitalin	$C_{35}H_{56}O_{12} + 2H_2O$	=	Gitoxigenin hydrate	$C_{23}H_{36}O_6$	+	2 Digitoxose	$2(C_6H_{12}O_4)$
Gitoxin	$C_{41}H_{64}O_{14} + 3H_2O$	=	Gitoxigenin	$C_{23}H_{34}O_5$	+	3 Digitoxose	$3(C_6H_{12}O_4)$
Digitalinum	$C_{36}H_{56}O_{14} + 2H_2O$	=	Gitoxigenin * (but see below)	$C_{22}H_{34}O_5$	+	Dextrose probably attached to the digitalose Digitalose (methyl ether of methy pentose)	$C_6H_{12}O_6$ $C_7H_{14}O_5$
Oleandrin	$C_{30}H_{46}O_9 + H_2O$	=	Gitoxigenin†	$C_{23}H_{34}O_5$	+	Digitalose	$C_7H_{14}O_5$
Strophanthin K	$C_{36}H_{54}O_{14} + 2H_2O$	=	Strophanthidin	$C_{23}H_{32}O_6$	+	Dextrose and Cymarose	$C_6H_{12}O_6$ $C_7H_{14}O_4$
Cymarin	$C_{30}H_{44}O_9 + H_2O$	=	Strophanthidin	$C_{23}H_{32}O_6$	+	Cymarose	$C_7H_{14}O_4$
Scillaren A	$C_{36}H_{52}O_{12} + H_2O$	=	Scillaridin	$C_{24}H_{33}O_3$	+	Dextrose and Rhamnose	$C_6H_{12}O_6$ $C_6H_{12}O_5$

* *Digitalinum verum:* The gitoxigenin in this instance again loses 2 mols. of water, to form digitaligenin, which is the cleavage product actually isolated.

† W. Neumann and Lindner, 1937, state that gitoxigenin is the aglycone of desacetyl-oleandrin, and that of oleandrin is acetyl gitoxigenin.

The *pharmacologic actions* of the genins are identical with those of the glycosides, and are about equally potent. The sugars are inactive in themselves, but they are chiefly responsible for the solubility characteristics, and probably through these they affect the velocity and firmness of the binding in the heart muscle, which is the chief difference between the genins and the whole glycosides. For instance, the effect of digitogenin on the Starling perfused cat heart can be removed by washing; those of digitoxin can not (Straub).

Strophanthus Glycosides.—The various species of Strophanthus (Apocynaceae), which are used by the natives of Africa for the manufacture of arrow poisons, contain several related cardiac glycosides, about which there is considerable confusion. The strophanthin of the U.S.P. and B.P. is the amorphous glycoside obtained from the seeds of Strophanthus Kombé and therefore (from the first letter of the species name) known as "*Strophanthin K.*" Its aglycone is *Strophanthidin.* The crystalline *Gratus (G) Strophanthin* or *Ouabain* is more uniform and is therefore used in research. It is about twice as potent as the official strophanthin. Solutions of either of these deteriorate rapidly and should therefore be prepared fresh.

The unsatisfactory knowledge of the strophanthin glycosides is due partly to incomplete identification of the plants, partly to incomplete isolation of the glycosides; and largely also to conflicting nomenclature: similarly named commercial products may differ widely in potency (Heffter, 1909). The strophanthin originally isolated by Fraser, 1870, was the amorphous Kombé variety (Gilg, 1904).

Strophanthin amorphous (Strophanthin-Boehringer) is the official strophanthin. It occurs in the Kombé, and hispidus. The two are similar, probably identical. Kombé further yields a crystalline strophanthin (Houghton, 1911; Brauns and Closson, 1913, 1914) which is similar. A. Stoll, 1939, reported that three-fourths of the cardiac activity of K-strophanthin is due to K-strophanthosid-beta. The amorphous is slightly more toxic for rabbits than the crystalline Kombé. All three are hydrolyzed by acids with the production of the crystalline *strophanthidin*. This is several times more toxic than strophanthin, and produces similar cardiac action (electrocardiographic, Dresbach, 1938), but with greater tendency to respiratory paralysis (Groeber, 1913). Dresbach and Wadell, 1924, found that the most characteristic effect of strophanthidin consists in emesis, which is also produced by intravenous injection. It is also diuretic; and its peritoneal injection provoked defecation. It is not irritant when applied to the conjunctiva. The *crude drugs* Kombé and hispidus are about equally active.

Ouabain, gratus strophanthin-Thoms; Crystallized Strophanthin-Merck.—This is the only "crystalline strophanthin" on the market. It is the best characterized of the principles. It does not yield strophanthidin. It was first isolated by Arnaud, 1888, from the wood of Acocanthera Ouabaio, and, 1898, from S. glaber. Later, 1910, Thoms obtained it from S. gratus, which was found to be identical with glaber. This is more readily obtained genuine than the other Strophanthus species. Strophanthin has been described as methyl-ouabain, and acocantherin as dimethyl-ouabain; but the evidence for these views is not convincing (Brauns and Closson). Ouabain is about twice as toxic as strophanthin; and this is twice as strong as acocantherin. S. gratus also contains a second amorphous strophanthin (Thoms). The "*pseudo-strophanthins*" of Feist were probably ouabain, but their identity is now obscure.

Cymarin is the active glycoside of *Apocynum* (Canadian Hemp), a plant employed therapeutically like digitalis. Cymarin was isolated and named by Impens, 1913, and investigated by Windaus and Hermann, 1915. It is closely related to strophanthin and yields strophanthidin on hydrolysis. The principles announced by previous investigators (cynotoxin and apocynamarin of Finnemore, 1909, and Moore, 1909; apocynin and apocynein of Schmiedeberg) were probably impure mixtures. Commercial apocynin is acetovanillin (Finnemore, 1908), and is practically inactive (Wood, 1904).

Scillaren.—By special extraction methods to prevent enzymatic decomposition, Stoll isolated a crystalline cardiac glycoside from squills, which he named *scillaren* A. It represents about two-thirds of the total potency of the drug. It yields the aglycone scillaridin. The remainder is constituted by an amorphous fraction, probably impure, which he named scillaren B. The activity of squills was formerly attributed to two amorphous glycosides, scillipicrin and scillitoxin; but Ewins, 1911, found these to be impure mixtures. Kopaczewski, 1914, claimed to have isolated two active principles: scillitin, the toxic constituent, a nitrogen-free glycoside; and scillidiuretin, water soluble, markedly diuretic, but of low toxicity.

Adonis resembles scilla more closely than digitalis (Chevalier, 1913). Roch and Cramer, 1914, found even large doses inefficient in cardiac diseases. Fuckelmann, 1911, claimed that "adonidin" is a mixture of an acid and neutral glycosides, both having digitaloid effects, the acid being also hemolytic. Its cardiac and diuretic actions were investigated by H. Hermann, Jourdan and Ribere, 1930. It has no advantage over digitalis (Hatcher and Haag, 1933).

Convallaria (root of Lily of the Valley); active constituent, the glycoside convallamarin; is considered rather uncertain (Roch and Cramer, 1914).

Helleborein is a glycoside from the rhizome of Helleborus niger (*Hellebore*). Its digitalis action depends on the presence of an acetyl group (Sieburg, 1913). It is not absorbed from the human intestinal tract and therefore produces only diarrhea clinically (Cushny, etc., 1912).

Erythrophleine is an alkaloid with digitalis action, obtained from "Sassy Bark" (chemistry, Power and Salway, 1912), and used by West African natives as emetic, cathartic and ordeal poison (G. W. Harley, 1941). Erythrophleum also contains five other alkaloids. One of these, coumingine, has a stronger cardiac action than erythrophleine; all are more potent in producing emesis, local anesthesia, rise of blood pressure, and stimulation of the uterus and intestines. Cassaine causes convulsions in frogs and cats (Chen, Hargreaves and Winchester, 1938). Cassaine and nor-cassaine produce relatively less cardiac irregularity in heart-lung preparations (H. M. Maling and Krayer, 1946). The erythrophleum alkaloids are esters of mono- and di-methylaminoethanols. *Dimethylaminoethanol* produces positive inotropic effects on the heart-lung preparations of dogs, similar to erythrophleum (A. Farah and Krayer, 1946).

Uzarin is a crystalline cardiac glycoside isolated by Hennig, 1917, from the root of an African plant, Gomphocarpus (Asclepiadaceae), used by the natives against dysentery and other diarrheas (Guerber, 1911, 1920). In addition to the cardiac effects of digitalis, uzarin acts on smooth muscle, small doses being stimulant, and large doses depressant. The stimulation is not inhibited by atropine or epinephrine. It sensitizes the sympathetic system to epinephrine stimulation (Raymond-Hamet, 1928; Gessner, 1930). Uzarin is easily hydrolyzed by acids into glucose and the inactive uzaridine. It is therefore much less effective by stomach than by rectum. *Uzaron* is apurified extract of secret composition.

DIGITALIS ACTIONS ON THE CIRCULATION

Digitalis produces the following important reactions:

(1) *Increased contractility* of the cardiac muscle, *i. e.*, lowered threshold of irritability, and more powerful and more prolonged contraction with corresponding *lengthening of the refractory period*. This entails corresponding changes in the conduction, which is a function of the contractility, *i. e.*, the conduction is *stronger but slower*, also with prolongation and intensification of its refractory phase. This lengthening of refractoriness is the more marked, the shorter the normal refractoriness of the structures. It is therefore most marked in the His bundle, and tends to produce auriculoventricular block.

(2) The *tonus of the heart muscle* is increased so that the *systolic shortening becomes greater and more prolonged.* In the ventricle of the

cold-blooded heart and in the perfused mammalian heart this culminates gradually in systolic arrest. In living mammals systolic arrest is impossible because the heart would be asphyxiated by impairment of the coronary circulation.

The *diastolic tonus* also tends to be increased, and the diastolic relaxation would be less complete. In the intact animal, however, the prolonged refractory condition may lead to a passive distention in diastole, due to the prolonged inflow of blood. This is seen most strikingly in the distended auricles of the digitalized heart of intact frogs. In mammals, the size of the heart is not diminished in diastole, but only in systole (Gold and Cattell, 1939).

(3) *Digitalis stimulates the vagus center* (along with other medullary centers). This is probably due to a reflex from the direct cardiac action, since the vagus action generally appears only after the muscle effects have reached a certain height.

Vagus stimulation diminishes the cardiac tonus and excitability; it weakens the cardiac contractions and therefore shortens the refractory period; the conduction is correspondingly weakened, although it is quickened. All these effects are the opposite of the muscular action of digitalis, and may represent an attempt at a central compensation against the peripheral action. Nevertheless, both actions coincide in interfering with conduction and therefore in tending to produce block, although by opposite mechanisms; the direct muscular action by prolonging the refractory phase, the vagus action by raising the threshold of excitability. Both actions may participate in the therapeutic effect on auricular fibrillation. The muscular action plays probably a rather larger share, for the greater part of the therapeutic effect persists if the vagus action is eliminated by atropine. As the dosage is increased, the vagus phenomena come to predominate; with fatal doses, the muscular action again obtains the upper hand. There is no evidence that the peripheral vagus distribution is stimulated or sensitized by digitalis: the susceptibility to acetylcholine is not increased, but may be abolished even by small doses (J. A. Wells *et al.*, 1943).

(4) Digitalis contracts arterial muscle directly, but this effect plays a relatively unimportant part in its ordinary actions.

The details will be presented in the order of the increasing complexity of the phenomena, *i. e.*, segments of cardiac muscle, perfused cold-blooded heart, excised mammalian heart, intact mammals, and therapeutic effects. In view of the complicated interactions, it is not surprising that results obtained on limited experimental material may sometimes appear contradictory.

Mammalian papillary muscle survives in suitable saline solutions for several hours, and may be stimulated rhythmically. The tension of the twitch is markedly increased by ouabain in very dilute solution (1:100 millions for cats, 1:20 millions for rabbits), especially with fatigued preparations. The diastolic tonus is not increased. With higher concentrations (1:40 millions, for cats) the primary increase is followed by depression (Cattell and Gold, 1938). Camphor, metrazol, coramine and barium do not produce this sustained force (S. Krop, 1944). Ouabain also increases the force and improves the contractile efficiency of depressed *skeletal muscle* (M. K. Cattell, 1942).

Isolated Purkinje Fibers.—The excised His bundle of mammalian heart, when placed in oxygenated Ringer's solution, makes rhythmic contractions like other cardiac muscle, and reacts similarly to pharmacologic agents: it is stimulated by strophanthin, barium, epinephrine, caffeine, calcium and camphor, depressed by quinine, chloroform, potassium and oxalate; vagotropic drugs are ineffective (Pick, 1923; Ishihara and Pick, 1926).

Embryonal Heart of Chick.—The heart of the forty-eight hour chick has not yet developed nerve fibers or a conducting system, but when placed in a 1:300,000 solution of ouabain, it develops A-V block, ventricular arrest, and finally sino-atrial arrest. The time of th- A-V block may be used for bio-assay: It appears cone stantly in four minutes, if the temperature is 39° C.; later, if the temperature or the concentration is lower. The heart revives on washing with Tyrode's solution (G. H. Paff and Johnson, 1938, 1940).

Segments of Frog Ventricle.—Sasaki, 1921, found that helleborein lowers the threshold to stimulation, increases contractility and rhythmicity and the refractory period (*i. e.*, the resistance to tetanus by faradization). Increase of tonus is shown by lengthened duration of the systolic peak and incomplete diastolic relaxation, the duration of the diastole not being increased. This terminates in systolic standstill.

Isolated Auricle of the Frog.—The toxic dose of digitalis is at least ten times as great as for the ventricle: the phenomena, however, are similar (W. Straub, 1915).

Ventricle Segments of Turtle.—Large doses produce acceleration (even after atropine or ergotoxine) and increase of amplitude and tone (Greene *et al.*, 1915). *Tonus waves in turtle auricles* are augmented by vagus stimulation and inhibited by the sympathetic (Rosenzweig); accordingly, they are increased by digitalis (0.3 to 0.5 per cent) and antagonized by epinephrine (Gruber, 1921).

Entire Frog Heart.—The phenomena are identical in perfused hearts, and with the natural circulation. They are preceded by a latent period of five to ten minutes, even if strong solutions are applied directly. Small doses of all digitaloids (Benedicenti, 1902; including barium, Poulson, 1910) produce an *apparently depressant effect, i. e.*, a gradual slowing and diminished tone (F. Williams, 1880, perfused heart), which may terminate in diastolic arrest, especially if the drug is applied to the exterior of the heart (Werschinin, 1910). It is rarely witnessed in intact animals, and is then followed by the usual systolic phase (Boehm, 1872). This depressant effect has been interpreted as vagus stimulation; but it is not prevented by atropine (Benedicenti, 1902), and is probably due to diminished conductivity and heart block (*i. e.*, increased refractoriness) between sinus and auricle, preventing the transmission of the pacemaking impulses (Clark, 1914). The heart still responds to mechanical stimulation. Submaximal vagus stimulation increases the block (Haldschinski, 1908). *If the rhythm is set by extraneous stimulation*, the systole, in its mechanical and electrical manifestations, is shortened by digitoxin; the diastole is lengthened; the refractory period is shortened; the threshold is not materially changed. Conduction is usually slowed (A. M. Wedd *et al.*; 1941).

Therapeutic Stage.—If the digitalis is injected or perfused, instead of being applied to the surface of the heart, the sinus block does not proceed to arrest (Clark, 1912), and the other parts of the heart participate in the effects. The typical course was described by Boehm, 1872. The increase of contractility is shown by increased systolic excursions, which prolong the refractory state, so that the rate is slowed. This offers opportunity for greater filling and therefore for greater diastolic distention. The output per beat is thus increased. The time output and the blood pressure may alter in either direction, according to the degree of slowing. The earlier effects are mainly on the auricles, and the auriculoventricular interval is unchanged (Clark and Mines, 1913). If the heart was weak, the stimulation may also be perceptible on the ventricle (Clark, 1914). Hearts exhausted by perfusion with a saline solution may be revived.

The *toxic irregularities* start soon after. The systolic phase of the ventricle becomes exaggerated, leading to intraventricular block, so that at times the apex, at times the base, remains firmly contracted during the diastole. These partial diastoles may alternate so that the blood is merely pumped back and forth from one part of the ventricle to the other. This has been called, rather inappropriately, "*cardiac peristalsis.*" (The "peristalsis" was first described by Vulpian, 1855). A part of the ventricle may remain firmly contracted for a considerable time, and then may resume rhythmic contraction. Eventually, the ventricular diastoles become weaker, until the ventricle finally goes into permanent *systolic standstill*, and appears as a small white lump, contrasting sharply with the turgid auricles. The apex is often arrested before the base. The auricles continue to pulsate for a time, and eventually stop distended. The ventricular systolic standstill is not paralytic, for if the ventricle is forcibly distended with fluid, it will again start effective beats (Schmiedeberg, 1874). The standstill is due to *excessive tonus*, which prevents diastolic relaxation under the ordinary venous pressure. It is not prolonged contraction, for the heart muscle is not in the refractory phase (Tait and Pringle, 1916). Other hearts may not show the "peristalsis," but instead the phenomena of *partial auriculoventricular "block," i.e.*, the ventricular rate suddenly falls to one-half, then one-third, one-fourth, and so on, of the auricular rate (Straub, 1901). The auriculoventricular interval is lengthened (Clark and Mines, 1913). Eventually the auricular rate, and finally the sinus rate may be halved. The block is explainable by *prolongation of the refractory period*, for Brandenburg, 1904, showed that the heart is now less easily excitable to extrasystoles. K. Junkmann, 1925, reported the refractory period as prolonged by barium and strophanthin, but more complex effects occurred with digitalis. K. Gies, 1927, found the refractory period at first shortened, then lengthened. On the other hand, the *spontaneous contractility* is increased, for if the sinus-auricular junction is crushed (I-Stannius experiment) the ventricles are not arrested as in the normal frog, but at once initiate a spontaneous rhythm. However, A. G. Macleod, 1939, found that the duration of the electrical systole of the auricles and ventricle is reduced and the refractory period shortened. De Noer, 1917, made detailed studies of the effects on existing irregularities, and the like. The *oxygen consumption* of the excised frog heart is decreased according to the diminished rate and excursions (Gottschalk, 1913). Pietrowski, 1917, found that *forcible distention of the auricles* of the normal frog heart produces a systolic tendency and arrest similar to the tonus effect of digitalis. This suggests that clinical auricular distention may potentiate the therapeutic response to digitalis. This tonus effect is not removed by atropine or epinephrine.

The heart of toads is resistant to the digitaloid drugs, so that the action proceeds only to diastolic arrest. It shows a similar peculiarity in its behavior to excess of calcium, which diminishes the tonus of the heart, instead of increasing it as in the frog. Wieland, 1922, suggested that the two phenomena are connected, on the basis of Loewi's interpretation of digitalis action as increased calcium susceptibility. The skin of the toad contains two principles which exert typical digitalis actions.

Perfused Mammalian Heart.—Moderate doses, corresponding to the therapeutic stage, increase the excursions, especially in systole, and slow by prolonging the diastolic pause. The output per beat may be more than double. The *time* required to produce maximal slowing is an hour for digitalis, one-fourth hour for strophanthin (Haynes, 1906). *Existing irregularities are removed*, and fibrillating heart may resume regular contractions (Bodo, 1928). With *toxic doses*, the contractions after the therapeutic stage become quicker and irregular. The diastolic relaxation becomes progressively less complete, and the heart has a systolic tendency. It finally passes through delirium cordis into systolic standstill, the tone increasing even after the heart has stopped. Stretching of the muscle (as by increasing the coronary pressure) may temporarily restore the pulsations (Gottlieb and Magnus, 1903; Etienne, 1909).

The *oxygen consumption* of perfused hearts varies with their rate; it is diminished when they are slowed (J. C. David, 1930, isolated frog heart), and increased when the cardiac activity increases (Rhode and Ogawa, 1912).

Dynamics of Cardiac Digitalis Action.—If the rate of intact dog's heart is kept constant (by auricular stimulation), the direct stimulation of ventricular muscle by digitals and ouabain is manifested as increased gradient of pressure development, higher blood pressure maxima within the ventricles, and quickened rate of systolic contraction. The diastolic excursions are not decreased until toxic effects set in (Wiggers and Stimson, 1926). *Extrasystoles* are produced by smaller stimuli in hearts under the influence of the therapeutic and the smaller toxic doses of digitalis (Pletnew).

Intact Mammals.—The typical phenomena may again be conveniently divided into the therapeutic and toxic stages. During intravenous injection of digitalis, there is a sharp "velocity" fall of blood pressure (Blake). Although this does not last long, it should be borne in mind when contemplating intravenous injections. It does not occur with other methods of administration.

Cardiac changes in the therapeutic stage are characterized by lowering and reversal of the T wave of the electrocardiogram, with relative shortening of the Q–T interval; marked slowing of the pulse, due to lengthening of the diastolic pause; increased diastolic distention of the heart; and more complete systole, if this has previously been incomplete. The heart is therefore both better filled and better emptied (Cushny, 1897). The output per beat is thus greatly increased; the "pulse pressure" or "pulse volume" is improved. This increase more than offsets the slowing, so that the minute output is also increased (Cohn and Levy, 1920). This tends to raise the blood pressure; in animals this tendency is supported by a more or less powerful vasoconstriction, involving particularly the intestines and liver. In man, the blood pressure is not much altered, presumably because of the more efficient vasomotor regulation; nor is the normal human heart usually slowed by ordinary doses, although the conduction of auricular impulses is delayed.

Behavior of the Different Chambers of the Heart.—The two sides of the heart behave very much alike to digitalis; but the auricles tend to show relatively greater inhibitory effects (since they are more subject to vagus control), while the ventricles are more disposed to the muscular action. In the therapeutic stage, the rhythm of the auricles and ventricles is synchronous.

Electrocardiographic Changes.—The reversal of the P and T waves which is characteristic of the therapeutic dosage in man occurs in dogs and cats promptly after the intravenous injection of about 30 per cent of the minimum fatal dose (ranging from 25 to 60 per cent in different cats, but constant in a given individual; Levine, 1919). The reversal occurs after section of the vagi and after atropine, and is therefore a muscular phenomenon (Cohn and Levy, 1918). In normal adults receiving a massive therapeutic oral dose of digitalis, the electrographic changes do not begin till after two hours; they may last for thirty days. About half responded with slowed rate (K. Larsen *et al.*, 1937). The range of sensitivity of the T wave change with oral doses is within 25 per cent in 70 per cent of the population, but 5 per cent differ by more than 50 per cent, occasionally even 300 per cent (H. Gold *et al.*, 1945).

The **digitalis slowing,** in *normal* animals, is practically entirely vagal, due to vasosensory reflexes arising partly from rise of blood pressure, partly by chemical stimulation of the afferent endings of the carotid glomus (Heymans *et al.*) and, perhaps chiefly, by sensitization of the myocardium to vagus stimulation, so that it is inhibited more effectively by rise of blood pressure and by acetylcholine (Abdon *et al.*, 1938). It is almost completely eliminated by section of the vagi (Traube, 1851; Kochmann, 1909); and atropinized animals show practically no slowing. The slowing produced by digitalis in *auricular fibrillation* is a different phenomenon. It occurs even after atropine, and is therefore peripheral (Cushny and Mackenzie; Gottlieb, 1914). It may be explained by the auriculoventricular blocking of some of the supernumerary impulses, through the lengthened refractory phase.

The slowing is due to chemical stimulation, and not merely to rise of blood pressure (as was supposed by A. B. Meyer), for it occurs in the clinical cases in which the blood pressure is unchanged or even diminished (Fraenkel and Schwartz, 1906). In animals the rise of pressure contributes to the slowing, for the slowing is about twice as great if the pressure rises as it is if the pressure is kept just level by hemorrhage (Kochmann, 1906).

With advanced digitalis action, the heightened contractility of the cardiac muscle renders the heart less responsive to inhibitory impulses. Vagus stimulation therefore fails to slow the heart in the later toxic stage (Liagre, 1906), but still weakens the beats. The *duration* of the actual contraction and relaxation are practically unchanged. The *speed* of the systolic contraction is somewhat increased (deHeer, 1912). The slowing occurs mainly in the diastolic pause; the systolic pause is also lengthened a trifle. The *dose required to produce distinct slowing,* on intravenous injection, is from 25 to 70 per cent of the minimum fatal dose (Robinson and Wilson, 1918); *i. e.,* it is about the same as that required to produce the muscular effect, the reversal of the T wave. The different digitalis drugs may differ quantitatively in the degree of vagus stimulation (Etienne, 1909).

The cardiac output per beat as well as per time depends on the venous return, and in pathologic hearts also on the improvement of the cardiac condition. In *normal man,* Burwell *et al.,* 1927, found the output actually diminished by 1.4 to 2.7 Gm. of digitalis, due to diminished *venous return* (Rytand, 1933). S. Weiss and Blumgart, 1929, found the *pulmonary blood flow* unaffected by large therapeutic doses in normal individuals, but increased by an average of 30 per cent in decompensated heart disease. In *dogs,* Cushny, 1897, estimated the output per beat as increased up to 50 per cent; the output per time to 20 per cent. Tigerstedt, 1907, also showed with the stromuhr that the output is generally increased. Heinz, 1900, found the flow of blood from the carotid, at a constant pressure, increased by 50 to 250 per cent. The *circulation time* is shortened in the pulmonary and in the general circulation (Langlois and Desbouis, 1915). The *vein pressure* is not materially altered, even when the arterial pressure rises (Capps and Matthews, 1913).

Blood Pressure.—In most animals (but not in man), there is marked and sustained rise of blood pressure during the therapeutic and toxic stage, except when the vagus slowing or the irregularities become excessive. The rise is due partly to the increased output of the heart, but mainly to the direct constrictor action on the arterioles, especially in the intestines.

The increased output of the heart should result in a rise of pressure. Accordingly, the pressure rises even when changes in the peripheral vessels are definitely excluded (*f. i.*, in Bock's method, where the aorta is tied, the circulation being shunted through the carotid directly to the jugular vein—Bock, 1898; C. W. Greene, 1910). While the digitalis heart can discharge a larger volume of blood against a normal pressure, the *maximal pressure*—*i. e.*, the rise of pressure on clamping the aorta—is not increased (Heinz, 1900).

Vasoconstriction.—The predominant share of this in the rise of pressure is shown by the decreased volume of the important splanchnic organs as the blood pressure rises (Gottlieb and Magnus, 1901). Further evidence is that the venous outflow is also decreased, and that the rise is not always accompanied by increased output of the heart (Tigerstedt, 1907, stromuhr). These experiments however, were made with doses far larger than are used in therapeutics. Small therapeutic doses may produce intestinal constriction even when the blood pressure does not rise. The vascular effects are more lasting than the cardiac (Joseph, 1913). The *vasoconstrictor effect is peripheral* because *it occurs in excised organs* (Brunton and Tunnicliffe, 1896). The action is presumably exerted directly on the arterial muscle. Strophanthus produces moderate stimulation of the *vasomotor center;* digitalis much less or none. The central action is not sufficient to make itself felt through the other actions of the drugs. Fatal doses result in sudden cardiac arrest and asphyxia, thereby producing intense stimulation of the vasomotor center (Pilcher and Sollmann, 1915). Very dilute solutions of digitalis produce dilatation of perfused vessels (Fahrenkamp, 1911).

Differences in Digitaloids.—The data are inadequate for definite conclusions; deHeer, 1912, and Joseph, 1913, found that ouabain had a strong constrictor effect in mammals; while Moog, 1912, claimed that its constrictor action is but one-tenth that of digitoxin. Stroomann, 1914, found strophanthin the weakest constrictor in frogs. Caffeine is antagonistic. Vogt, 1909, claimed that strophanthin does not produce constriction in *man*, but Straub, 1909, brought evidence of constriction with the string galvanometer.

Blood Pressure in Rabbits.—These do not show so great or constant a rise as do other animals; but if the pressure has been lowered by hemorrhage, digitalis produces an effective rise toward the normal level (Hernando, 1911). Digitalis did not produce much rise after chloral, presumably because the heart was too greatly injured.

Differences in Vascular Areas.—The constriction is strongest in the intestinal and splenic vessels, less in the renal, and weak in the vessels of the skin and brain. The *blood flow* is decreased in the intestines and muscle, increased in the kidneys by therapeutic doses, slightly increased in the brain. The coronary flow follows the cardiac output; it is decreased for normal hearts, increased for damaged hearts (F. Hildebrand, 1941, thermostromuhr, anesthetized dogs). Toxic doses constrict the renal vessels.

In the *kidneys*, the dilatation is partly direct, for with excised organs certain concentrations dilate the renal vessels, while they constrict the intestinal vessels. However, in eviscerated rabbits with automatic blood pressure compensation, digitalis produced renal constriction (Ogaki, 1927). *Pulmonary vessels* are somewhat constricted in perfusion experiments (Tschistowitch). Excised arterial rings are also constricted by all digitaloids, except digitonin, which dilates (Macht, 1914). In life this action is unimportant; for the slight rise of pressure in the pulmonary artery is mainly cardiac (Plumier, 1905; Wiggers, 1911). The filling of the *vessels of the pia mater and retina* follows the general blood pressure (Hirschfelder, 1915).

Coronary vessels may be constricted, especially by digitoxin, less by strophanthin (Rabe, 1912). Excised arterial rings are also constricted (Voegtlin and Macht, 1913). The constriction would be overcome by the improved cardiac contraction; so that the *coronary flow in life* was found unaltered by therapeutic doses (Bond, 1911), or even increased (Sakai and Saneyoshi, 1915). Essex *et al.*, 1938, found no significant change in the coronary flow in the dog after nine days of digitalization; but continued toxic doses may decrease it (W. H. Dearing, Essex *et al.*, 1943). J. L. Miller, 1908, found that digitalis enabled the heart to tolerate a greater degree of *coronary obstruction*, but Kisch and Schwarz, 1936, did not obtain improvement of the anemic changes in the electrocardiograms, in rabbits. Large toxic doses contract the coronary vessels even in life, with rising blood pressure; this is sometimes followed by increased flow with falling pressure (Sakai and Saneyoshi, 1915).

Thoracic Lymph Flow.—In normal animals, this is not changed during the rise of arterial pressure; nor is the pressure in the portal capillaries increased (Yanagawa, 1916).

Toxic Effects on the Circulation in Mammals.—These are characterized by irregularities of the rhythm and strength of the cardiac pulsations. They are exaggerated manifestations of the vagus and cardiac stimulations which were initiated in the therapeutic stage. The *vagus effects* (slowed rhythm, diastolic tendency, lessened conductivity) reach their acme most rapidly; so that the first indications of overdosage are commonly those of marked inhibition. This inhibition is in turn overcome as the *muscular excitability* becomes greater and greater; thus the final effects are mainly muscular (increased tone, heightened irritability, spontaneous ventricular rhythm, extrasystoles). The irregularities which result from these interactions weaken the circulation and interfere with the nutrition of the heart, until this becomes arrested. Cushny, 1897, divided the successive effects into the inhibitory stage and the stage of muscular irregularity. *In the typical course,* the effects pass successively through the therapeutic, vagus and muscular stages; but the vagus stage is often omitted in animals. The "toxic effects" in man are generally of the inhibitory type.

The **inhibitory stage** corresponds to strong vagus stimulation. The rhythm becomes very much slowed—to 40 or 50 beats per minute. It is often irregular; there are scattered diastolic pauses which become more frequent and lasting, particularly in the auricles. These irregularities are partly exaggerations of the normal respiratory variations, but they are often independent. The two sides of the heart contract at the same rate, but the ventricles are likely to assume a spontaneous rhythm, which may be faster or slower than that of the auricles. This independent rhythm is due to the blocking of the auricular impulses by the lessened conductivity. The excessive slowing and the irregularity diminish the time output of the heart in this stage, although the amplitude is increased. The blood pressure falls.

In the stage of muscular irregularity, the rate, rather suddenly, becomes more and more accelerated, as if the heart escaped from the vagus influence. Electric vagus stimulation has less and less effect on the rate; but since it still increases the diastole the vagus cannot be paralyzed. The escape is due to the excitability of the heart becoming so greatly increased that the vagus is unable to restrain it. The auricles and ventricles may at first keep the same rate; but the ventricles soon assume a rapid rhythm independent of that of the auricles; for the conduction of the auricular impulses is more and more blocked, while the spontaneous excitability of the myocardium is more and more increased. The accelerators usually do not respond to stimulation (Fredericq, 1913).

This independence of the auricular and ventricular contractions results in curious *periodic variations* in the volume of the pulse, the rhythm at this time being fairly regular. One or more enormously strong beats are followed by much weaker beats, sometimes quite imperceptible in the pulse, which is therefore *intermittent.* These phenomena recur in groups, which remain fairly regular for a short time, but soon change to some other type. These effects are sometimes due to respiration; in other cases they are cardiac. These are also seen in the atropinized heart, and are mainly due to the *arrhythmia of the auricles and ventricles* (Cushny, 1899). As a consequence, the contractions will sometimes alternate, sometimes coincide, forming groups. If the auricular systole occurs during the ventricular diastole, the ventricles will be filled with blood when they contract, and the result will be a large pulse wave; if the auricular and ventricular systoles coincide, no blood will be moved, and there will be no pulse The two sides of the heart continue to beat synchronously, although the periodic variations of strength have no relation. After a time, *extrasystoles* (*i. e.,* premature contractions by which no blood is expelled) appear, and the pulse shows corresponding intermissions. These become more numerous. The rate continues to increase, becoming faster than in atropine poisoning. Various complex irregularities are superadded, and the contractions become thoroughly disorganized.

Terminal Changes.—The quickening of the rate soon exceeds the optimal limits. The contractions become superficial, fluttering, much less effective, and more fatiguing. The blood pressure falls and the heart is unable to keep the pace. First the auricles, then the ventricles, pass into fibrillation and the circulation is arrested. The chambers stop in median position, and then gradually become greatly dilated.

Racial Tolerance.—Great differences exist in the susceptibility of different species to digitalis poisons. Rodents, toads (Vulpian, 1856) and the grass snake are especially resistant, but not immune. The *resistance of the toad and snake* does not extend to the related action of barium or saponin (Clark, 1913). The toad resistance is generally attributed to habituation for its own poison; and Filippi, 1913, claimed that toads deprived of their poison are sensitive to digitalis. The fatal dose for *rats* is nearly a thousand times greater (per kilogram) than that for cats, even hypodermically (Hatcher, 1909), and thirty times as much as for rabbits. Gunn, 1913, found that the concentration required to arrest the isolated heart in a given time is also forty times greater for rats than for rabbits, showing that the difference lies chiefly in the heart itself. Excised papillary muscle of *rabbits* is considerably less susceptible than that of cats to minimal doses of ouabain (Cattell and Gold, 1938). Rabbits also *excrete digitaloid glycosides more rapidly* (Hatcher, 1912). Salvisberg, 1907, claimed that ruminants are more resistant to oral administration, but not to intravenous, indicating that in these animals the drugs are partly destroyed in the digestive canal. Lhota, 1909, stated that young animals are more resistant than adults. *Pigeons* tolerate intravenously twenty-five times as much digitalis (per unit of body weight) as do cats, but only about twice as much ouabain or strophanthin. However, many of the pigeons injected with 75 per cent of the acute M.F.D. of digitalis die somewhat later; especially with digitoxin (Haag, 1936). *Seasonal variations in susceptibility* occur in frogs and guinea pigs. They run reverse to the seasonal variations of acetonitrile and diphtheria toxin (Haskell, 1914).

Influence of Various Conditions on Digitaloid Effects.—The response to digitalis is influenced not only by its concentration, but also by other conditions, especially by pathologic changes in the heart which will be discussed in the therapeutic actions; and also by temperature and by the chemical agents. The effects of the latter may be somewhat different with intact animals from those with excised hearts. The *additive effects* of *calcium* are of practical importance, because of the danger in the simultaneous use of these drugs. Intravenous injection of calcium in mammals is generally believed to render these materially more susceptible to the toxic cardiac effects of the digitaloid drugs (Gold and Edwards, 1927). The subject is in dispute.

Contrary results of Nahum and Hoff, 1937, are criticised by Gold and Kwit, 1937; but P. K. Smith, Winkler and Hoff, 1939, reported a further series of intravenous injections of dogs which failed to show that the fatal dose of calcium is smaller in digitalized animals, or that digitalis renders the heart more susceptible to calcium fibrillation, or that calcium increases the toxicity of digitalis. They attributed the potentiation reported by others to the variable toxicity of calcium and digitalis. The toxicity of digitalis is also increased (by 20 to 30 per cent in cats) by the rapid intravenous injection of *hypertonic solutions* of sodium chloride, dextrose or urea, and by theophylline or theobromine. It is decreased by caffeine. Mercurial nephritis and ligation of the ureters increase the toxicity (R. Kohn and Costo-Panageotis, 1933). Strophanthin action on isolated frog heart is intensified by adding urea, presumably through increased adsorption on the surface (Heim, 1939). *Hyperpyrexia* (by hot baths) increases considerably the toxicity of digitalis for intact mammals; the effects, including the reversal of the T wave, are qualitative as in normal mammals (Hirschfelder *et al.*, 1920). *Beriberi* patients are said to be resistant to digitalis. Beriberi pigeons are reported to be more resistant to both the cardiac and emetic actions of digitalis, but more susceptible to strophanthin (Mehes and Peter, 1934).

Influence of Conditions on the Digitalis Response of Excised or Perfused Hearts.—Sollmann, Mendenhall and Stingel, 1915, determined the *ratio of concentration and activity.* The feebler the actions of ouabain, the more is its activity increased by doubling the concentration. Holste, 1912, and Weizsaecker, 1913, found that the *vigor of the heart* influences the response quantitatively. The greater the intensity of the cardiac functions, the prompter the strophanthin effect. The cardiac effects of the digitaloids on frogs increase with the *temperature* (Trendelenburg, 1909), the increase being greater for low than for high temperatures. The activity is increased by heat, not only directly, but also through the more rapid heart rate (Sollmann, Mendenhall and Stingel, 1915). In the perfused mammalian heart, the effects are also quickened by heat; in this case the more rapid coronary flow is a contributing factor (Gunn, 1914). Werschinin found the systolic action much weaker in Ringer's solution than in *serum* solutions of the drugs. Oppenheimer, 1913, observed that serum inhibits the action of the less soluble digitaloids, but not of strophanthin. Cholesterol and egg albumen did not have equivalent effects. *Oxygen* increases the digitalis effect (Gruenwald, 1912).

Influence of Ions.—The systolic digitalis action occurs only if the perfused solution contains *calcium ions* Excess of alkali or absence of potassium rather increases the systolic action; excess of Ca has little effect (Clark, 1912). On the other hand, strophanthin delays the standstill of the heart when this is perfused with Ca-free solutions or with pure K solutions; but it hastens the arrest when added to a solution from which Ca and K are both absent (O. Loewi, 1912; Konschegg, 1913). Strophanthin may therefore to a certain extent replace Ca, and thereby antagonize the K ions. The effects of the ions on the vagus action are quite different (Clark, 1914). Addition of decalcifying agents restores the beat of embryonic chick hearts when this has been arrested by digitalis (Paff, 1940). The potency of digitalis glycosides for embryonic chick hearts is inversely proportional to the *potassium* ion content of the medium (R. A. Lehman and Paff, 1943). Oral administration of potassium chloride (5 to 10 Gm. for man) abolishes ectopic beats resulting from digitalis (J. J. Sampson *et al.*, 1943). Therapeutic doses of digitalis in cats produce a significant increase of the potassium and water within the cardiac muscle cells, and decrease their chloride (P. K. Boyer and Pointdexter, 1940).

Hypertonic Solutions.—Gramenitzky, 1937, reported that if a heart which has been arrested by digitalis is transferred to Ringer's solution rendered hypertonic by the addition of 1½ to 2 per cent of sodium chloride, the auricle is immediately revived.

Antagonism with Alkaloids.—A perfused frog heart that has been slowed and weakened by the vagus action of pilocarpine is strengthened but not quickened by digitalis (Ransom, 1917). Lhota, 1909, claimed that cocaine diminishes the toxicity of strophanthin by lessening the cardiac excitability. Wilbur, 1911, found that strychnine often removed the ouabain heart block in terrapin's heart. He reported that *irritants* (iodine) produce effects similar to those of digitalis on terrapin's heart. *Procaine, quinidine, 883F and 933F,* which inhibit ventricular fibrillation from epinephrine, are not effective against that of digitalis (G. A. Emerson, 1943).

Blood Coagulation.—Digitalis glycosides have a thromboplastic effect *in vitro,* and intravenous toxic doses shorten the coagulation time. Heparin lowers the toxicity (S. C. Werch, 1943; D. I. Macht, 1943). Massie *et al.*, 1944, report that coagulability increases during long-continued clinical digitalis therapy. N. C. Gilbert *et al.*, 1944, suggests that this is responsible for the incidence of thrombosis in digitalized patients. Others, however, failed to demonstrate a significant change of coagulability with oral digitalis therapy of patients (Sokoloff and Ferrer, 1945) or on dogs (J. A. Richardson and Walton, 1946).

Central Effects of Digitalis.—The peripheral effects dominate the symptom-complex so greatly that the direct central effects appear unimportant. The cardiac action is so selective that frogs whose hearts have been stopped by digitalis may hop about as if normal. The *medullary* centers are probably stimulated directly, but the indirect effects from the altered circulation are much more important than any direct actions.

Central Symptoms.—When digitalis is injected into the ear vein of *unanesthetized* rabbits, or subdurally, symptoms occur immediately and appear to be largely central. They consist in dyspnea; tremors and convulsions; miosis; debility and paralysis of certain muscle groups, especially the neck; abolition of certain reflexes. These effects are followed by asphyxial convulsions with mydriasis and death by paralysis of the respiration or heart. The later symptoms are, at least partly, due to the circulatory changes; but the earlier symptoms are probably due to direct central actions (Santesson and Strindberg, 1916).

Direct application of strophanthin to the cerebral motor cortex produces clonus and generalized convulsions (as do also nicotine and caffeine; Rizzolo, 1929).

Respiration.—Hypodermic or intravenous injection produces a primary increase of the respiration in rabbits. Larger doses depress (Gross, 1914). *Excised bronchial muscle* is not affected by strophanthin (Trendelenburg, 1912).

The **gallbladder** is stimulated (Lieb and McWhorter, 1915).

Uterus.—Strophanthin revives the movements of the excised uterus when these have been arrested by calcium-free Ringer's solution. Short exposures to strophanthin render the uterus hypersensitive to calcium (Ransom, 1920).

Skeletal Muscle.—If a frog's sartorius muscle is immersed in dilute ouabain solution (1:1,000,000) and then suspended in air, it reacts to stimulation with gradually increasing twitch tension and increasing heat production. This is followed by abrupt diminution of both functions and finally complete loss of excitability. Rapid recovery occurs on immersion in Ringer's solution, even that containing the ouabain; nor do the toxic effects develop while the muscle is kept immersed in ouabain-Ringer solution (Cattell, 1938). The effects resemble those of potassium, and the changes are consistent with the assumption of escape of *potassium* from the muscle cell, which has been demonstrated for striated frog muscle and for the tissues of dog's heart-lung preparation (M. K. Cattell, 1943).

H. Freund, 1936, reported that the effects of digitaloids on the metabolism of skeletal and cardiac muscle are similar; therapeutic doses increase the formation of lactic acid from glycogen, with the opposite effect from toxic doses. Skeletal muscles take up active quantities of strophanthin from the circulation.

The **chromatophores** of toad skin are contracted by cardiac glycosides with the minimal concentrations that cause systolic arrest of the heart (Hargreaves *et al.*, 1938).

The epinephrine output is not affected by strophanthin (Stewart and Rogoff, 1919). Previous workers used inadequate methods.

Local Actions.—Digitalis and the allied drugs, when injected hypodermically, cause fairly severe irritation, pain and abscess formation, which practically preclude their use by this channel. Intramuscular injection is feasible, although not painless. Cardiac glycosides lack *carcinogenic action* when tested on mice (P. K. Smith and Gardner, 1939).

Relative Irritant Action.—Holste, 1913, from hypodermic and conjunctival application to rabbits, established a series for the isolated principles as: most irritant = digitoxin; then digitonin, then digitalein and cymarin (from apocynum). Practically nonirritant = digitalin, ouabain and strophanthin. Digalen was much more irritant than digipuratum. On the skin of young pigs, O. Loeb and Loewe, 1916, also found digitoxin and digalen the most irritant. Digipuratum, strophanthin and ouabain were about as irritant as digitalis infusion. Strophanthin does not inhibit the *emigrations of leukocytes* from inflamed mesentery (Ikeda, 1916). Steinach, 1888, and Panas, 1890, found that application of strophanthin to rabbit's conjunctiva produces *local anesthesia* lasting several hours. In man, however, there is considerable inflammation. Other digitaloids are also anesthetic.

THERAPEUTIC USE OF DIGITALIS

Historical.—The professional use of digitalis is relatively recent. It was recognized by William Withering of Birmingham (Cushny, 1915) as an ingredient of an old woman's secret formula. After ten years of experimentation, he published his results in 1785. He was chiefly interested in the diuretic effect, and mentions the cardiac action only incidentally. The evidence for the connection of the circulatory and diuretic effect was first emphasized by John Ferriar in 1799. The drug quickly assumed an important place, though its proper field was not recognized. The cardiac slowing particularly attracted attention, and as late as 1851 Traube referred the clinical effects entirely to this "depressant" action; hence, digitalis was used in aneurysm, internal hemorrhage, and the like, for which it would be entirely unsuitable. Ten years later, Traube accepted the rise of blood pressure, which had been discovered in animals, as the basis of the therapeutic effect. *Strophanthus* was brought to Europe in the early sixties, and its cardiac actions were promptly discovered. Its introduction into medicine is due mainly to Th. R. Fraser, 1885. The use of *Scilla* dates from the ancient Greeks, although its cardiac action was not recognized. *Apocynum* was used by the early settlers as a hydragogue cathartic and diuretic; presumably they learned of its use from the Indians. *Convallaria* has also been used for several centuries in domestic medicine, against cardiac symptoms.

Clinical Field.—Digitalis and the allied drugs are especially useful to secure and maintain compensation in chronic cardiac diseases, when the heart contracts imperfectly and becomes dilated; either because of incoordinated or irregular contractions, as in auricular fibrillation, or because of exhaustion of the cardiac muscle by its inability to compensate for the mechanical defects of structural lesions. The indications for its employment are governed by the functional conditions of the cardiac muscle, and only indirectly and to a minor degree by the gross anatomic lesions. The most striking results are seen in auricular fibrillation; but definite though less obvious improvement occurs in chronic dilatation with normal rhythm. In this case, the improvement tends to be self-perpetuating, so that digitalis needs to be given only at intervals. With auricular fibrillation, the effect must generally be maintained by more or less continuous administration. Digitalis medication has not given definite clinical results in acute cardiac conditions, other than exacerbations of chronic lesions; partly perhaps because it was administered by methods in which its action is developed too slowly to meet acute conditions; but mainly because acute heart failure is generally due either to profound intoxication of the cardiac muscle, or is secondary to other conditions (for instance, vascular paralysis in fevers, and so forth), which must be the real object of treatment.

Explanation of Clinical Effects.—The slowed conduction and the muscular stimulation are both important; the slowed conduction is the more important in auricular fibrillation; the muscular stimulation in uncomplicated dilatation. The improved tone and contractibility of the muscle increases the amplitude of the systolic contraction, and thus the time output. It counteracts the dilatation directly, and may narrow a leaking valvular ring. In auricular fibrillation the slowed conduction is especially important. This blocks the majority of the confusing impulses and permits the ventricle to make effective contractions. All these actions increase the efficiency of the circulation, insuring a better filling of the arteries, improving nutrition and oxygenation, and relieving the congested veins. The heart is among the first to feel the effects of this improvement. The vicious circle of weaker heart, poorer circulation is reversed into the beneficial stronger heart, improved circulation; so that the effects outlast the administration of the drug, and the improvement is perpetuated. At the same time, the circulation in the kidneys is improved by the faster blood flow, the increase of pulse pressure and the relief of the venous pressure. The kidneys are thus placed in the best condition for filtration or secretion. The anuria is relieved. If there has been edema, the improved kidney action results in extensive diuresis and thus in the absorption of the edematous fluid. This in turn improves the heart action and the whole circulation, by relieving them of the compression of the ascites. The vasoconstrictor action may also play some part; since it is strongest in the intestines and liver, it may help to relieve the congestion of these organs. Rise of blood pressure, as such, has no important share in the action, for it rarely occurs clinically, even with intravenous injection, or in cases which are greatly benefited (Fraenkel and Schwartz, 1907).

Recapitulation of the Effects of Clinical Doses of Digitalis on Normal Man.—The most constant and definite change is the *reversal of the T wave of the electrocardiogram* (Cohn, 1915). It is ascribed to the increased muscular irritability. Diminution of the wave is distinct in about ten hours, with relatively small doses ($\frac{1}{4}$ minim of the standard tincture per pound bodyweight); this may serve for a physiologic assay. With the intensive dosage (1 minim per pound, at one dose), the effect is visible in two hours and reaches its maximum in eight or nine hours (Pardee, 1923). *Auriculoventricular conduction in man* is always impaired, being an early and positive sign of digitalis action. It may be observed within forty-eight hours, and increases with the administration, from simple lengthening to heart-block. After withdrawal, it persists generally about two days, but sometimes two weeks. Full therapeutic doses (a total of about 25 cc. of the tincture) are required to produce a definite lengthening of the auriculoventricular interval. The effect is largely vagal, for it is generally removed by atropine (White and Sattler, 1916).

Heart Rate in Man.—Patients with auricular fibrillation, or with adynamic or unstable hearts, respond by slowed pulse to ordinary doses; but the rate of the normally rhythmic heart, whether the rate be fast or slow or normal, is generally slowed only moderately, and only by doses that produce toxic effects (0.4 Gm. per day for five to seven days). Some patients, especially children, may react to smaller doses. Slowing of the rhythmic heart is therefore generally a toxic rather than a therapeutic phenomenon. It is partly but not entirely vagal, for in many patients it cannot be completely removed by atropine (Wedd, 1919).

Blood Pressure in Man.—The rise of pressure which is characteristic for most animals is not often seen in man, either in health or disease (Czylharz, 1900; Schwartz, 1906; Cushny, 1911; Mackenzie, 1911; Price, 1913; Cohn, 1915; Eggleston, 1917). In heart disease, the improvement under digitalis may even be accompanied by a fall of pressure, if this has been abnormally high (Fraenkel, 1905; Price, 1914; Martinet, 1914). A rise is exceptional, occurring only if the pressure has been below the normal level. The diastolic pressure is always lowered when digitalis relieves uncompensated lesions, no matter what the changes in the systolic pressure. The pulse pressure is therefore generally increased (Martinet, 1914).

The difference cannot be explained by dosage, for in animals the rise occurs with the smallest doses which have a noticeable effect on the heart. It is explained by the more perfect blood pressure regulation of man, which compensates the pressor tendency by inhibition of the vasomotor center and by stimulation of the vagus center. If the digitalis slowing is prevented by atropine, the pressure rises also in the human subject (Fraenkel, 1905).

Digitalis in Auricular Fibrillation.—This condition, which constitutes a half of all cardiac irregularities (Lewis), and two-thirds of all serious cardiac failures (Mackenzie), shows the most striking improvement under digitalis (Cushny, 1911; Mackenzie, 1911). The effect on the auricles themselves is relatively slight; the auricular tone should be increased, and the auricular distention would be relieved by the improved circulation; but the multiple irregularity of the fibrillating auricle is not notably altered, even under continued digitalization. The fixed circuit of auricular flutter (Lewis, Feil and Stroud, 1920) is often broken up by the increase of the refractory phase, under digitalis, and is temporarily split up, as it were, into multiple circuits, *i. e.*, fibrillation (Lewis, 1911); and with further increase of refractoriness, these temporary paths may also be blocked and a regular rhythm attained (review, Garrey, 1924).

The main improvement, however, is in the ventricular contractions. These do not become regular, but the irregularity is decreased, and the rate is reduced from 120–160 to 80–100. The ventricular efficiency, which was greatly impaired by the disorganized rhythm, is much improved, and with it the cardiac output and the blood flow (G. N. Stewart and Scott, 1915). The dyspnea and all the other symptoms of cardiac insufficiency are relieved, including the exaggerated acceleration of physical exercise (W. Modell *et al.*, 1941). The slowing and regularization of the ventricles is due mainly to decreased auriculoventricular conduction, which blocks many of the excessive auricular impulses from the ventricle (Cushny, 1917; 1918), so that the ventricles respond more forcibly and more effectively to the remaining impulses. The block is effected by the summation of vagus stimulation, which tends to predominate with moderate doses; and a myocardial factor, the increased refractoriness that follows stronger contraction of the bundle, which is involved especially with full doses. Atropine, 2 mg. intravenously in man, which eliminates the vagus factor, usually prevents slowing by conservative digitalis dosage (Cushny *et al.*, 1912), but not with intensive digitalization (Gold, Kwitt *et al.*, 1939).

A third mechanism of blockage is illustrated by quinidine, which increases refractoriness directly, *i. e.*, by checking the restorative metabolism. The effects of the three measures are contrasted in the table. It may be added that overdosage with digitalis (also with barium, aconite, etc.) may produce auricular fibrillation (Cushny, 1911), by causing intra-auricular blocks that interfere with the orderly progress of the excitation wave. This is especially likely to occur with intravenous injections if the myocardium was severely damaged, and in coronary occlusion (Robinson *et al.*, 1924).

To obtain the best results in auricular fibrillation, the digitalis must be started with full doses. Smaller doses must then be continued for a long time, giving just enough to keep the rate between 70 and 80 per minute. Overdosage is often indicated by occasional reduplication of the pulse ("coupled beats," "pulsus bigeminus"), due to ventricular extrasystoles (Lewis, 1911). Although this may occur with relatively small doses, it is considered an indication to reduce or to discontinue the digitalis. If the auricular fibrillation occurs in cardiosclerosis or when the myocardium is excessively weakened, digitalis is much less effective and much more dangerous.

Influence of Cardiac Irregularities on Cardiac Output.—Experiments on dogs show that *extrasystoles* have little effect, even when they are frequent (1 in 4 to 8). *Auricular flutter* and especially *auricular fibrillation* reduce the output considerably. This is due to the irregularity (premature beats and the like) rather than to the rapid rate. *Heart block,* partial or complete, diminishes the output greatly, proportional to the slowing (Eyster and Swarthout, 1920). Cardiac insufficiency generally increases the *oxygen consumption of the heart,* especially in relation to the output. This uneconomical oxygen use decreases with the first sign of improvement (Gremels, 1933).

Other Arrhythmias.—Irregularities other than those arising from auricular fibrillation and flutter are not materially improved by digitalization, and this is contraindicated in partial heart block. It must not be forgotten that over-dosage of digitalis may provoke any of the clinical types of irregularity even in a healthy heart, and this may occur more readily when the heart is disposed to them by disease. It is therefore necessary to watch carefully for the appearance of any irregularities.

Partial Heart Block (diminished conductivity of the auriculoventricular bundle).—This is always exaggerated by digitalis: a slight retardation between the auricular and ventricular contractions may thus be converted into a partial block, so that the ventricles respond only to every second or third beat of the auricles; or a partial block of this kind may be converted into a complete block, the ventricles assuming their characteristic slow independent rhythm. In partial heart block (even when the a-c interval in the jugular tracing is merely lengthened) digitalis should be avoided, and employed only with caution when it is otherwise urgently needed. If the need for it exists, however, it may relieve the symptoms even though it exaggerates the partial block.

TABLE OF CONTRAST OF CARDIAC ACTION

Function		Digitalis	Vagus Stimulation	Quinidine
Tonus		Increased	Decreased	Decreased
Contractions		Stronger	Weaker	Weaker
Refractory phase		Longer	Shorter	Longer
Conduction		Stronger but slower	Faster but weaker	Slow and weak
Partial heart block		Exaggerated by long refractory pause	Exaggerated by weak conduction	Probably exaggerated by long refractory pause and poor conduction
Auricular Fibrillation	Aur. rate	May be decreased by lengthened refractory or increased by heightened irritability	Increased by shortened refractory period	Decreased by lengthened refractory per. and diminished excitability
	Ventr. rate	Slowed by lengthened refract. per. of bundle	Slowed by weak conduction in bundle	Slowed by lengthened refract. per. and diminished excitability of bundle and muscle

Complete Heart Block.—In this, digitalis can do no further harm, for it does not slow the spontaneous ventricular rhythm. On the contrary, it would tend to quicken the beat; at all events it would tend to render it more effective. It might therefore be of some use (Bachmann).

In complete experimental heart block (dogs) strophanthin first increased the rate and strength of the ventricular contraction. This was followed by sudden ventricular arrhythmia and tachycardia, increasing to fibrillation. The auricles were strengthened, their rate sometimes quickened or slowed. The blood pressure rose in the first, and still more in the second stage (van Egmond, 1913).

Irregularities in the Strength of the Cardiac Contractions (Pulsus alternans).—These are attributed to exhaustion of the myocardium. They are therefore improved by digitalis (Windle, 1917; Christian, 1915). It must be employed with caution, for similar irregularities are prominent in digitalis poisoning, and an exhausted heart is more subject to these effects.

Extrasystoles are not removed by digitalis since they are probably due to heightened irritability of the myocardium—a condition which could only be exaggerated by digitalis. Extrasystoles due to nervous exhaustion, indigestion, nicotine, and so forth, do not require medicinal treatment; they tend to disappear under suitable hygiene, and in any case they have no serious significance. (The influence of various drugs on extrasystoles was studied by McCord, 1912). Guthrie, 1917, reported that digitalis (toxic doses) decreases the irritability of frog and turtle heart to extrasystoles by electric stimulation.

Periodic changes in sinus rhythm (such as the exaggerated respiratory variations, which occur in general nervous exhaustion, rather than in cardiac disease) are not benefited by digitalis. On the contrary, the vagus stimulation would tend to render them more marked.

Paroxysmal Tachycardia.—The response varies. In some cases, digitalis is practically ineffective; in others, intravenous strophanthin reduces the rate strikingly.

Febrile Tachycardia.—The heart rate in fever is not materially affected by digitalization, although the reversal of the T wave and the effect on auricular fibrillation are produced in fever just as with normal temperature (Cohn and Jamieson, 1917).

Irritable Heart.—The simple tachycardia of the "effort syndrome" is not slowed by digitalization (J. Parkinson, 1917), nor is that of Basedow's disease (Cohn, 1915).

Myocardial Insufficiency with Normal Rhythm.—In functional impairment of the efficiency of the cardiac muscles, without changes of rhythm and without lesions of the valves, digitalis does not usually slow the heart rate even when this is fast; but it increases the excursions (roentgen observations, A. E. Cohn and Stewart, 1924), and causes the disappearance of the symptoms, including the edema (Cushny, 1911). This may be attributed to the direct muscular stimulation. If the cardiac muscle is degenerated, as in cardiosclerosis, digitalis will be useless or even harmful, by imposing too great a task on the few weakened muscle fibers remaining.

Use of Digitalis in the Special Cardiac Lesions.—No cardiac lesion, as such, either indicates or contraindicates digitalis. Whatever the lesion, digitalis would be superfluous so long as compensation is fairly perfect. The indications for its use arise only when compensation fails; then its possibilities for good or harm are determined by the functional conditions, and not by the location of the anatomic changes.

Mitral Stenosis.—It has been suggested that the lengthened auriculoventricular pause would permit a better emptying of the auricle (Cohn and Fraser, 1913).

Aortic Insufficiency Not a Contraindication.—The older clinicians, since Corrigan, considered digitalis contraindicated in this condition, fearing that the prolonged diastole would give the blood in the brain a chance to gravitate back into the heart, and thus produce syncope. Although this explanation may be questioned, acute or chronic surgical injury to the aortic valves in animals increases their sensitiveness to digitalis, by as much as a fourth (A. E. Cohn and Stewart, 1928; Weese and Dieckhoff, 1934). However, the clinical use of digitalis in this condition is not unduly dangerous (Christian, 1919) and it is now given freely, as in other lesions. It is advisable to keep the patient in bed during the digitalization.

The occurrence of syncope on changing suddenly from prostrate to the upright position may occur under the influence of digitalis, even with other lesions; the patient should be cautioned as to this.

Cardiosclerosis.—Digitalis is useless with a heart which has undergone marked fatty or fibrous degeneration. In this condition it is often contraindicated, because the overworked muscle is more readily poisoned.

High blood pressure has little bearing on the usefulness of digitalis. Its existence does not contraindicate the administration.

Acute Myocarditis and Endocarditis.—The use of digitalis is debatable: it can easily lead to dangerous overstrain of the hypersensitive muscle.

Coronary Insufficiency.—The effects of digitalization on the coronary circulation of animals are variable. The observations of Gold, Otto *et al.*, 1938, on 120 patients who had cardiac pain without congestive symptoms showed that changes in the pain or in the course of the condition occurred with equal frequency with a placebo as with digitalis. However, coronary infarcts in cats distinctly increased their susceptibility to the toxic actions of digitalis (Travell, Gold and Modell, 1937). In patients who have auricular fibrillation with *myocardial infarcts*, digitalis generally is more harmful than useful, tending to mobilize thrombi and produce embolism in the greater circulation (Askey and Neurath, 1945).

Aneurysm.—The sudden distention of the aneurysmal sac by a larger mass of blood, which would be the result of digitalis, is exactly contraindicated.

High altitude fatality is decreased by digitalization (E. Fischer, 1941; mice).

Digitalis in Infectious Fevers.—Fever does not modify the digitalis actions, the heart responding essentially as in nonfebrile individuals (Hirschfelder, 1920). Therapeutic doses have little effect on the febrile tachycardia, since this is due chiefly to increased metabolism. However, very large doses of digitaloids are required to produce cardiac stand-still (F. Herzog, 1930), owing perhaps to more rapid fixation of the glycosides in noncardiac tissues, such as in skeletal muscle and in liver, and their more rapid destruction. Digitalis would be indicated in fever patients with cardiac lesions, and particularly with auricular fibrillation. In the absence of these, however, its usefulness is doubtful (Hart, 1919).

The terminal collapse in fever is not due primarily to cardiac failure, but to capillary injury and blood concentration. When the heart muscle is affected, the injury is more profound than digitalis can correct; in fact, ordinary doses of digitalis are likely to become toxic to such hearts (for instance, with *diphtheria toxin* in guinea pigs and cats; Edmunds and Mayer, 1937) and digitalis is practically ineffective, just as in other forms of "shock" (G. Schwartz, 1906).

Digitalis has been prescribed in *pneumonia* as a prophylactic precaution against cardiac fibrillation (Cohn, 1915), but it is conceivable that it may dispose toward fibrillation, as it seems to do in diphtheria (Robinson). The parallel comparative study of Wyckoff, Du Bois and Woodruff, 1930, on nearly 750 pneumonia patients, showed a mortality rate of 34 per cent in the patients without digitalis, and 41 per cent in those with digitalis. Conservative doses of digitalis did not definitely influence the outcome, and the larger doses definitely increased the mortality, even when there was no direct sign of digitalis toxicity. Digitalis, therefore, does not appear advisable in pneumonia, except for the patients with definite auricular fibrillation.

Diuretic Action.—The digitalis drugs are potent diuretics in cardiac dropsies; the diuretic effect is proportional to the improvement of the circulation and to the absorption of the edemas. In all other conditions they have little or no effect on the urine. Practically negative results are obtained in normal individuals (Schwartz, 1906), in heart disease without effusion (Cohn, 1915) and in purely nephritic edemas (J. Miller, 1912). Moderate doses of digitalis have no effect on either the renal blood flow or the diuresis of normal animals; excessive doses slow the urine and blood flow, although they raise the blood pressure (Cushny and Lambic, 1921; externalized kidney, W. E. Reed).

The *factors involved in the improvement of the renal circulation* are mainly the relief of the venous pressure; the increased output of the heart; the increased "pulse pressure"; and the hydremia resulting from the absorption. These mechanical conditions cause corresponding increase of urine filtration even in dead kidneys (Sollmann, 1915).

Gremels, 1929, reported increased oxygen consumption by the kidneys and some diuretic action apart from circulatory changes in Starling heart-lung-kidney preparations; and Weese, 1934, concluded from the Rehberg method that digitalis diuresis involves diminished tubular reabsorption.

Gesell, 1913, found that artificial *changes in the pulse pressure* produced parallel changes in the excretion of urine, chlorides, urea and nitrogen.

Influence of Hydremia.—This is not the primary cause of the diuresis. Martinet, 1914, found that the viscosity of the blood and the protein content of the serum remain unchanged so long as the absorption of edema is in progress. When the edema has disappeared, but the diuresis still persists, the viscosity increases. Calvin *et al.*, 1940, reported that in patients with congestive heart failure the plasma volume falls during the diuresis induced by digitoxin.

TOXIC EFFECTS IN THE CLINICAL USE OF DIGITALIS

Digitalis is practically useless unless the dosage is sufficient materially to impair conduction; this impaired conduction is itself capable of causing arrhythmia, *i. e.*, of producing toxic effects. In other words, the full therapeutic effect practically coincides with the minor toxic manifestations (Eggleston, 1915). There is a fairly wide margin, however, between the therapeutic and the fatal dose (the therapeutic representing about one-third of the fatal; Robinson and Wilson, 1918); and the minor toxic effects do no permanent harm, if the dosage is reduced promptly on their occurrence. If they are disregarded, permanent irregularities may result. The emetic action furnishes a fairly efficient protection against overdosage by oral administration, but with intravenous injection fatalities are fairly common.

Digestive disturbances are important signals, since they occur early and are easily recognized. They consist in nausea, great malaise and often headache which may be very distressing. Vomiting occurs if the drug is continued. *Diarrhea* is not common with digitalis, is more frequent with strophanthus, squill and helleborein. When any of these digestive symptoms occur the dosage should be reduced or stopped. They subside in one or two days (Cohn, 1915).

With *normal individuals,* receiving standardized digitalis powder at the rate of 0.5 Gm., followed by 0.2 Gm. every six hours, intense nausea occurs when the total reaches 1.4 to 1.8 Gm. This also causes inversion of the T wave, and sometimes sino-auricular block (H. Feil, 1939).

Ratio of Emetic Potency.—With intravenous administration, Eggleston and Hatcher, 1913, found true digitalis the most emetic (emetic dose = 22 per cent of the fatal); then came strophanthus, ouabain, digitalis, digipuratum, digalen and adonis (ratio = 40 to 50 per cent); then digitoxin and amorphous strophanthin (58 to 65 per cent); least emetic were squill and apocynum (75 to 88 per cent).

Mechanism of the Emetic Action.—The nausea and emesis are not due to local gastric irritation, as was formerly thought. They set in only when the cardiac effects are manifest (Eggleston, 1913), and are perhaps best explained on the assumption that the emetic center is stimulated by reflexes set up chiefly by the cardiac actions (Hatcher and Weiss, 1923); in other words, the emesis seems to be a secondary manifestation of the cardiac action. It would therefore be useless to search for "nonemetic" digitalis preparations.

The *small importance of local irritation* is indicated by the fact that emesis occurs more readily with intravenous than with oral administration (Hatcher and Eggleston, 1912).

Very sensitive individuals may be nauseated by the acrid taste of even small doses, but local irritation sufficient to produce emesis could only occur with doses much larger than the clinical. The *digitonin* must play a very insignificant part, for it is not emetic in doses much larger than occur in the usual administration. The *fat* of the leaf is also nonemetic (Eggleston and Hatcher, 1913). The oil of strophanthus seed is emetic, but only in quantities 10,000 times as high as are present in a therapeutic dose of the tincture (Hatcher, 1916). *Squill* was formerly used as a nauseant expectorant; *euonymus* (wahoo) as cathartic.

The action is not directly on the vomiting center, for digitalis does not produce emesis if the spinal cord is divided at the second dorsal vertebra. If the brain is artificially perfused, emesis results from injection into the femoral vein, from where it cannot reach the brain; and emesis does not result if ouabain is added to the fluid that perfuses the brain, but does not reach the general circulation (Hatcher and Weiss, 1923).

The origin of the emetic impulses is disputed. Hatcher and Weiss, 1922, reported that digitalis does not produce vomiting if the heart is denervated, and the close correspondence of the emetic dose with that which produces cardiac disturbances suggests that these are the ordinary sources of emesis. However, Dresbach and Waddell. 1929, did obtain vomiting after cardiac denervation, and Hanzlik and Wood, 1929, found that emesis may arise from hepatic irritation. It has also been produced by applying digitalis to the peritoneum. It appears, therefore, that the emetic impulses may also be extracardiac. Indeed, Dresbach, 1941, throws doubt on the reflex explanation by a report that the emesis occurs not only after denervation of the heart, but of all viscera below the neck, and with about the same dosage as in normal animals. Nor is emesis prevented by denervation of the aorta, carotid sinus and carotid body (N. W. Pinschmidt 1946), or by pithing the spinal cord from the sixth thoracic vertebra downward (Haney and Lindgren, 1942).

Interesting antagonisms have been described. Hatcher and Weiss, 1927, found that *nicotine* prevents emesis from intravenous or intramuscular injection of digitalis, but not from intraperitoneal injection. As nicotine does not prevent emesis by apomorphine, they suggested that it paralyzes the afferent endings in the heart, but not in the peritoneum. The antagonism of nicotine to digitalis emesis persists more than three hours, while the other manifestations of nicotine toxicity disappear rapidly (N. B. Eddy and Hatcher, 1928). Neither atropine nor ergotamine prevents the digitalis emesis in pigeons (Hanzlik and Wood, 1929).

Visual Disturbances.—Purkinje in 1825 described flickering lines produced by full doses of digitalis (Hanzlik, 1925; F. D. Carroll, 1945). They are probably indirect results of the digestive or circulatory disturbances. Some patients complain of chromatopsia during clinical treatment. No fundus changes are observable, and the symptoms disappear on withdrawal (L. H. Maxwell and Mulberger, 1945).

Exanthemata.—A few cases of urticaria and scarlatiniform rashes have been reported after digipuratum and digalen

Cardiac irregularities from digitalis may simulate any of the clinical irregularities, so that it may be difficult to distinguish between them, particularly in advanced poisoning. To establish their causation by digitalis, it must be shown that they were absent before the drug was given, and that they disappear in a reasonable time after its discontinuance. The early effects, however, are fairly characteristic. The most common is excessive vagus stimulation (sinus irregularity). It is best seen when the heart is slowing after a little exercise. The rate may fall to 50 or even lower; so that syncope may occur between the contractions. The rhythm may remain regular; but ventricular extrasystoles are common. This stage would not occur in auricular fibrillation, or in absolute heart block. The next stage is usually *partial heart block* (Mackenzie, 1905), especially if the conductivity was naturally low. It may occur with relatively small doses (Windle, 1911), and may be permanent (Taussig, 1912); Christian, 1915, recorded transient auriculoventricular dissociation. The blocking by therapeutic doses of digitalis is apparently not additive to that of organic heart disease (Blumgardt and Altschule, 1939). The final stage is *muscular irritability*, first indicated by extrasystoles (Levine and Cunningham, 1920). These are particularly common in auricular fibrillation, giving the "coupled beats." With more advanced toxic action, there occur the same effects as in animals: high blood pressure (vasoconstriction); rapid rhythm, with periodic changes in amplitude, pulsus alternans (rarely).

Dosage.—Eggleston, 1912, found that the toxic effects depend mainly on the total dose, modified by the weight of the patient, absorption, individual susceptibility and the nature of the heart lesion. With the ordinary energetic administration, the characteristic coupled beats occur when the total quantity of digitalis has reached 2.25 to 6.25 Gm. Since the action persists partly from one to three weeks, these irregularities will recur with a smaller dosage.

Ratio of Toxic and Lethal Doses.—With intravenous injection, the lethal dose of any digitalis preparation is constant for cats. The toxic dose, however, varies with different animals. According to electrocardiograms, it ranges from 25 to 60 per cent of the lethal dose, averaging about 50 per cent. In any individual cat, however, it is fairly constant (Levine, 1919).

Duration of Irregularities.—This depends on the total dosage, and therefore on the severity of the phenomena. Eggleston, 1912, found that coupled beats generally outlasted the administration by four to twelve days; heart block, three to six; auricular fibrillation, three; muscular irritability, two; sinus irregularity, two days.

Fatalities with Intravenous Injections.—Deaths occurring within a few minutes to an hour after the injection of strophanthin or digitalis must be charged to these drugs, and are not uncommon (Rahn, 1920). They are probably due to ventricular fibrillation (Levine, 1919), which can apparently be induced in some diseased hearts, particularly those with impaired conduction, by the too abrupt introduction even of therapeutic doses (Robinson and Wilson, 1918; Levine, 1919), and especially by overdoses, *i. e.*, when insufficient allowance is made for previous digitalis medication. The course is too rapid to permit treatment.

The *intravenous injection of fatal doses of strophanthin into cats produces* vomiting, diarrhea, high rise of blood pressure, arrhythmia, then sudden ventricular fibrillation, with abrupt fall of blood pressure to zero, violent asphyxial convulsions, and death in a few seconds (Hatcher, 1909).

Fatalities from oral administration are rare with fractionated doses, since emesis sets in when one-third to two-thirds of the drug has been absorbed (Eggleston and Hatcher, 1913), and this would tend to prevent further absorption. Single massive doses (above 2.5 Gm. of the leaf) may be fatal.

The symptoms set in relatively late (one to twenty-four hours) and generally run a long course, so that a week or two may elapse before death. The symptoms are gastro-intestinal disturbances, slow and arrhythmic pulse, and the like, lassitude, muscular and sensory derangements. Death generally occurs suddenly, with dyspneic convulsions. Consciousness persists late. The *symptoms in mammals* are similar. The *treatment* consists in evacuation, quietness, possibly diffusible stimulants, and other symptomatic treatment. A cathartic should be given. The *fatal dose* varies greatly, on account of the variable absorption, the occurrence of vomiting, and so forth: 2.5 Gm. of digitalis have been fatal, while 4 Gm. have been followed by recovery (Lewin).

Delayed Deaths and Anatomical Injury.—If a large dose (about three-fourths of the acutely fatal) of a digitaloid drug is injected intravenously, many of the animals die several days later, with focal degenerative and necrotic changes chiefly in the papillary and trabecular muscles and the endocardial surface of the left ventricle. These are present to a less degree in the animals that survive. They were first observed in cats (H. Bauer, 1934; W. Lindner, 1939), but also occur constantly in dogs dying from cumulative poisoning by cardiac glycosides (Hu, Lieu and Li, 1936); in rabbits, only if they are first rendered anemic by bleeding (Remé, 1935). They are perhaps due to ischemia of the myocardium from prolonged coronary constriction; but similar and sometimes more severe degenerative and necrotic lesions are found in the brain, adrenals, kidney and liver (Hueper and Ichniowski, 1941). They have only been observed with toxic doses, and are not found in postmortem examinations of patients who have been under digitalis treatment (J. Travell *et al.*, 1942). Frogs poisoned with fatal doses show hyaline changes in the myocardium, but not focal necroses (Hu *et al.*, 1936).

DEVELOPMENT AND PERSISTENCE OF ACTION; FATE

Onset of Action.—When small therapeutic doses of digitalis drugs are administered by the alimentary canal, the effects develop slowly. It may be several hours before any action can be noted. The full effect is reached much later: twenty-four to thirty-six hours for the circulatory actions; seventy-two hours for the diuresis. This delay is due mainly to the insufficient dosage; *i. e.*, several doses must accumulate before the effective dosage is reached. When full therapeutic doses are given at once, as in the Eggleston method, definite effects (T wave) occur within two to four hours, and reach the maximum in six to twenty-four hours (Pardee, 1920). With therapeutic doses the *channel of administration* has relatively little effect on the onset of the therapeutic action (Pardee, 1925). The variations are probably within the experimental error, *i. e.*, absorption from the alimentary tract does not noticeably delay the development of the effects. This would not hold for strophanthus, which is generally absorbed more slowly; nor for the intravenous injection of strophanthin or ouabain, or of dangerous doses of digitalis: with these the circulatory response begins at once, and the diuresis starts in a few hours, although the maximal effects require somewhat longer (Hatcher and Bailey, 1910).

Absorption.—With oral administration, the rate of absorption increases with the *dose*, but is always quantitatively uncertain. The variation is especially great with *strophanthus* (Hatcher, 1909). This accounts for the unsatisfactory clinical results from the oral use of this drug. The safe dose would be so small as to be generally ineffective; a really effective dose could be highly dangerous, according to the individual absorption. *Helleborein* is probably not absorbed at all from the alimentary canal, since it commonly produces only diarrhea, without cardiac effects (Cushny, etc., 1912). Digitoxin appears to be better absorbed than digitalis (Eggleston, 1915) or strophanthin (Hatcher and Eggleston, 1919). The tincture of digitalis is absorbed more rapidly than the infusion. The chloroform-soluble extract is absorbed more completely and uniformly (Hatcher, 1920; Eggleston and Wykoff, 1922). Digipuratum and digalen are decidedly superior (Haskell, McCants and Gardner, 1916).

Different Portions of the Digestive Tract.—Quantitative studies by Ogawa, 1912, indicate that digitalis is not absorbed from the stomach. From the intestines, 34 to 45 per cent was absorbed in two hours from digitalis leaves; with digipuratum, the absorption was 52 to 61 per cent in two hours; 65 per cent in three hours.

Destruction in Alimentary Canal.—The digitaloids are practically unaffected by pepsin or trypsin (Goodall and Reid, 1914); but a small quantity of the glycosides, varying for the different glycosides, is destroyed by the acidity of the gastric juice; colloids tend to protect against this destruction (Hale, 1911; Brücke, 1936; Svec, 1937). Johannessohn, 1914, found that alkalis weakened only crystalline K-strophanthin; acids, this and amorphous K-strophanthin and strophanthus tincture. The amorphous strophanthin is changed mostly to strophanthidin, and partly to an inactive resin. Ouabain is unaltered by either acids or alkalis, which is an advantage in its administration. However, with the usual short contact, the destruction of the other principles is probably also unimportant (Hatcher, 1909). In the rat, with oral administration, strophanthin is mostly destroyed in the large intestine. Of digitoxin, also, variable amounts are destroyed before absorption (Hatcher and Eggleston, 1919).

Duration of Action.—The digitalis effects last for a long time after the administration has stopped, whether the drug was given by mouth or by vein. It is difficult to establish a time for the clinical action, because when compensation has been established it tends to persist, independently of the drug (except in auricular fibrillation), until some extra demand causes a fresh break of compensation. This probably holds true to some degree of the other cardiac changes. The effects of a "full" dose of digitalis or digitoxin seem to persist, with gradual decline, for one to three weeks, according to the total dosage; but for shorter periods with some of the other digitaloids, especially strophanthin and ouabain. Clinically, the duration of the actual digitalis action can be judged by the alteration in the T wave of the electrocardiogram. This persists from one to twenty-two days, averaging about nine days after discontinuance of the administration (G. C. Robinson, 1919). Other clinical facts lead to the same conclusion (Eggleston, 1912). Pardee, 1919, estimated the rate of disappearance in man, after full therapeutic doses, as averaging 0.15 Gm. of digitalis per day.

In *animals*, the duration of the digitalis effect can be measured accurately by Hatcher's method (differential fatal dose). In cats, one-half of the original effect of an intravenous injection persists for the following number of days: digitalis, five to twelve days; digitoxin, fourteen (dogs, two days; rabbits, less than one day); digitalein, three; digitalin German, three; digitalin true, less than two; ouabain and strophanthin, less than one (Hatcher, 1921). Klein, 1914, believed that the action of strophanthin may persist for a month in cats. The duration is much shorter in dogs and especially in rabbits, as quoted for digitoxin.

Apparently, the more resistant a species is to digitalis, the shorter is the action.

Cumulative Action.—The effects of digitalis tend to be cumulative, so that the same doses, continued day by day, tend to produce ever-increasing effects; or more commonly, toxic effects develop suddenly, without warning, after small doses have been continued for some time. In the therapeutic use, the dose must therefore be diminished, or toxic phenomena result, often abruptly. This cumulative action may be explained in part by the slow and uncertain absorption and excretion. The principal factor, however, is probably the slow, persistent and progressive action. Since the effects of a single dose may persist over several days or weeks, the effects of all the doses given in the meantime are more or less summed up; the effects of digitalis are determined by the total dose, and not by the single or even by the daily dose. The various cardiac glycosides differ in degree of cumulation. Those with the most persistent action are most cumulative, digitalis more than strophanthin (Li and Van Dyke); but the details are not well known.

Comparative Time of Action with Intravenous Clinical Injection of Digitalis Glycosides.—H. Gold *et al.*, 1943, reported that the *latent period* increases from ouabain (shortest), to digifolin, to lanatosid C, to digitoxin (longest); the *duration of action* is in the same sequence (ouabain shortest, digitoxin longest).

Chronic digitalis poisoning in animals was studied by von Lhota, 1910 to 1912, on dogs poisoned for several months by slowly increasing doses of digitalis. The phenomena correspond closely to those observed in man: the pulse after nine or ten days shows occasional short periods of slowing, but with the heart regular and strong. If the administration is continued, the slowing becomes more persistent and more marked and arrhythmic. Later, the pulse rate again increases to normal or somewhat above. The pulse changes outlast the administration for a long time; in severe acute poisoning, they may persist for several weeks; after chronic poisoning, they may last for over a month. The susceptibility to toxic doses increases (by the focal necrosis of the cardiac muscle), so that a smaller amount is fatal if it is given in fractions than if it is administered at one time (Lü, 1936). Typical cumulative poisoning has also been observed in cats (Klein, 1914). In pigeons, a single injection of digitalis, exceeding half the fatal dose, increases the glycogen content of the heart to about double. This is first noted about six hours after the administration and persists two days (F. Hahn, 1939).

Disappearance in the Body.—The digitaloids disappear from the blood almost immediately after the injection of even much more than fatal doses (Hatcher and Eggleston, 1912; Lhota, 1912). This rapid disappearance is due to wide distribution in probably all the tissues, for it occurs if the circulation is restricted to limited areas, but not if it is restricted to the heart and lungs alone. The liver plays perhaps a larger part than other organs. In rats, the greater part is fixed by the liver (Hatcher and Eggleston, 1919).

Excretion.—The digitaloids are partly destroyed in the body, mainly by the liver, and partly excreted unchanged. The excretion occurs chiefly through the bile, so that the substance may be demonstrated in the feces after intravenous injection. A small fraction is excreted by the kidneys. This increases if the bile duct is tied (Hatcher and Eggleston, 1919).

Combinations with serum proteins are formed by digitoxin and by the aglycones, but these do not influence the cardiac potency or lethal dose (A. Farah, 1945).

Fixation of Cardiac Glycosides in Heart Muscle.—The time and concentration relations of the cardiac actions involve peculiar characteristics connected with their penetration and fixation in the heart muscle, as revealed especially by quantitative studies on the "*Straub*" *excised frog heart* attached to a reservoir cannula (review, W. Straub, 1931, Lane Lecture). Even with this direct contact of the solution, there is a considerable delay before digitalis effects appear—about ten minutes or more, varying for the different glycosides—in contrast with most other drugs, such as muscarine, which act within a few seconds. The delay is not due to slow penetration, for increase of concentration does not shorten the incubation period below the minimum characteristic for each glycoside—although dilution may lengthen it (Straub, 1910 and 1913), as may also decrease of the total quantity of glycoside (Clark, 1912). If the heart is removed from the digitalis solution in one minute when no action is perceptible, the cardiac arrest will occur in the ten minutes, just as if the heart had been left in the digitalis solution. The full toxic amount has therefore been absorbed in one minute, but the effects appeared only after some ten minutes. Conversely, the muscarine effects can be removed almost immediately by washing, but the digitalis effect persists in spite of prolonged washing, indicating that the glycoside is firmly bound in the heart in such form that it continues its action. With small doses, the heart may indeed appear to recover completely on washing, but when immersed anew in digitalis solution, even after a long time, its threshold is found lowered (Gottlieb, 1914; Issekutz, 1915). The recovery of intact animals from subfatal doses is probably due to gradual destruction of the poison in the muscle metabolism, rather than to "washing out."

The retention capacity varies for the different glycosides, inverse to their solubility in water. It is much less for the aglycones. The amount bound is small in any case (Holste, 1912); somewhat greater with digitalin than with strophanthin (Weizsaecker, 1913). Fuehner, 1912, found thamethyl violet, which has a typical digitalis effect, act cumulates in the cardiac muscle of frogs, the effects corresponding to the quantity of dye so fixed.

Isolated hearts of embryonic chicks, when arrested by digitalis, recover completely on washing with Tyrode solution. Digitoxin is more, ouabain less, persistent than digitalis (Paff and Johnson, 1940).

Perfused mammalian hearts (Starling cat preparation) show similar fixation. The actual amount of glycosides they take up from the blood is limited to that which is fatal to the heart (Genuit, 1935). Anything beyond this remains in the blood. Smaller amounts are taken up completely, if sufficient time is allowed, the speed depending on the concentration.

In the intact body, other tissues compete with the heart for the glycosides. Their affinity is less, per gram of tissue (about 1/4 for skeletal muscle, 1/5 for liver, 1/2 for kidneys); but because of their greater mass, they can dispose of considerably more than the heart. With intravenous injection of just fatal doses, only 1/20 to 1/10 of the different digitaloids is bound in the heart (H. Weese, 1928 to 1933; Genuit, 1938), and the remainder by the tissues, especially the skeletal muscle, but also in the liver and other viscera (Hanzlik and Wood, 1929). For this reason, intra-arterial injection, which passes through muscle before reaching the heart, requires much larger doses than intravenous injection. For the same reason, the fixation in the heart is completed in the first passage of blood through it—what is not bound then is lost to the other organs.

The ratio bound by extracardial tissues varies for different glycosides, and the ratio of the concentration which arrests excised papillary muscle, to the lethal dose on intravenous injection for cats, being twenty times higher for digilanid C than for ouabain and for digitoxin (Cattell and Gold, 1939).

The *persistence of active glycoside within the heart muscle of mammals* is shown by the greater susceptibility of Starling heart preparations from animals which had previously been treated with these drugs. With digitoxin, this could be demonstrated for some weeks; with ouabain for fifty-four hours; with scillaren A for two hours. Earlier evidence for such persistence had been brought out by Cloetta and Fischer, 1906, and Hatcher, 1912.

ADMINISTRATION OF DIGITALIS DRUGS

Digitalis is usually started after decompensation has occurred. It is then desirable to induce the effects as promptly as may be safe, and to maintain them as long as necessary. Intravenous administration would be the promptest method, but it has drawbacks that restrict it mainly to emergencies. Ordinarily, the objects are fully met by proper oral administration. In this, it is necessary to remember the long duration of the digitalis action, and the consequent cumulative action. It must be emphasized that the total accumulated dosage is of more importance than the single doses; that practically no therapeutic effect is produced until the total dosage approaches the toxic; that the dosage must be reduced when the desired action has developed; that the patient must therefore be closely watched. He should be seen at least daily, while under active medication; the intensive methods are safest under hospital conditions. If toxic symptoms appear, the administration should be temporarily suspended; *i. e.*, if nausea develops; if the pulse falls below 50; or if any of the characteristic digitalis irregularities arise. In the intensive methods it is indispensable to employ digitalis preparations of known activity, tested first on animals, and then checked by cautious observation in the clinic. The dosage should be measured accurately, and not estimated by "drops." Febrile temperature renders the heart more susceptible to digitalis, so that the dosage should be reduced.

The **quantity of digitalis present in the body** determines the response. It may be calculated by subtracting the total quantity destroyed (estimated at 1.5 cc. of the tincture per day, multiplied by the number of days since the administration started) from the *total* quantity of tincture administered within the preceding two or three weeks. The result is only a rough approximation, since the rate of destruction is not constant, but varies, for instance, with the quantity present (Gold and DeGraff, 1929); but it furnishes the best available estimate of cumulation. The student will profit by working out the following problems:

Problems of Digitalis Retention.—1. A patient has received by the cumulative method, 4 cc. of tincture per day for the first week; 3 cc. of tincture per day for the second week, none for the third week.

Assuming that digitalis disappears from the body at the average rate of 1.5 cc. of tincture per day; and assuming the "toxic dose" at 22 cc. of tincture (actually present in the body), what percentage of this amount is present at the end of the first, second and third week?

2. If he received 6 cc. per day, and destroyed it at the above rate, how soon would he reach the toxic dose?

3. How long must it then be withheld before the quantity retained falls to one-third of the toxic dose?

Systems of oral administration may be grouped as intensive, cumulative, constant dose and maintenance methods. The intensive methods aim to give the greater part of the total dosage at once, and practically the whole within a day. The cumulative methods accumulate the effective dosage by divided doses in two or three days. The constant dose methods tend to err on the side of safety, and often do not reach the effective dosage at all. The intensive methods are most effective, and under the best hospital conditions are probably the most satisfactory. The cumulative method occupies a middle ground.

Intensive Method.—Eggleston, 1915, determined the total dosage of standardized digitalis necessary to produce full therapeutic or minor toxic effects, as 0.15 "cat units" per pound of body weight. This corresponds approximately to 1.5 Gm. of the official Powdered Digitalis or 15 cc. of the Tincture per 100 pounds of body weight (⅓ cc. per Kg.). Eggleston therefore proposed to give half of this dose at once (*i. e.*, 7.5 cc. of standardized tincture per 100 pounds, or 1¼ minims per pound); followed in six hours by one-fourth of the total dose, then smaller fractions (*f. i.*, dividing the dose each time successively by ½), every fourth to sixth hour till the total dosage or full response is reached. This has been somewhat simplified in practice, practically disregarding body weight with adults; for instance, 0.5 Gm. of powdered digitalis for the first dose, followed by 0.2 Gm. every six hours till a definite effect is observed, as nausea, apex rate, diuresis or diarrhea. This requires a total of 1.4 to 2 or even 3 Gm. in the course of two or three days. The response starts definitely in two to five hours after the first dose, reaching its maximum within twenty-four hours, and continuing without further administration for four to fifteen days.

The *relation of therapeutic effects to dosage* was worked out by Eggleston, 1915, in terms of "cat units"; a "*cat unit*" corresponding to the quantity of the drug per kilogram of cat, that is just fatal by intravenous injection under suitable conditions (Hatcher, 1910). Eggleston found that the relation of effect to dose (cat units) is remarkably uniform for a given drug, regardless of the presence or nature of cardiac disease. Whatever the condition, the total dose of digitalis by mouth, to the appearance of the first improvement, averages 0.09 cat units per pound of body weight (about 0.9 Gm. of good digitalis per 100 pounds); for full therapeutic or minor toxic effects, 0.146 cat units per pound (about 1.5 Gm. per 100 pounds). With digitoxin, the corresponding doses are: first improvement, 0.04 cat units per pound (1.4 mg. per 100 pounds); full therapeutic effect, 0.066 cat units per pound (2.3 mg. per 100 pounds). The other digitaloids give variable results, by mouth, because of uncertain absorption. They are therefore unsuited for the intensive oral method. By vein, however, a cat unit of all digitaloid substances is equally potent.

Cumulative methods start with a *daily dose* equivalent to 3 to 6 cc. of the Tincture of Digitalis (MacKenzie and Cushny), divided into three or four portions, and continued until the desired effect is obtained, when the dose is reduced to the maintenance dosage.

Maintenance Dosage.—When decompensation is only temporary the improvement is often lasting, and the digitalis may be discontinued when compensation has been restored. In auricular fibrillation, however, it is necessary to keep up a continuous digitalis effect. Ambulatory patients respond to about half the dosage needed for seriously ill patients (Gold and DeGraff, 1930). Clinical experience has shown that this should not exceed the daily dosage of 1 cc. of Digitalis Tincture (A. Fraenkel, 1907). This is not quite equivalent to the capacity of destroying digitalis, which Pardee, 1919, calculated to average 1.5 cc. of Tincture (1 cc. = 1 cat unit). There is therefore little danger of cumulation.

Continuous Methods.—The older methods of using digitalis employed a dosage approximating the maintenance dosage. This would be unsuccessful, except when employing preparations stronger than the standard.

Rectal administration may be used when oral administration is not feasible; for instance, because of emesis. The absorption is at least as rapid as with the oral route, and the dosage is the same. The alcoholic tincture is too irritant to be retained, so that an aqueous extract must be employed (R. L. Levy, 1924; Zondek, 1925).

Hypodermic or intramuscular administration should be avoided, because of local irritation; nor is the absorption materially more rapid than with the intensive oral method (Barley, 1909).

Intravenous Administration.—Prompt results ensue if a *full* dose (corresponding in effect to the "intensive" oral dosage) of strophanthin, ouabain or appropriate digitalis preparation is injected by vein. A few patients are very resistant, although absorption does not come into play; but ordinarily in auricular fibrillation definite slowing may be perceptible in five minutes and becomes marked in fifteen minutes, nearly maximal in half an hour, and maximal in two to three hours, and remains at this level for twelve to twenty-four hours. The T wave is reversed in two to four hours. Diuresis begins in a few hours (Wyckoff and Goldring, 1927, ouabain; Pardee, 1928, digitalis preparations). This avoids the delay incident to oral administration, but is distinctly more dangerous, especially if the heart has not been thoroughly studied (G. C. Robinson, 1912), and if information as to previous medication is incomplete. Intravenous administration should not be used routinely, but only if the patient is critically ill, so that it is imperative that full digitalis effect be secured in less than the two hours which would be required by the intensive oral method; or if the patient is unable to retain digitalis by mouth or rectum. The *full intravenous dosage* on the basis of 150 pounds

(70 Kg.) body weight is $\frac{1}{2}$ mg. of ouabain, or 1 mg. of strophanthin, or 15 cc. of digitalis preparations standardized to correspond to the tincture (or 1.2 mg. of digitoxin); but the full dosage should be fractioned, *giving half at the first injection* and the remainder in fractions of $\frac{1}{10}$ to $\frac{1}{8}$ of the full dose, at intervals of two hours, if necessary. When a satisfactory response has been secured, these injections ($\frac{1}{10}$ to $\frac{1}{8}$ of the full dose) may be continued at four to six hour intervals; but it seems safer to follow the first dose (*i. e.*, half of the full dose) with oral administration of 0.3 Gm. of digitalis, or 3 cc. of the digitalis tincture, or 0.1 to 0.2 mg. of digitoxin, every four hours till the therapeutic result is obtained.

Recapitulation of Time of Clinical Onset and Duration

Method of Digitalis Administration	The Effect			
	Becomes Perceptible (After Starting of Administration)	Becomes Complete (After Starting of Administration)	Persists after Discontinuance	
			Practically Complete	Partial
Oral, cumulative......	12 to 24 hrs.	24 to 72 hrs.	4 to 15 days	1 to 3 weeks
Oral, intensive........	2 to 4 hrs.	12 to 24 hrs.	4 to 15 days	1 to 3 weeks
Vein, intensive.......	5 to 15 min.	2 to 3 hrs.	12 to 24 hrs.	....

The full or half dosage should not be injected unless it is definitely known that the patient has not received digitalis during the last two weeks. *If digitalis has been taken, the dosage should be reduced* according to the amount calculated as remaining in the body. If no data are available, the one-tenth full dosage (*i. e.*, 0.1 mg. of strophanthin or 1.5 cc. of the digitalis preparations per 150 lb. body weight) may be injected and repeated at intervals of one-half to three-quarter hour until the therapeutic response is secured; this is safe, but may not gain any time over oral administration. Doses smaller than these (0.1 mg. of strophanthin or 1.5 cc. of the digitalis preparations) produce little effect on the heart rate in auricular fibrillation, and no effect on the T wave, unless the patient is already partly digitalized.

Intravenous digitalis therapy was tried clinically by Kottman and by Mendel in 1905, but the preparations they employed were not satisfactory. The method was put on a better basis by the introduction of strophanthin (A. Fraenkel and Schwartz, 1907). Intravenous injection sometimes produces cyanosis, chills and slight fever.

DRUGS AND PREPARATIONS OF THE DIGITALIS GROUP

Choice of Preparations.—Everything that can be accomplished in heart disease by drugs of this group can be secured with the official powder and tincture of digitalis for oral, and strophanthin or ouabain for intravenous, administration, quite as well as by any of the other drugs. The therapy of heart disease is probably better served at this time if the practitioner confines his prescribing to these official preparations, thus gaining a thorough experience with them, than if he dilutes and probably confuses his experience with the large variety of other drugs, preparations and isolated principles. These may sometimes succeed when the others have failed, but this is generally because the dosage was inadequate until the added dosage of the new drug brought it to the therapeutic threshold. It is possible that some of these may have special advantages, but so far at least these are not sufficiently clear to balance the confusion of their multiplication.

Preparations of Digitalis.—The powdered standardized leaf (*Digitalis Pulverata*, U.S.P.), dispensed in tablets, is perhaps the best form of oral digitalis medication. It avoids the taste of the tincture, and is stable if kept reasonably dry. *Digitalis Tincture*, U.S.P., which is also standardized, has some advantage when the dose is being adjusted. It does not deteriorate materially within a year. Variations in the alcoholic strength of the menstruum between 35 and 95 per cent make little difference. The *Fluidextract* is unreliable

The *Infusion* has been dropped from the U.S.P. It is active, but dangerously variable, and as dispensed it is often unreliable. It does not keep. All the glycosides are extracted from the leaves by either hot or cold water; but according to Straub, hot water destroys part of the amorphous active glycosides (the gitalin fraction) so rapidly that the infusion made by heat is materially less active than that made with cold water. Hatcher, however, found the same activity in both.

Deterioration of Digitalis.—The principles are stable when dry or in alcoholic solutions; but like all glycosides, they are subject to decomposition in the presence of water, especially by bacteria, moulds or acids. This results in loss of activity; but Hatcher and Eggleston, 1915, found the infusion practically unchanged a week or longer under ordinary conditions. The addition of alcohol is not necessary. *Acids are incompatible* with the *digitaloid glycosides.*

Tinctures and other preparations containing at least 50 per cent of alcohol generally keep satisfactorily, their deterioration averaging perhaps 10 per cent per year (Hamilton, 1918). There are marked discrepancies, however. Haskell *et al.*, 1923, found that a tincture kept five years under store conditions had not lost any activity. The storage temperature is a material factor (Newcomb and Rogers, 1918).

The *dry leaves*, so long as they are not mouldy, keep indefinitely (Sharp and Lankaster; Hatcher and Eggleston, 1913), without the necessity of the elaborate precautions advocated by Fock, 1906. They are not injured by heat of 120° C., but suffer above 140° (Hale, 1911).

GALENICAL PREPARATIONS OF DIGITALIS.—*__Digitalis Pulverata__, U.S.P. (Foxglove), represents the leaves of Digitalis purpurea dried, powdered, and adjusted by bio-assay with an intravenous cat method so that 0.1 Gm. equals 1.0 U.S.P. digitalis unit. Dose, 0.1 Gm., 1½ grains. *Digitalis Capsules*, U.S.P., and *Digitalis Tablets*, U.S.P., are usually available as 50 and 100 mg. (¾ and 1½ grains). The United States Pharmacopoeia Digitalis Unit is identical in potency with the International Digitalis Unit, adopted in 1928 by the Permanent Commission on Biological Standardization of the Health Organization of the League of Nations. One International Digitalis Unit represents the activity of 0.1 Gm. of the "International Standard Digitalis Powder." The reference standard and the assay method differed for successive revisions of the U.S.P., that of the XI being something like a fourth more potent than the preceeding and succeeding editions (G. G. Nelson, 1941; H. Gold and Cattell, 1943). The activity of different samples of digitalis varies considerably, so that they should be standardized by bio-assay. The leaves of the first year plants are as good as the second (Sharp and Lankaster; Caesar and Loretz, 1910). Plants cultivated in America (Newcomb, 1912) are as good as the wild European (Rowntree and Macht, 1916). Those grown during a wet season are less active (Caesar and Loretz, 1907). The petioles, ribs and hairs of the leaves are relatively inactive (Newcomb and Rogers, 1918). Other species of digitalis, *e. g.*, *D. Thapsi*, also have the actions of the group (Farwell and Hamilton, 1917). White and Morris, 1918, claimed that *D. lutea* is as effective as purpurea on the heart, and appears to be less emetic and less convulsive. *__Tincture of Digitalis__, U.S.P., represents 10 per cent of drug, and is standardized to contain 1 digitalis unit per cc. Dose, 1 cc., 15 minims. Tinctures deprived of fat do not become turbid when mixed with water, but have no other advantage.

Injectable digitalis preparations are solutions of the partly purified water-soluble principles, generally the gitalin fraction. They have no advantage over ordinary digitalis preparation for oral use. It may be questioned whether they are superior to strophanthin for parenteral use, although their action is more lasting.

The U.S.P. has a title of "*Digitalis Injection*," without further identification except that it is "a sterile solution of a mixture of glycosides or therapeutically desirable and cardio-active constituents of digitalis in water for injection." Its potency is to be indicated in U.S.P. units. A working formula was published by Hatcher and Haag, 1929. A number of *proprietary preparations* are listed in N.N.R. (Digitan, Digalen, Digifolin). Comparisons of the potency of digitalis specialties by the pigeon method were published by A. J. Lehman and Hanzlik, 1933.

Digalen ("Digitoxin soluble," Cloetta, 1904) was widely advertised as an amorphous and soluble isomer of digitoxin. Kiliani, 1907, stated that it consists mainly of digitalein Schm.; his opinion should carry weight. It was said to be free from the disadvantages of digitoxin; but it is of variable activity, unstable (Hale, 1910), produces considerable irritation, is not suitable for hypodermic injection and causes cumulative effects (Fraenkel, 1907; Westenrijk, 1908). It therefore has no real advantage over a good tincture (Dixon, Cow, 1912), except for venous injections, which cause pain and sometimes thrombosis. It is marketed as ampuls for injection (1 cat unit in 2 cc.), and as a solution for oral use (1 cat unit in 1 cc.), and as tablets of ½ and 1 cat unit.

Digitan (Digipuratum) is a purified solid extract containing chiefly the tannates of digitoxin and digitalin, freed from digitonin, and standardized to the same activity as digitalis leaves. It is relatively nonirritant (Dixon, 1912; Cow, 1912). It is marketed in ampuls for intramuscular (not intravenous) injection, 0.1 Gm. in 1 cc.; and as tablets, 0.1 Gm., for oral use.

Isolated digitalis glycosides proved rather disappointing. None appears to be more efficient, or quicker in action, or more prolonged or less toxic than the standardized leaf (Stroud and Van der Veer, 1937). They are difficult to obtain pure, and many commercial medicinal preparations are of uncertain activity. Digitoxin, however, has aroused renewed attention, especially in the form of "Digitalin Nativelle."

Digitoxin is probably the most important constituent of the leaves, in activity and in quantity (0.22 to 0.4 per cent). It is crystalline, but Cloetta found that the best commercial products are impure; and the medicinal may contain only one-third of digitoxin. It has the undesirable features of producing excessive irritation, and of being nearly insoluble in water. It may be dissolved in 25 per cent of alcohol.

Digitoxin, U.S.P., is "either pure digitoxin or a mixture of cardio-active glycosides from Digitalis, consisting chiefly of digitoxin," assayed against the U.S.P. Digitoxin Reference Standard. It is a microcrystalline powder, insoluble in water, soluble in alcohol (1:60). Average dose, oral, 0.1 mg. (1/600 grain). *Digitoxin Injection,* U.S.P., a solution in 40 to 50 per cent alcohol, for intravenous injection. Usual size, 0.1 mg. in 1 cc. *Digitoxin Tablets,* U.S.P.; usual sizes, 0.1 and 0.2 mg. "*Digitaline Nativelle*" appears to be a reliable form of crystalline digitoxin. It is absorbed practically completely from oral administration, so that the full therapeutic effect in patients with auricular fibrillation is the same for oral and intravenous administration, 1.26 mg. equal to 3 cat units; while 15 units or 1 Gm. of powdered digitalis are necessary for the same effect. The full amount of this digitoxin may be administered in one dose, which would not be safe for digitalis. Intravenous administration acts somewhat more promptly than oral, but in three or four hours the effects are about the same. The incidence of toxic manifestations appears somewhat lower for the oral digitoxin than for the leaf. The cardiac slowing is apparently less and shorter than with the leaf. The cumulative action is similar. The most favorable maintenance dose is 0.2 mg. per day (H. Gold *et al.*, 1942, 1944; L. N. Katz and Wise, 1945). It is marketed in *Tablets* of 0.1 and 0.2 mg., and in *Solution,* 1:1000 (1 mg. per cubic centimeter).

Gitalin (Verodigin), the *amorphous* constituent of the leaf, prepared according to the method of Kraft, is marketed as tablets of 0.8 mg. (1/80 grain), equal to one cat unit.

Digoxin, U.S.P., is a glycoside obtained from the leaves of Digitalis lanata or orientalis by hydrolytic removal of the acetyl and glucose groups from Digilanid C, and assayed against the U.S.P. Digoxin Reference Standard. It is insoluble in water. It is used especially for rapid digitalization. The average oral dose is 0.5 mg. *Digoxin Tablets,* U.S.P., are usually available as 0.25 mg. *Digoxin Injection,* a solution in 70 per cent alcohol, for intravenous administration, is usually available as 0.5 mg. in 1 cc.

Lanatoside C, U.S.P. (Cedilanid), is a glycoside from the leaves of Digitalis lanata. It is slightly soluble in water (1:20,000). Average oral dose, 0.5 mg. *Lanatoside C Tablets,* U.S.P.; usual size, 0.5 mg. *Lanatoside C Injection,* U.S.P., in 70 per cent alcohol, for intravenous administration. Usual sizes, 0.4 mg. in 2 cc., 0.8 mg. in 4 cc. *Lanatoside C Tablets,* U.S.P.; usual size, 0.5 mg.

Digilanid, a mixture of the "original" crystalline glycosides of Digitalis lanata, isolated by Stoll, is claimed to form a stable solution which can be injected by vein or hypodermically, and to be readily absorbed from the alimentary canal. It is marketed as *Solution,* in ampuls of 2 and 4 cc., each cubic centimeter equal to 0.2 mg. or 0.6 cat unit; and as *Tablets,* 0.33 mg. = 1 cat unit. The daily cumulative dose is 2 to 4 tablets, or 2 to 4 cc. of solution, until therapeutic or minor toxic effects appear. Then the dosage may be reduced to half.

Digitalins.—The uncertain composition of these mixtures, and the danger of confusing the similarly named but very different preparations, should preclude their use. At least, "digitalin" should never be prescribed without specifying the variety (verum, German, French, and the like).

Digitalin "True" is almost insoluble and not irritant. Clinically, it has proved too feeble, a variable quantity being probably decomposed in the stomach (Deucher, 1896). It has been used in *doses* of 1 to 3 mg. per day; even 50 mg. have been given without toxic effects (Pfaff, 1892). It is administered in pills or dissolved in dilute alcohol.

Strophanthins have the advantage of being less irritant and less cumulative than digitalis; but the absorption is so uncertain that their use by mouth is not advisable (Hatcher and Bailey, 1909). This is reflected in the different doses of strophanthins used by various clinicians. It is also liable to produce diarrhea. The main field of the strophanthins is for intravenous injection. Ouabain has the advantages that its identity is assured.

Ouabain, U.S.P., g-Strophanthin-Crystalline, was originally obtained by Arnaud from Acokanthera Ouabaio, which was used as arrow poison in East Africa (Santesson, 1928); now generally from Strophanthus gratus. Assayed on cats to equal the U.S.P. Ouabain Reference Standard. Soluble in water (1:75) and in alcohol; difficultly in fat solvents. Dose, for intravenous or intramuscular injection, 0.25 to 0.50 mg., not to be repeated in less than twenty-four hours. *Ouabain Injection,* U.S.P., in water for injection; usual sizes, 0.25 and 0.5 mg. in 1 cc.

***Strophanthin,** U.S.P. (Strophanthinum; Amorphous or k-Strophanthin); a glycoside or mixture of glycosides from Kombé Strophanthus. Very soluble in water or diluted alcohol; nearly insoluble in fat solvents. Standardized by bio-assay on cats to a potency of 50 per cent of the U.S.P. Ouabain Reference Standard. It is about a third more potent than in U.S.P. XI (Vos and Braun, 1945). Dose (daily), intravenous or intramuscular, 0.5 mg. *Strophanthin Injection,* U.S.P., in ampuls, of 0.5 mg. in 1 cc.

Apocynum and Cymarin.—The rhizome and roots of Apocynum cannabium, *Canadian Hemp,* produce potent digitalis effects and have been used as a fluidextract (average dose, 0.75 cc., 12 minims).

Cymarin, the active constituent, has been used clinically like strophanthin, by vein or muscle, 0.1 to 0.5 mg.; hypodermic injection is too irritant. It is difficultly soluble in water, easily in alcohol. It has also been given by mouth, 0.3 mg., three to five times daily (von Noorden, 1916; bibliography). Gaisböck, 1915, on the basis of his clinical and experimental studies, emphasized the need of caution in its use. The drug could probably be spared. Its *actions* agree with those of digitalis (Dale and Laidlaw, 1909, who studied the pure principles). The cardiac action, therapeutic and toxic, of cymarin (frog, Kuroda, 1914; electrocardiograph, Hecht, 1915) is somewhat weaker than that of strophanthin. It produces practically no irritation, but relatively strong vasoconstrictor effect. Kuroda claims that the cumulative and emetic effects are weak; but Taviani, 1915, found the serious disadvantages of uncertain absorption, and variable strength of the commercial cymarins. Large doses are also nephritic. Beco and Dossin, 1919, with intravenous injections in dogs confirmed the slowing, by vagus stimulation (central and peripheral); but claimed that the cardiac tonus was decreased, and never raised. The blood pressure rose by general vasoconstriction, especially splanchnic (direct action on vessels). The urine flow was hindered, the renal vessels being constricted even by minute doses.

Scilla (*Squills*) produces the same effects as digitalis, experimentally and clinically (in auricular fibrillation). The dosage required to produce the typical response of heart block and reversal of T wave is from 24 to 48 cc. of tincture per day (Viko, 1920), *i. e.*, considerably larger than the official dose. Toxic symptoms are rare. The milder action and larger dosage are due to poor absorption, for the intravenous dose is about the same as for digitalis (Eggleston). The poor absorption renders it undesirable as a digitalis substitute (Dixon, 1906), although it was advocated by Haynes, 1906. Scilla was formerly used as expectorant (nauseant) and general diuretic. It is not well suited to either purpose. There are much safer expectorants; and diuresis occurs only when cardiac edema is relieved (Viko).

Squills contains a crystallizable cardiac glycoside *Scillaren A*, which is sparingly soluble in water, and an amorphous fraction, *Scillaren B*, which is marketed for therapeutic use. A mixture of all the glycosides is marketed as "*Scillaren*." The action is less persistent and therefore less cumulative than that of digitalis, and it is claimed to be more diuretic, perhaps by a direct action on the renal epithelium. The official Scilla is collected from the countries on the north shore of the Mediterranean and is known as "*White Squills*." Another variety of the same plant which grows in Algeria yields "*Red Squills*," which is widely used as a rat poison. It contains the same cardiac glycosides in about the same quantity, but it also contains scilliroside, a glycoside with digitalis actions, apparently absent from the White Squills, that is toxic to rats, causing deaths after some days of alternating convulsions and paralysis (F. R. Winton, 1927; F. S. Philips, 1946). A product about a hundred times more toxic to rats has been obtained by extraction with 80 per cent alcohol (Leblanc and Lee, 1939). "*Urginea*," B.P., a distinct species, has the same effects as the White Squills, and is used in India in the same dosage.

Squill, N.F. (Scilla), is the dried fleshy scales of the bulb of the white variety of Urginea maritima (Urginea Scilla, B.P.). Dose, 0.06 to 0.2 Gm., 1 to 3 grains. The *Compound Syrup*, N.F., contains in each 2 cc. (30 minim) dose 0.16 cc. of fldexts. of squill and senega and 4 mg. of tartar emetic.

Scillaren, N.N.R., is a mixture of the natural glycosides of fresh squill. Sparingly soluble in water, the action is apparently less lasting than with digitalis. Oral dose, 1.6 mg. three or four times daily till effective; then half this dosage. Marketed in tablets of 0.8 mg., and solution of 0.8 mg. in 1 cc. *Scillaren B*, N.N.R., an amorphous natural glycoside from fresh squill, and as *solution* for intravenous injection, in ampuls of 0.5 mg. in 1 cc. *Dose*, not to exceed 0.5 mg. in 24 hours. *Urginin*, N.N.R., a mixture of two water-insoluble glycosides from squill. Oral maintenance dose, 0.5 to 2 mg. daily, as *Tablets* of 1 mg.

Thevetia Glycosides.—The fruit of a South American tree, Thevetia neriifolia, "Yellow Oleander," contains cardiac glycosides, principally *Thevetin*, isolated by De Vry, 1863, and studied by König and Hasemann, 1876, and recently by Chopra and Muckeyee, 1933, and by Chen and Chen, 1933 and 1934. It is soluble in alcohol and in water, and the watery solution is fairly stable. It produces typical digitalis actions, but it does not appear to have any special advantage. Its potency is about an eighth that of ouabain, measured on cats. It is too irritant for oral administration, but may be administered intravenously, 2.75 mg. three times daily, till the therapeutic effect is secured. A second glycoside, *thevetoxin*, has been isolated. Its actions are similar, but less potent (Bhatia and Lal, 1934).

Toad Poisons.—The dermal glands of toads secrete several kinds of toxic substances, differing in importance in different species (review, O. Gessner, 1938): (1) *Digitaloids*, cyclopenteno-phenanthrene derivatives, the *bufotoxins*, the aglycones *bufagins*, and the *bufotalins*, probably formed from cholesterol, closely related to the digitalis glycosides in structure as well as in action (especially scillaridin; Chen and Chen, 1933). Frog skin also has a weak digitalis action (Fuehner, 1910). (2) *Several alkaloids*, not present in sufficient quantities to exert any action: bufotenine (Handovsky, 1920); bufotenidine, bufothionine; a few species contain epinephrine. (3) A variety of other compounds with local irritant action.

Resistance of Toads to Cardiac Glycosides.—Toads tolerate much higher doses of all cardiac glycosides than do frogs (150 times as much ouabain). The tolerance is localized in the cardiac tissue. They are somewhat more resistant than frogs to picrotoxin, strychnine, cocaine and pentobarbital, but have about equal susceptibility toward other drugs acting on the central and autonomic nervous systems, and toward curare (Chen and Chen, 1933).

Bio-Assay of Digitalis and Related Drugs.—Different samples of the crude drugs differ seriously in potency, and they must be adjusted by bio-assay to uniform potency by comparison with an international reference standard sample of the drug. The "International Unit," which is official in the U.S.P. and B.P., corresponds to 0.1 Gm. of this standard digitalis powder. Various methods of bio-assay are available, giving often discordant results because they differ in principle, especially as to absorption, sometimes as to criterion of action. They are, moreover, complicated by technical difficulties, so that the prescribed minutiae must be meticulously followed.

The current U.S.P. directs a fatal dose "*intravenous cat method*," which measures the concentration of active principles since the end point, the sudden cardiac arrest, is a specific digitalis effect; but it entirely disregards absorbability, and therefore is misleading for the oral dosage of different digitalis principles. It is fairly reliable for different samples of the leaf and tincture, since the ratio of glycosides does not usually vary widely.

The U.S.P. digitalis bio-assay, in principle, macerates the powdered drug (and the standard) with an alcoholic medium. The solution is infused by femoral vein into lightly etherized cats, in fractional doses five minutes apart, until cardiac arrest occurs after 13 to 19 doses. At least a dozen cats are required for a complete test. The *U.S.P digitalis unit* is the amount which equals 0.1 Gm. of the U.S.P. standard reference powder. It is identical with the International Unit, but is a third stronger than the "cat unit" of Hatcher, 1916, which is the amount fatal to 1 Kg. of cat, as determined by the original method.

The intravenous cat assay was introduced by Hatcher and Brody, 1910, and has been variously modified, especially as to anesthetic and rate of injection (Magnus; Van Wijngaarden, 1926; Burn, 1928). The influence of *anesthesia* is reported by Holck *et al.*, 1945. The fatal dose is almost 50 per cent higher with dial or pentobarbital than with ether anesthesia; with urethane it is 20 per cent higher than with ether. The *age* of cats does not affect their susceptibility (Haag and Corbell, 1940). Statistical analysis shows that ten and eleven cats each for the standard and specimen are required to obtain an approximation of plus or minus 20 per cent. Most experienced assayists can distinguish a difference of 20 per cent, but not of 15 per cent. The $LD_{(50)}$ of the U. S. standard reference powder is 0.77 units per Kg. of cat (C. I. Bliss, 1944).

Although the cat assay disregards absorption, its potency accords fairly well with the oral clinical assay (average divergence of 44 per cent), but not for isolated principles (Cattell and Gold, 1944).

Intravenous assay may also be made on *other mammals* (dogs, McGuigan and McGuigan, 1938; guinea pigs, Bose and Mukerji, 1942), and on *heart-lung preparations.*

Clinical Standardization may be made quite conveniently by the change in the RT-T segment of the electrocardiogram, which is sensitive to a dosage change of about 25 per cent (H. Gold, 1944). Comparisons of the human, cat and frog method are reported by H. Gold *et al.*, 1941.

Frog-Heart Systolic Standstill Methods.—These determine the dose that must be injected into a lymph sac to produce the characteristic systolic arrest of the ventricle with dilated auricles, in a specified time, an hour (Famulener and Lyon), U.S.P. XI, or less (thirty to forty-five minutes, Gottlieb, 1908); or the time of arrest with a fixed dose (Focke, 1906). The method measures the true digitalis effect, and takes account of absorbability; but absorbability from the lymph sac does not necessarily parallel that from the alimentary tract. The time does not suffice for complete absorption (Schmiedeberg), so that the results are more variable than with other methods. When properly performed, however, with adequate numbers of animals, the average error can fall within 15 per cent. Dooley and Higley, 1923, advocated intramuscular injection.

Further difficulties arise from the *varying susceptibility* of different individuals. This is particularly great in frogs. It can be minimized by using a considerable number of animals and treating the results statistically, using the 50 per cent fatality as end point (L. C. Miller, Bliss and Braun, 1939). A part of the variability is due to differences which could be met by injection into the abdominal vein (F. Uhlmann, 1927); but it is chiefly inherent in the heart, for it occurs even with Straub hearts (Nyiri and DuBois, 1929). Frogs also show *seasonal variations*, the susceptibility being about 15 per cent higher in December than in June and July (Munch, 1931). This is one reason why control tests must be made with the standard specimens. The temperature must be carefully controlled not only during the test, but also for the prior day (Baker, 1912 and 1913). Alcohol (25 per cent) is not disturbing for frogs (Haskell, 1913).

Frog fatal dose methods determine the smallest dose which kills a given weight of animal in a given time regardless of the specific *cardiac action*. The most convenient is the twelve or twenty-four hour frog method (suggested by Cushny, and elaborated by Houghton, 1898; being the first commercial bio-assay process). They give more consistent results than the short time methods (L. C. Miller, 1944), but they may involve noncardiac constituents. The same precautions must be observed as for the systolic standstill methods. The M.F.D. of digitalis averages about 1.5 mg. per Gm. of frog.

The fatal dose for guinea pigs has also been used (Reed and Vanderkleed, 1914), and gives consistent results, but is open to the objection of nonspecificity. The M.F.D. of digitalis is from 0.06 to 0.1 Gm. per 240 Gm. of pig (Reed). Age, sex and weight are unimportant; but there are considerable individual and marked seasonal variations, and the food also has an influence (Vanderkleed and Pittenger, 1913; Haskel, 1913).

The fatal dose for goldfish was proposed by Pittenger and Vanderkleed, 1915, but is also nonspecific.

Pigeon Emesis Method.—The dose required to produce vomiting in pigeons correlates well with the clinical therapeutic and emetic potency (Hanzlik and Stockton, 1929). The results are comparable with those of the cat and frog method, provided sufficient animals are used (Burn, 1930). It can also be used for *ergot* (Lieb and Mulinos, 1934). Haag and Woodley, 1934, proposed intravenous injection, analogous to the cat method.

The sassy-wood ordeal of the West African natives is an assay directed to the suspect rather then to the drug. A decoction of erythrophleum is administered: vomiting with recovery establishes innocence; absence of vomiting, guilt. It has been suggested that the fear of the guilt serves to inhibit emesis (G. W. Harley, 1941).

Embryonic chick heart appears to furnish an ideal method of directly evaluating the specific cardiac action that is used in therapeutics, by the sharply defined time of appearance of A-V block without regard to absorption (Paff, 1939; R. A. Lehman and Paff, 1942). It is especially convenient for appraising relations of constitution and potency (R. A. Lehman, 1946). The material is always universally obtainable, which is an important advantage.

Excised or perfused frog hearts have been used mainly in scientific investigations (Schmiedeberg, 1910; Hartung, 1912; Gros, 1913; Straub; Santesson, 1915), as also excised sinus pieces (Mansfeld and Horn, 1928). They are not very practical.

The isolated papillary muscle of cat heart has been used by Cattell and Gold, 1941, especially for quantitative comparisons of the therapeutic concentration (increased contractile force) and toxicity (irregularity). This ratio was found similar for ouabain, digitoxin, and the lana glycosides.

Daphnia, a small crustacean, shows cardiac phenomena that reflect the digitalis potency (Viehoffer), but it is questionable how far its pharmacology corresponds to that of vertebrates.

Colorimetric Assay.—A chemical colorimetric method (Bell and Krantz) with an alkaline picrate solution, similar to the creatinine reaction, gives results that may approximate those of the cat method, both for digitalis and strophanthus (Knudsen and Dresbach, 1923), but it is not reliable (Vos and Welsh, 1945; Danow *et al.*, 1946).

◆

BARIUM

This stimulates all muscle, striped, unstriped and cardiac, irrespective of innervation. It is mutually antagonistic with all muscular depressants, regardless of whether these act on the receptive or on the responsive mechanism. Unlike the other elements of its group, Ca and Sr, barium is very toxic. Its chief effects resemble those of the digitalis group: it produces a similar action on the cardiac muscle; a strong vasoconstriction by direct stimulation of the arterial muscle (occurring therefore after apocodeine, Dixon, 1903); violent stimulation of peristalsis, even on intravenous injection; and stimulation and later paralysis of the central nervous system. It also produces local irritation, and is inimical to the lower forms of life such as yeast cells. The soluble barium salts, and the carbonate and sulfide, are sufficiently absorbed from the alimentary canal to produce the fatal effects. The sulfate, which is used in roentgen work, is insoluble and nontoxic; and sodium or magnesium sulfate are antidotes for barium poisoning. Barium is but little used in therapeutics, for fear of toxic effects.

Cardiac Action.—A. S. Cohn and Levine, 1925, reported that barium chloride (30 mg., ½ grain, by mouth, three or four times per day) suppressed permanently the syncopal heart block attacks of the Stokes-Adams syndrome, and it was also tried in angina pectoris (Levine, White). Others, however, failed to obtain good results (F. Parsonnet and Hyman, 1930) owing perhaps to the difference in the sulfate income?) and it has been abandoned, especially as the ordinary dosage may produce dangerous irregularities (Strouss and Meyer, 1928; McMillan and Wolferth, 1929).

Experimentally it acts like digitalis, increasing the excitability of the cardiac muscle and the force of the contractions (Wertheimer and Boulet, 1911). The rate is slowed even after atropine, so that this effect is muscular (Filippi). Slow intravenous injection of 8 mg. or more of barium chloride per kilogram, into dogs, produces extrasystoles and sharp rise of blood pressure, then ventricular fibrillation or tachycardia, and other irregularities. These are prevented or removed by inhalation of 20 per cent of CO_2 in oxygen, and less effectively by quinine. Sodium sulfate intravenously sometimes confers partial protection (Friedberg and Levinson, 1931; P. K. Smith, Winkler and Hoff, 1940). *Excised papillary muscle* of cat does not show the sustained systolic force characteristic of true digitalis action (S. Krop, 1944). Intracardiac application causes systolic arrest; dilute solutions, or exocardiac application, produce diastolic arrest, just as does digitalis (Poulsson, 1910; Werschinin, 1911; Delcorde-Weyland, 1913). The effects in complete heart block are similar to those of calcium (van Egmond, 1913). Whole auricles and ventricular segments of *turtle heart* show increased rhythmicity; contractility is usually depressed, excitability but little changed (Wedd and Blair, 1945).

Arterial Muscle.—The high rise of blood pressure under barium is due mainly to vasoconstriction. The effect is directly on the arterial muscle, and involves all arteries, regardless of their innervation (Cow, 1911). This might suggest its use in pulmonary hemorrhage, the lung vessels being strongly constricted (Berezin, 1914). However, the increase of the general blood pressure more than offsets the local constriction, so that the bleeding becomes more profuse (E. Frey, 1909). The liver veins are constricted in the guinea pig, not in the frog (Berezin, 1914).

Intestines.—Barium chloride produces violent peristalsis, culminating in intestinal spasm, which may be removed by magnesium (Sollmann and Rademaekers, 1925). The purgative effect may also be produced by intravenous injection in dogs (3 mg. per Kg.); but 7 to 8 mg. are rapidly fatal by the circulatory effects, without purgation. Rabbits are not purged by any dose although 18 mg. per Kg is fatal (Chistoni, 1918). The intravenous injection of 0.5 to 1.25 Gm. was used on horses to remove tympanites; but there were so many fatalities that it was generally abandoned (Dieckerhoff, 1895). The barium contraction of frog's intestine may be completely antagonized by epinephrine or pilocarpine (Roth, 1923).

Bronchial muscle is also constricted (Trendelenburg, 1912; Titone, 1913; Baehr and Pick, 1913).

Gallbladder.—The isolated organ is constricted (Lieb and McWhorter, 1915).

Salivary Secretion.—Intravenous injection of 5 to 10 mg. of barium chloride per kilogram into dogs or cats increases the flow of submaxillary saliva, resembling the response to chorda tympani stimulation, which is abolished by atropine. The secretion is accompanied by diminished blood flow through the gland, notwithstanding the rise of blood pressure. The contractile mechanism is not involved (Stavraky, 1932).

Skeletal Muscle.—Barium has two distinct actions on frog's gastrocnemius muscle (Zoethout, 1919): (*a*) Direct stimulation, persisting as long as the muscle remains in the solution. This requires the presence of Na ions, and is therefore abolished by isotonic sugar solution. (*b*) Contact irritability, seen only when the muscle is immersed or removed from the solution, being produced by the inward or outward passage of Ba ions. It is antagonized by certain Na salts. Both actions are antagonized by K, Ca and Mg ions, and by procaine or strychnine. Immersion of the muscle in barium chloride solution, 1:1000, produces rapid tremor and gradual rise of tonus. In the progress of nerve degeneration following section of the sciatic, the tremor response disappears much earlier than the tonus response; but the latter also fails when acetylcholine, nicotine and potassium chloride are still effective. Fuehner, 1926, attributed the barium effect to displacement of calcium from the motor nerve-endings.

Fowl's Muscle.—Injection of $BaCl_2$ produces only increase of muscular tonus in the normal leg, but after denervation it causes a strong contraction. The degenerating muscle has therefore become more susceptible to Ba. A similar result can be secured by preliminary injection of nicotine. Curare does not influence this contraction, indicating that Ba acts more peripherally than curare, nicotine or physostigmine.

Cerebral Stimulation.—Direct application of barium salts to the cerebral cortex stimulates the white matter, and increases the irritability of the gray matter (Maxwell, 1906)

Hematopoiesis is stimulated in rabbits by small doses; toxic doses are hemolytic (Zolezzi and Stazzi, 1939).

Excretion.—The main channel is by the intestine, only traces appearing in the urine even after parenteral administration (G. M. Meyer, 1909). A small amount may be deposited in the bones. Barium lessens the elimination of uric acid (Abl, 1913).

Mechanism of Action.—The effects of barium are perhaps due to the precipitation of a *film of colloidal barium sulfate*, which would modify the permeability of cells analogous to anaphylaxis (Lumière). Kundel suggested *deprivation of sulfate ions*, and Januschka thought to confirm this by the observation that a frog heart poisoned by barium can be restored by sodium sulfate, but not by phosphate or oxalate, although these are barium precipitants. However, Hermann, 1932, found that this is explained simply by the higher solubility of barium phosphate and oxalate, and that barium can be detoxified by less than the chemical equivalent of sulfate, so that the restoration does not leave any free sulfate ions.

Roentgenology.—The insoluble $BaSO_4$ is used in x-ray diagnosis. It is tasteless, inexpensive, and does not delay the gastric movements, as does Bismuth.

Barium Sulfate, U.S.P. (the title should never be abbreviated, to avoid confusion with the poisonous sulfide or sulfite), is nontoxic. For roentgen examination of the stomach, 300 Gm. are administered, suspended in 400 cc. of water; for the colon, 750 Gm., suspended in 1500 cc. of water, by enema (N.N.R.).

Toxicology.—Barium poisoning arises from the use of the barium carbonate as rat poison (1:4 of corn meal, made into a dough with water; Holsendorf, 1937). Mistakes have occurred by dispensing the sulfide instead of the sulfate for radiologic use. The sulfide is also available in depilatories. A. S. Allen, 1943, reported mass poisoning by the use of table salt containing up to 25 per cent of barium. Barium determination in atmospheric dust is described by H. Yagoda, 1944. Crawford, 1908, attributed "Loco poisoning" to the Ba contained in the western plants. This could not be confirmed (Alsberg, Black and Marsh, 1912).

The *symptoms of barium poisoning* consist in excessive salivation, vomiting, colic, violent diarrhea; convulsive tremors; slow hard pulse and high blood pressure; hemorrhages into the stomach, intestines and kidneys; muscular paralysis. Death occurs after a few hours or days. The fatal dose is probably 0.8 to 0.9 Gm. of the chloride. Barium carbonate and sulfide are also toxic, but act more slowly, and the sulfide requires relatively large doses (Stedem, 1920). The *treatment* consists in administering magnesium or sodium sulfate.

◆

SAPONINS (SAPOTOXINS; SAPO-GLYCOSIDES)

These comprise a series of related compounds, generally non-nitrogenous glycosides, which occur in many plants. The actions are somewhat related to soaps and bile salts. The saponins lower surface tension, and therefore concentrate on the surface. They form a solid and resistant pellicle, and when even very dilute watery saponin solutions (1:10,000) are shaken, each air bubble becomes coated with this tough surface film, producing a persistent foam. When shaken with oil or powders, the saponin film prevents the droplets or fine particles from coalescing, so that permanent emulsions or suspensions are easily formed. Saponin tends to displace other substances or absorbates from the surfaces; for instance, it liberates rennin that has been absorbed by charcoal. In these ways the saponins tend to alter the permeability of the protoplasmic surface of cells, and are generally protoplasmic poisons. They have a particular affinity for cholesterol. They hemolyze blood cells, even in isotonic or hypertonic salt solutions.

Fish are killed by high dilutions (1:200,000). Saponin has been used to kill *snails*, in schistosomatous waters (C. Pinto, 1944). In *higher animals* they are but little absorbed, so that they act mainly as local irritants to the mucous membranes. A few, however, are absorbable and toxic, producing hemolysis; in large doses also degeneration of liver cells, followed by fibrosis. They have been administered to increase gastro-intestinal absorption, for instance, of insulin, but with doubtful results. Senega is used somewhat as nauseant and emetic. Sarsaparilla and guaiac were formerly employed as "alteratives" in syphilis. Quillaja (soap bark) and saponaria (soap root) are used technically for cleansing. "Merck's *Saponin Purissimum*" is prepared from saponaria.

Chemical Properties.—Many of the typical members of the group have the composition $C_nN_{2n-8}O_{10}$. They are glycosides and give a purple color with concentrated sulfuric acid. They are generally not attacked by animal enzymes. They have the characters of colloids: they do not dialyze; most are soluble in water, and are not precipitated by moderate amounts of alcohol; but they do not dissolve in pure alcohol or in fat solvents. Many are precipitated by saturation with neutral salts, especially ammonium sulfate; by basic lead acetate, and so forth. Some behave as acids, others are neutral. When heated with dilute mineral acids they are decomposed into sugars (differing for the individual saponins) and a *sapogenin*. Schmiedeberg calls these decomposition products "saponins," and all the original substances "sapotoxins." Others apply this name to the more toxic saponins (review, Kobert, 1914).

Occurrence.—Sapo-glycosides are widely distributed through the vegetable kingdom, occurring in at least 400 plants, belonging to 50 different families. They are probably formed in the leaves, but are found in all parts of the plants. The foaming is so conspicuous that many of these drugs have received suggestive popular names, soap bark, soap root, and the like. They are employed even by noncivilized peoples, for cleaning, and on account of their high toxicity to fish as fish poisons. Some cause poisoning of grazing stock (Vaccaria). *Ophiotoxin*, a definite principle isolated from snake venom, is believed to be closely related to the saponins (Faust). *Crocus* bulbs contain a saponin toxic to young animals, but not to old (Kobert, 1917).

Local Actions.—Most of the sapo-glycosides are irritant to *mucous membranes*. They have an *acrid taste* and provoke a flow of saliva (sialogogue action), nausea, vomiting and diarrhea. The gastric mucous membrane shows transient turgescence, with marked increase of mucus and moderate increase of fluid (Ivančevič and Kadruka, 1939). If snuffed, they cause sneezing; if injected hypodermically, they produce *subcutaneous inflammation.*

Therapeutic Uses.—Senega is used as nauseant expectorant, especially in chronic cough, and as emetic. Its nonabsorption constitutes an advantage. The emulsifying action determines the use of quillaja as detergent, especially for the cleansing of articles which are injured by alkalis. The use of quillaja in medicinal emulsions or for producing foam in soda water is not admissible.

Some of the less toxic saponins might be used for this purpose (Kobert, 1904), but they have not been sufficiently studied to be entirely safe.

Sarsaparilla, which owes its activity entirely to the sapotoxin or saponin which it contains, formerly enjoyed considerable reputation as an *alterative*. This is no longer accepted (H. C. Wood, Jr., 1916); if it possesses any action at all it is simply that of a mild nauseant and cathartic.

Saponin on Absorption.—It has been claimed that saponin (clinically, 0.1 to 0.2 Gm. of Merk's Saponin Puriss.) increases the absorption of sugar (Lasch and Brügel) and of a variety of drugs (Korfler, 1932) from the alimentary tract, but the evidence is not conclusive, as the differences lie within the natural variation (Petschacher and Nageeb, 1929), and reliable workers (Dingemanse and Laqueur, 1927) failed to obtain increase of insulin absorption.

Systemic Actions.—If sapo-glycosides are injected directly into the circulation they produce hemolysis, diuresis (B. MacCallum, 1905; Asher, 1908), and direct actions, especially on the central nervous system, which may be rapidly fatal. At first there are violent convulsions; then paralysis, especially of the respiratory center. The effect on fish is also paralytic. Rapid absorption through the gills makes even small doses effective. *Smaller doses given by the blood* cause especially *intestinal symptoms*, and death after several days by collapse. Why the symptoms are so largely intestinal is unexplained. Given subcutaneously, they produce these same symptoms, but much more slowly. If they are applied directly to skeletal or cardiac *muscle* or to nerve trunks, these lose their irritability at once, and if the solution is fairly strong (1 per cent), there is rigor. Saponins act on amebae, but apparently not on bacteria (Bacon and Marshall, 1906).

Effects on Circulation.—Intravenous injection of Merck's purified saponaria saponin into rabbits, 20 mg. per Kg., produces a slight rise of blood pressure; larger doses cause rapid fall with extreme cardiac dilatation. Perfusion of *rabbit's ear* gives vasodilatation and then edema. Dog's heart-lung preparations show dilatation of the coronary vessels. Excised *auricular segments* of rabbits react with depression, arrhythmia and arrest (Gottdenker, 1938). Nearly all saponins are toxic to the *frog heart* (I. Traube, 1919). The addition of saponin increases the toxicity of digitoxin for the frog heart (Postoiev, 1911).

Effects of Hemolysis.—Hemolysis liberates potassium and other toxic substances from the corpuscles (Gottlieb and Lefmann, 1907; W. H. Brown, and Loevenhart, 1913); but these are not concerned in the systemic saponin actions: the latter occur with doses which are not hemolytic; nor are the systemic saponin effects avoided by cholesterol, which prevents the hemolysis. Presumably the permeability of the nerve cells is directly affected by the saponin.

Poisoning.—Most sapo-glycosides are absorbed so poorly that they produce only local effects: gastroenteritis, vomiting, persistent diarrhea, and so forth. However, the violent local action may lead to corrosion and this to absorption (*f. i.*, with quillaja). Agrostemma, the common corn cockle (chemistry, Brandt, 1906) is absorbed fairly readily and thus produces systemic poisoning. This is important since its seed may be admixed with grain. The systemic symptoms agree with those of intravenous injection. The toxicity of various saponins is ten to a thousand times higher by vein than by mouth, and is generally (but not always) proportional to the hemolytic action. The liver affords some protection, but larger doses produce degeneration of the hepatic cells, followed by fibrosis (Ewart, 1931). Some saponins have different toxicity for different species. Certain vegetables, for instance, *spinach*, contain saponins which appear harmless for man (Kobert, 1914).

Experimental Saponin Anemia.—Injections of subethasl doses of saponins cause destruction of the erythrolcyte by an indirect action on hemoclastic organs, especially the spleen. The liberated iron is stored mainly in the spleen; if this has been removed, it is stored in the liver. The urinary iron is not increased; the fecal iron is (T. Fukui, 1926). Daily intravenous injection of the maximum tolerated dose of saponin into rats gradually reduces their erythrocytes and hemoglobin to half or less. When the injections are discontinued, there is little change for ten to twenty days; then regeneration sets in, with nearly complete recovery in another three weeks (Stohlman and Smith, 1934).

Hemolytic Action.—Saponins lake blood even in an isotonic medium. The phenomenon depends on their affinity for the lipoids of the cell envelope and stroma. It is prevented by the addition of cholesterol or other lipoids which combine with or bind the saponin.

Hemolytic Concentration.—The limital concentrations 1:400,000 to 1:10, vary enormously, but are characteristic for the different saponins (Kobert, 1914).

Phenomena of Laking.—Saponin hemolysis occurs in two stages, which are practically distinct: the liberation of hemoglobin; and increased permeability of the envelope (G. N. Stewart, 1899 to 1909; Woelfel, 1908). The latter occurs even in formaldehyde-fixed corpuscles. Saponin does not cause the complete disappearance of the stromata; bile salts do (Neuberg and Haendel, 1908). The hemolytic activity of different saponins has no relation to their effect on *surface tension* (Woodward and Alsberg, 1916).

The saponin acts chiefly, if not solely, on the envelope, presumably on its cholesterol. The quantity of saponin or sodium oleate required for hemolysis is similar to the quantity required to cover the surface of the cell with a monomolecular layer. Smaller quantities sensitize to other hemolytic agents (E. Gorter, 1937). The electron microscope shows that the erythrocyte is enclosed in a membrane consisting of a framework of long protein threads in which cholesterol and lecithin are imbedded. Saponins precipitate cholesterol, forming definite crystalline compounds (Windaus, 1923). This combination so disorganizes the membrane that the hemoglobin escapes (J. Schmidt-Thomé, 1942).

Protective Action of Cholesterol.—Hemolysis may be prevented by adding cholesterol to the erythrocyte suspension before the saponin (Ransom, 1901). The protective action of *serum* is due chiefly to its cholesterol (Laube, 1911; E. Ponder, 1944). Pure lecithin does not protect. Cholesterol also protects the erythrocytes against toluidine compounds (Hildebrandt, 1911), sodium oleate, immune serum hemolysin, cobra lysin and some bacterial lysins, but not against some other hemolytic agents; for instance, the resistance of the blood of different animals varies inversely for saponin and water laking (Rywosch, 1911). The cholesterol protection does not extend to the central saponin actions. Cholesterol protects the heart against digitoxin, but not against all digitaloids (Karanlow, 1912). It antagonizes the systemic toxicity as well as the hemolytic action of sodium oleate (Klotz and Bothwell, 1915).

Acquired Resistance.—Repeated injections of saponin and other hemolytic agents raise the general resistance of the corpuscles (Kobert; R. Weil, 1910; contradicted by Kagan, 1913). No true antibodies occur. Prolonged saponin feeding increases the resistance, both of the corpuscles proper and of the serum (Alsberg and Smith, 1914). A similar increase of resistance occurs also in certain diseases in which hemolytic poisons are probably produced, *f. i.*, in syphilis, advanced cancer, and so forth. (Weil; McNeil, 1910).

Mixed Hemolysis.—Fuehner and Greb, 1912, found that the combination of various hemolytic agents (aliphatic, alkaloidal and glucosidal) gave complex results; the summation of the effects being sometimes simple, excessive or deficient. Saponin hemolyis is powerfully accelerated by proflavine and by 9-aminoacridine (H. B. Collier, 1945). The hemolytic action of watery solution of saponin is rapidly destroyed by the addition of *fluorescent substances*, eosin and erythrosin (Noguchi, 1906). Infusion of *tea* also has an inhibiting effect on saponin hemolysis; this has been proposed as a test for genuine tea (Maggiora and Ferron, 1914); but is probably due merely to the tannin.

Preparations.—*Sarsaparilla*, U.S.P., is the dried root of Smilax species. The Jamica variety contains a single saponin glucoside, "sarsasaponin" (Power and Salway, 1914). The *Fluidextract* is given in a dose of 2 cc., 30 minims, and is an ingredient of the *Compound Sarsaparilla Syrup*, used as an aromatic vehicle, especially for iodides. *Caulophyllum* (Blue Cohosh), the rhizome and roots of Caulophyllum thalictroides (chemistry, Power and Salway, 1913), is used as diuretic, emmenagogue and anthelmintic (see article under Nicotine and Ergot). Dose, 0.3 to 2 Gm., 5 to 30 grains. *Guaiac Wood* (Guaiaci Lignum), the heart wood of Guaiacum officinale or sanctum, contains 20 to 25 per cent of resin and some saponin (a trace of the latter is also contained in the Resin). There is some reason to believe the saponin is the bearer of the nauseant and purgative action. Guaiac, an almost obsolete remedy for syphilis, gout, rheumatism, tuberculosis, and so on, was introduced soon after the discovery of America, about 1501-1503. Nicholaus Pohl, 1517, stated that it had cured 3000 Spaniards. Its popularity was proclaimed in a famous pamphlet of Ulrich von Hutten, 1519. It was still strongly endorsed by Boerhaave (1668–1738), who wrote that "it will act as a purge, reaching places that mercury cannot reach, and there dissolve the poison." As early as 1538 Ruiz Diaz de Isla gave the credit to the associated regimen, and indeed von Hutten had some suspicion in this direction. *Guaiac Resin*, obtained from Guaiac Wood, contains a number of resinous acids, especially guaiaconic acid, which is colored blue by oxidation. This is inhibited by many anticatalytic agents; hydroquinone, epinephrine, gallic acid and cyanide are especially effective (E. Baur and Brunnschweiler, 1941). Dose, 0.3 to 1 Gm., 5 to 15 grains. The resin is commonly used as a reagent for oxidative ferments. Schaer, 1913, found the best results with resin extracted from the wood by chloroform; then the natural resin; then alcoholic extract of the wood. Solutions lose their sensitiveness with age. *Quillaja* (Soap Bark) is the dried inner bark of Quillaja Saponaria. Dose, 0.06 to 0.2 Gm., 1 to 3 grains. *Saponaria* (Soap Root) consists of the root or leaves of Saponaria officinalis. The dried powder contains 30 to 40 per cent of saponin. *Senega*, the dried roots of Polygala Senega, is given in a dose of 0.4 to 0.8 Gm., 6 to 12 grains. *Githagin*, a saponin glucoside from the seeds of *Agrostemma* githago, is readily absorbed, the seeds causing serious poisoning. Intraperitoneal injections into guinea pigs produce multiple internal hemorrhages in a few hours. Sublethal doses impair the adrenals (Buu-Hoi *et al.*, 1944).

The pharmacology of *horse chestnut saponin* is described by H. Hindemith, 1943.

SOLANINE

The glucosidal alkaloids, solanine, solaneine, and solanidine, which occur in plants of the potato genus (Solanum nigrum, dulcamara, tuberosum [Potato], Carolinense and Tomato), produce typical sapotoxin actions. Solanine splits into sugar and solanidine. The solanine literature is reviewed by Meyer and Schmiedeberg, 1895. In certain species, particularly in S. dulcamara, the solanine alkaloids are associated with a small quantity of atropine-like alkaloid and with a saponin (dulcamarin).

Potato (*Solanum Tuberosum*).—The toxic principles are distributed throughout the plant, but only small quantities are found in the pulp of the tuber—too small to produce any action. The quantity is larger in the peel, and especially in young and in sprouting potatoes and in the green-colored skin and flesh; but it is not increased by storage. The amount in potato is ordinarily too small to be harmful (less than 0.01 per cent), and it was doubted whether "potato poisoning" could be due to solanine (Droste, 1915). However, under conditions that are not understood the solanine may occasionally rise to four or five times this quantity. Since 0.2 Gm of isolated solanine provokes untoward symptoms in man, potatoes containing this high quantity of solanine are poisonous, as shown in the outbreaks of Leipzig (Rothe, 1919) and Glasgow (Harris and Cockburn, 1918). In both, the suspected potatoes contained over 0.4 Gm. of solanine per kilogram. The symptoms pointed to gastro-intestinal irritation: vomiting, diarrhea, colic, headache, depression, and the like. They may be severe, but no fatalities have been recorded (Pohl, 1924).

Solanum dulcamara ("*Bittersweet*") has been used as a nauseant (*Dose*, 4 cc. of the fluidextract, prepared from the young branches). The berries of *Solanum Carolinense* were used in epilepsy (dose, 4 cc. of the fluidextract), generally with bromides, so that the effects are difficult to judge. *Tulip bulbs* contain an alkaloid, tulipine, closely related to solanine and colchicine (Kobert, 1917).

◆

COLCHICUM

Colchicum (Meadow Saffron), and its active alkaloid colchicine, a phenanthrene derivative, are used empirically to avert or mitigate acute attacks of gout. Colchicine has a remarkable effect on cell division, arresting it in metaphase, even when it is administered to intact animals. Toxic doses produce a characteristic late gastro-intestinal irritation, even on hypodermic administration. The vomiting, purging and intestinal congestion may be so violent as to lead to fatal collapse, so that the plant (all parts) is of toxicologic importance. The other actions are relatively insignificant.

Therapeutic Use in Gout.—Colchicum and colchicine are credited with prompt and sometimes dramatic effects on acute gouty attacks, relieving the pain in one or two hours, the heat and swelling subsiding soon after, and the attack ending in a few days instead of weeks. It must be used early and rather freely, in doses large enough to produce some diarrhea. It does not prevent recurrence, soon loses its efficiency and is often unsuccessful. It gives little or no relief in nongouty arthritis (Lockie, 1939). It prevents or diminishes the experimental inflammatory reactions of local joint anaphylaxis (A. Beck, 1932). The effect is probably connected with its irritative *dilator* action on capillaries; but it also causes characteristic changes in the blood picture, leukopenia followed by leukocytosis. These reactions resemble those of nonspecific protein injection.

Administration.—Tincture of Colchicum Seed may be given in divided doses, 0.5 cc., 8 minims, every three hours (advantageously with an equal quantity of magnesium carbonate or sodium salicylate), until a therapeutic response or slight gastro-intestinal disturbance and weakness occur. Some disturbance of digestion and soft stools are the rule, and in susceptible patients there may be considerable purging and faintness. This may be lessened by atropine, but if possible should be avoided by proper dosage. A single large dose, 2 to 5 cc., ½ to 1 ʒ of tincture, acts more promptly, but may cause severe nausea, diarrhea and great muscle weakness. Prolonged administration is generally harmful and therefore inadvisable. *Colchicine* permits more definite dosage. It may be given, 0.5 to 1 mg., 1/120 to 1/60 grain, three times daily, for one or at most two days. This usually causes considerable diarrhea, beginning on the second day, and with its appearance the drug should be discontinued. The stools remain loose for another day.

Historical.—The toxic properties of colchicum are mentioned by Dioscorides. It was used against gout or rheumatism by the Arabian school (sixteenth century), and since then in domestic practice; but was abandoned in regular practice on account of its poisonous action, till it was reintroduced by Stoerck, 1763. The weakness of the earlier pharmacologic explanations is reflected in the references of S. Loewe, 1920.

Metabolism.—The *urine* secretion is sometimes slightly increased, sometimes greatly diminished, probably depending on the catharsis. The statements as to uric acid and urea (*e. g.*, Noel Paton, 1886; Maurel and Arnaud, 1910; Abl, 1913) are so contradictory that they can have little importance. With the modern methods, Denis, 1915, found neither increased elimination of urates in the urine, nor diminished concentration in the blood. The *bile* flow is slightly increased (Kionka, 1906).

Leukocytes.—Hypodermic injection of colchicine, 3 mg. per Kg., into rabbits, produces leukopenia lasting about an hour and followed in two to six hours by remarkable leukocytosis. The polymorphous cells may attain a maximum of two to five times the normal in ten to twenty-four hours. The effect may persist as long as eight days; with repeated administration it is cumulative (Dixon and Malden, 1908). The *blood coagulability* is accelerated during the leukopenic stage, and retarded with the leukocytosis (Loicq, 1937).

Mitogenetic Activity.—Administration of colchicine (0.2 mg. per 100 Gm., hypodermically, for mice) arrests mitotic division of cells in general in the metaphase (Lits, 1934; Brues and Cohen, 1936; E. Allen, Smith and Gardner, 1936; Ludford, 1937). This effect occurs also in *plant cells*, suppressing spindle fiber formation and inhibiting the separation of the cell after the division of the chromosomes, so that the number of chromosomes is doubled (polyploidy). If the drug is now removed, the nucleus divides normally, producing plants in which the double number of chromosomes is reproduced indefinitely, and this is transmitted to the seed and descendant (Nebel and Ruttle, 1938; R. I. Walkers, 1938).

With *chick embryos* it results in retardation of growth and various abnormalities (Paff, 1939; Angel and Tallemand, 1940). The effect on mitosis is observable on tissue cultures of embryonic chick heart, but these are killed by concentrations above 1:1,000,000 (Törö and Vadász, 1939). It is useful *to demonstrate the active growth stimulation* of genital tissue by theelin (E. Allen, Smith and Gardner, 1937; E. Shorr and Cohen, 1941, vaginal suppository of 1 to 3 mg.), or by androgenic hormone, thyroid stimulation by pituitary hormone, and so on (Fleischmann, 1938). The arrest of mitosis in metaphase leads to the death and destruction of normal tissues with rapid cell division (Clearkin, 1937).

Frog ova fertilized with *sperm* exposed to 0.04 per cent for three hours show various developmental anomalies (T. S. Hall, 1946). Local application of colchicine to normal human or rabbit *skin* results in transitory alterations of the nuclear pattern of the epidermis, similarly to podophyllin (J. S. King and Sullivan, 1946).

Colchicine checks the growth of certain mouse *tumors* (Lits and Kirschbaum, 1938); but curative results were not obtainable with tolerated doses (E. Schairer, 1940). The tumors recur except with doses just short of lethal, which produce vascular injury (R. J. Ludford, 1945). In other types it appears unsuccessful. In one form (sarcoma S37) it does not inhibit the growth of transplants in the animal, but it checks tissue cultures of the tumor from the treated animals (Clearkin, 1937). Rat carcinoma is rapidly destroyed by local injection of water, fifteen hours after administering colchicine (Guyer and Claus, 1940). Doses approaching to toxic cause hemorrhages in tumors (but no more than with bacterial filtrates, Andremont, 1940) with decrease of their ascorbic acid content and metabolism. They also decrease the ascorbic acid content, but not the metabolism, of the liver and intestines (Boyland and Boyland, 1937). *Plant tumors* are killed by brushing with a 2 per cent solution (N. A. Brown, 1942).

Mitosis effects identical with those of colchicine, including polyploidy, are produced by a whole series of derivatives and chemically related substances; by veratrine and sanguinarine; and by acenaphthene, α-methylnapthalene, α-nitronaphthalene, 3-5 dibromopyridine, and by apiol (C. F. Branch, 1942; Lettré and Fernholz, 1943).

The **symptoms of colchicum poisoning** set in only after three to six hours, even with large doses. They begin with burning and rawness in the mouth and throat, sensation of strangling, difficulty of swallowing, nausea, abdominal discomfort, followed by violent and uncontrollable vomiting and purging, colic and tenesmus, spasm of the bladder and great prostration. The stools are at first normal, but become dysenteric and bloody. They are not especially painful, but are exhausting, so that the patient passes into collapse, with the nervous and muscular symptoms of cholera. Death occurs in seven to thirty-six hours from exhaustion, consciousness being preserved nearly to the end; or by respiratory paralysis, with the patient unconscious and deeply cyanosed. The *fatal dose* varies; ½ ounce of the Tincture has been fatal. This would correspond to about 8 mg. of colchicine; but recovery has occurred from much larger doses, presumably with imperfect absorption. The *treatment* includes evacuation by emesis and catharsis, if necessary, and diuresis. Tannin is a chemical antidote, but not very effective. Opium and belladonna are given against the gastroenteritis, and the collapse is treated as usual. *Autopsy* reveals intense and often hemorrhagic congestion of the intestines, especially the lower portion.

Gastro-Intestinal Irritation.—The intense congestion and violent peristalisis occur even on parenteral administration, but this has no special significance, since the colchicine is excreted into the intestines (Speyer, 1870). The action is not directly on the muscle or its innervation, for excised intestine is depressed in tone and excursions by colchicine or oxydicolchicine (Fuehner and Rehbein, 1915). Rossbach, 1876, stated that the motor response to the intestinal vagus or splanchnic is not affected. Fuehner and Rehbein refer the entire action to irritative capillary vasodilatation analogous to the local actions elsewhere, and produced by contact with the drug, reaching the intestine directly or by excretion. They find this hyperemia of the stomach and intestines even with small doses. Lipps, 1920, confirmed the occurrence of hemorrhagic gastro-enteritis after hypodermic administration. He assumed that a capillary hyperemia occurs in other organs, including inflamed regions, and that this is the basis of the therapeutic results.

Local Action.—Strong solutions applied locally to the conjunctiva or subcutaneous tissue produce hyperemia, irritation and anesthesia.

The *central nervous system* is gradually paralyzed from below upward, partly directly and partly by the collapse.

Therapeutic doses exert no *appreciable direct effect on the circulation* (but the pulse may be somewhat slowed by the relief of the symptoms); *nor on the glands, striped muscles, or motor nerves* (Rossbach; Dixon and Malden). In *excised frog heart*, colchicine paralyzes the vagus endings (Jacobson, 1925). On *excised skeletal muscle*, it acts analogous to veratrine, causing higher and longer single twitch, and more rapid fatigue on rhythmic stimulation (Frey, 1923).

Explanation of the Delayed Action.—The long period before the symptoms appear cannot be materially shortened by increasing the dose (Schorff and Rossbach, 1896), or by intravenous injection. Colchicine itself has relatively little effect on frogs; but its toxicity for these can be increased four hundred times by raising their temperature from 19° to 30° C. (Sanno, 1911). This corresponds strikingly with the observation of Fuehner and Wagner, 1932, that colchicine is four hundred times more toxic to mice than to frogs at room temperature; *i. e.*, heated frogs react to colchicine as warm-blooded animals.

Jacobj, 1890, concluded that it is not the colchicine itself which produces the symptoms, but an oxidation product—oxydicolchicine—which is formed from it in the mammalian organism—even by circulating it through excised organs—but does not seem to be capable of formation in the frog's at a low temperature. Once formed, whether in the above manner or artificially by the action of ozone, it is toxic to frogs also.

Bio-Assay.—The toxicity to mice or heated frogs may be used (Fuehner, 1910).

Colchicine Derivatives.—The structure of colchicine was established by Zeisel, 1888, and Windaus (Fuehner, 1913). By treatment with acids, a methyl group is split off and replaced by OH, yielding *colchiceine*. This and various other derivatives were studied pharmacologically by Fuehner, 1913. The relative toxicity for various animals shows interesting differences.

PREPARATIONS.—***Colchicum Seed Tincture,** U.S.P., represents 10 per cent of the dried, ripe seed of Colchicum autumnale, and contains 0.04 per cent of colchiceine. Dose, 0.3 to 2 cc., 5 to 30 minims. *Colchicine*, U.S.P., is sol. in water (1:25) and in alcohol. Average dose, 0.5 mg., $\frac{1}{120}$ grain. *Colchicine Tablets*, U.S.P.; usual size, 0.5 mg.

ACONITE

Aconite (grown in gardens as "Monkshood" and "Venus' chariot") owes its activity to the rather unstable alkaloid, aconitine. This is a peripheral and central stimulant and depressant. Locally, the peculiar stimulation (tingling) and anesthesia (numbness) of sensory nerves, without inflammatory phenomena, is used against neuralgic and rheumatic pains, but has no advantage over capsicum. Systemically, therapeutic doses produce mainly a slowing of the heart (central vagus stimulation) which has been employed in sthenic fevers. Larger doses are highly toxic, producing great general depressions, extreme irregularity of the heart (mainly by direct action on the cardiac muscle), and death by arrest of the respiration or heart.

It is doubtful whether the systemic use of aconite is advisable. Effective doses are practically toxic, and safe doses are practically ineffective. The difficulty is increased by the variability and instability of aconite preparations.

The tincture, the most commonly used preparation, contains 10 per cent of aconite, U.S.P. (Formerly the strength was 35 per cent, U.S.P. These differences must be remembered in connection with older clinical papers.)

Historical.—The toxic properties of aconite were known to the ancients; however, there is considerable confusion, since the Roman poets used "Aconite" to denote vegetable poisons generally (Fleming). Various species, most of which are toxic, grow in different parts of the world. They were used as arrow poisons by the ancient Chinese and Gauls. The therapeutic use dates from Anton Stoerck ("Observations on the Use of Conium, Stramonium, Aconite, and Colchicum," 1763), who described the tingling without reddening or corrosion, the salivation and sweating, and proposed its use against rheumatic and neuralgic pain, and for "dissipating" swellings and healing ulcers. Alexander Fleming, of Edinburgh, 1845, published a comprehensive experimental and clinical "inquiry" of Aconitum Napellus, which is still a good model for therapeutic observation. Aconite is a favorite remedy of the homeopathic school. Several species are used in China as local anesthetic (H. P. Chu, 1927).

Chemistry of Aconitine.—The chief active constituent of Aconitum Napellus is the alkaloid *aconitine*. It is the acetyl-benzoyl-ester of *aconine*, a base derived from quinoline (Ehrenberg and Purfürst). *It decomposes readily*, even on boiling, with water, into benzoyl aconine (picroaconitine, iso-aconitine), and this again into aconine (Freund and Beck, 1894). They have the same actions as aconitine, but picroaconitine is only about $\frac{1}{60}$ as potent as aconitine; aconine, $\frac{1}{2000}$. These and other decomposition products preexist in the drug, and are probably formed in its extraction and especially in the manufacture of the alkaloid. *Commercial "aconitines"* may represent mixtures of varying strength, some being a hundred times more active than others. Several fatal accidents, to which it gave rise, have led to the practical abandonment of the internal use of aconitine in therapeutics. *Other species of aconite* contain related alkaloids, with similar actions: pseudaconitine or nepaline; indaconitine; bikhaconitine; japaconitine, and so on. T. R. Fraser, 1873, showed that the effects of aconitine and pseudaconitine are qualitatively alike; but that aconitine acts much more on the heart, pseudaconitine on the respiration. He further reported in 1916 on some East Indian species.

Local Actions.—*In the mouth* even a small quantity of dilute solutions of aconite produces a peculiar warm and *tingling sensation*, a sour rather than bitter taste, followed by numbness and anesthesia. The lips, tongue and mucous membrane of the mouth and throat feel as if swollen. The flow of saliva is increased reflexly. The apparent irritation is not accompanied by redness, pain, objective swelling or other sign of inflammation. It is therefore purely sensory. Analogous effects—heat, tingling and succeeding numbness, without inflammation—are produced in any other situation to which the drug may be applied; and even on the systemic administration of large doses. From the *skin*, watery solutions are but slightly absorbed, and friction must be employed to secure the local effect. Oily solutions and ointments are absorbed readily.

Eye.—Fleming claimed that the application to one of the temples, or one side of the forehead, may produce more or less (temporary) *blindness* on that side. The *pupils* are then dilated, presumably to admit more light. The application to the conjunctiva constricts the pupils. In systemic poisoning, they are constricted until the final asphyxial dilatation.

Therapeutic use of the local action is made for the relief of toothache, neuralgia, migraine, rheumatic and other similar pain. For this purpose it may be employed by thorough friction of the tincture, undiluted or with the addition of 1 to 10 parts of soap liniment. This is probably as effective as the expensive Unguentum Aconitinae (2 per cent).

Fleming claimed that the internal use of the tincture is often more effective in neuralgia. He started with about 1 cc. of the U.S.P. tincture, three times daily, and increased the dosage until the full therapeutic effect (pulse of 54, lethargy, and so forth) was obtained.

The systemic effects of therapeutic doses consist mainly in more or less pronounced *slowing of the heart rate*, to 60 or 54 beats per minute, according to the dose and the susceptibility of the individual. The pulse is also softer and weaker, but remains regular as long as the dosage of slowing is not surpassed. The blood pressure falls slightly. The therapeutic slowing (often absent in anesthetized dogs) is due mainly to stimulation of the vagus center, for it is practically absent if the vagi have been divided (S. A. Matthews, 1897). The typical slowing, which occurs in one and one-half to two hours if the tincture has been taken by the mouth, is preceded by *subjective sensations* of evanescent warmth, and persistent numbness and *tingling*, beginning in the finger tips and extending along the arm, as the dosage is increased. The *respiration* is moderately slowed and more or less labored. With the full therapeutic dosage, the patient is weak, giddy, confused, lethargic and cold. These phenomena last for three to five hours and are as far as the therapeutic action should be carried. They are produced by doses corresponding to 0.15 to 0.3 Gm. of aconite (Fleming), *i. e.*, by 1.5 to 3 cc. (20 to 45 minims) of the 10 per cent U.S.P. tincture.

Sweating may occur, but is not constant. The *urine* is not increased. The *temperature* is not markedly affected by the therapeutic doses. *Digestion* and *peristalsis* are not disturbed. *There is no cumulative action.* The *vasomotor center* is not affected by nontoxic doses. Toxic doses, however, produce a maximal stimulation, more intense than can be obtained from stimulation of sensory nerves (Pilcher and Sollmann, 1915).

Inactive Tinctures.—Several observers have been unable to obtain effects on the pulse and blood pressure, from small and fairly large doses, in a variety of clinical conditions. These negative results are probably ascribable to inactive preparations of the drug, as with Robinson, 1915.

Therapeutic Uses.—The slowing of the circulation has been utilized in heart disease, in hypertension and in sthenic fevers, but is of doubtful value, especially in view of the total inefficiency of the dose ordinarily given.

Sthenic Fevers.—In these it was supposed to "calm" the overactive heart and to promote the action of mild diaphoretic agents (spirits of niter, ammonium acetate, and so on). It is used in this way during the sthenic stage of acute fevers, especially in children, for the "abortion" of colds. According to Ringer, it is administered in small and frequent doses (3 to 5 drops of the 10 per cent tincture for adults, at first every fifteen minutes for two hours, then every hour, until the pulse returns to normal), and only for the first day of the fever, to avoid depression. It is difficult to judge its usefulness under such conditions.

Toxic doses increase the force and especially the rate of the heart, at the same time rendering it extremely arrhythmic. The beats may occur in groups, as with digitalis. The heart finally goes quite suddenly into delirium cordis, and stops. During the earlier stages of this action the blood pressure is extremely variable, according to the varying force of the heart, and the successive stimulation and depression of the vasomotor center. Toward the later stages, the pressure drops severely (Matthews, 1897; for further details of the interesting cardiac irregularities consult Fleming, p. 31; and Cushny, 1909). *Electrocardiograms*, in dogs, show ventricular tachycardia, fibrillation, flutter and death (J. B. Wolffe and Munch, 1934).

The cardiac effects are due partly to stimulation and depression of the vagus and accelerator mechanisms, but mainly to direct action on the cardiac muscle. The excitability of the latter is greatly increased, somewhat as with digitalis. The quickening occurs in the nerve-free heart of the embryonal chick; in mammals also it is seen after all the nerve endings in the heart have been paralyzed by apocodeine. With *isolated mammalian heart* (Hedbom-Langendorff) the initial effects are inconstant; the frequency is then enormously increased and the amplitude lessened below what is accounted for by the quickening (increased irritability and weakened muscle). Then follows a transient increase of amplitude (muscular stimulation), and sudden stoppage of the left ventricle (paralysis of automatic property). The right ventricle and the auricles make a few more contractions. Caffeine may start a few beats.

Perfusion of Medulla in Turtle.—Aconitine stimulates the cardio-inhibitory center (Bush, 1920).

The actions of aconite on the frog's heart are practically identical in the intact frog and in perfused excised heart. They are therefore peripheral. They consist in heightened irritability of the auricular, and especially of the ventricular, muscle; disturbed conduction; lessened contraction intensity, and finally paralysis. The successive effects are described as follows (Boehm, 1871; Fuehner, 1911). (1) *Preliminary slowing* is sometimes observed. It is probably due to stimulation of the vagus endings. (2) *Acceleration.*—Rather suddenly the beats become quickened and at first strengthened. The acceleration is attributed to heightened irritability of the cardiac muscle. The time of contraction and the refractory phase are shortened. (3) *Incoordination.*—Ventricular extrasystoles appear (even when the auricles are removed). The rate of the ventricle increases above that of the auricles, at first in a regular ratio. The combination of the two rates results in "periodic dissociation" or grouped beats. As the rate continues to increase, the contractions cannot be maintained regular, and become extremely incoordinated, resulting in the characteristic "*peristalsis*" of the heart muscle. This begins in the auricles, but soon extends to the ventricle. It consists in vermicular movements, in which the blood, instead of being propelled, is merely moved about in the heart. The localized contractions may lead to a mulberry appearance. Sometimes the contraction sequence is reversed so that the ventricular contraction initiates the auricular beat. These irregularities may alternate with periods of quite normal beats. The regular rhythm can often be restored by stimulating the accelerator nerve. (4) *Standstill.*—The extreme irregularity always passes off after a time, and is succeeded by slow and weak, but fairly regular, contractions, except that the ventricle beats much slower than the auricles. Eventually the ventricle stops relaxed, and then the auricles, usually rather suddenly. The peculiar heart "peristalsis" is the most delicate and characteristic *test for aconitine.* Fuehner, 1911, could detect 1/100 mg. in intact frogs and 1/1000 mg. in excised hearts. Similar effects are produced by the related delphinine. The digitalis group also produces peristalsis, but this is of short duration and followed by systolic standstill.

Respiration is progressively slowed in proportion to the dose (Fleming). It is labored, and the later stages become irregular. The slowing resembles that of vagus stimulation; but since it occurs also after section of the vagi (Boehm and Wartmann, 1873), it must be due to direct depression of the respiratory center, or perhaps to a cardiovascular reflex. It is characterized by prolonged expiratory pauses. Primary increase of respiration has been claimed, but it is small and inconstant, and probably due to other factors (Hartung, 1912).

The **temperature** falls in severe poisoning, by the collapse and consequent paralysis of heat regulation. The temperature of the animal falls and rises with the external temperature (Brunton and Cash, 1886).

Summation of Dosage.—The influence of this on temperature was studied by Cash, 1906. He found an imperfect summation of effect if the dose is repeated at sufficiently close interval. But if this exceeds two hours, the later doses may produce actually less effect, *i. e.*, the temperature may not fall so low as with the first dose. *Repeated administration* produces some tolerance in rabbits (Hartung, 1912).

Reflexes generally are diminished, on account of the sensory paralysis.

Skeletal Muscles and Motor Nerves.—Strong concentrations of aconitine at first stimulate and then paralyze the motor nerves peripherally. The stimulation is manifested by *fibrillary twitching,* occurring in muscle-nerve preparation, spontaneously or especially after stimulation of the nerve. The threshold of stimulation is lowered. The twitchings do not occur after curare, and must therefore be in the endings. They may be seen in living animals. The subsequent paralysis of the nerve, and eventually of the muscle substance, cannot occur during life, since the dose and the time required are greater than what would paralyze the heart (Hartung, 1911). The allied *delphinine* has been recommended as a substitute for curare in frog work (Schiller, 1904).

Infusoria and plants are also killed by aconite (Fleming).

Absorption and Excretion.—The absorption occurs readily from mucous membranes; alcoholic and oily solutions are absorbed from the skin. Lewin states that it is excreted promptly by the urine, feces, saliva and intestinal mucosa.

Symptoms of Aconite Poisoning in Man.—With large doses death may occur almost instantly, presumably by ventricular fibrillation. With moderately toxic doses, there is *tingling* in mouth, stomach and skin (the *most important diagnostic feature*); excessive salivation; nausea, retching, *vomiting* and *diarrhea* (the mechanism of the emesis is central; Eggleston and Hatcher, 1915) The burning passes into anesthesia. There is great restlessness. The *pulse* is slow and feeble, later arrhythmic and rapid. *Respiration* is dyspneic. There are muscular weakness, incoordination, vertigo. The *skin* is cold and livid. The *pupils* are first constricted, then dilated from the asphyxia and convulsions. The *intelligence* does not usually suffer, but there may be stupor and even unconsciousness. The *special senses and speech* may be impaired. *Convulsions* are common. *Death* may occur by heart paralysis or by paralysis of the respiratory center (the heart beating after death; Fleming). The symptoms may appear almost instantly, and are rarely delayed beyond an hour. In fatal poisoning death occurs usually in two to six hours. There are no constant *postmortem changes.* Severe symptoms follow from 5 cc. of the Tincture; 20 to 40 cc. may be fatal. For *treatment,* the common alkaloidal antidotes and evacuations should be employed. The symptomatic treatment should be mainly stimulating: warmth, ammonia, atropine. Artificial respiration may be life saving (Lewin, 1875). In extremis, cardiac stimulants (epinephrine) may be used intravenously.

Etiology.—*Accidental poisoning* from the fresh plants—which, as monkshood and the related larkspur, are common in gardens—as also from liniments, and so forth, is fairly frequent. On account of the small dose, the absence of postmortem signs, and the difficulty of chemical proof, aconitine was used for *suicide*. The use of the plant for *criminal poisoning* is widely spread in the East. The symptoms are so unmistakable—especially the tingling—that it has not found many users in civilized countries.

Variability and Instability.—Bio-assays show that the alcoholic tincture deteriorates materially within a year, and is practically inactive in three years after manufacture. The deterioration is said to be prevented by acidification (Swanson and Walters, 1923). Commercial tinctures were found by Haskell *et al.*, 1915, to vary 1000 per cent; commercial solid extracts differ even more widely, some being 5000 times more active than others (A. R. L. Dohme, 1918). It may be expected that there is now much less variation in the United States, since the bio-assay is compulsory.

Aconite, N.F. (Wolfsbane, Monkshood), the dried tuberous root of Aconitum Napellus, is frequently cultivated in gardens. All parts of the plant are poisonous. Dose, 60 mg., 1 grain. *Aconite Tincture*, N.F., 10 per cent; dose, 0.6 cc., 10 minims. The tinctures of the older pharmacopoeias were of different strength: 35 per cent in U.S.P. until 1890; 5 per cent in B.P. until 1915. Various species of *Larkspur* seed (*Delphinium*) contain alkaloids closely related to aconitine, both chemically and pharmacologically, and have been used for the destruction of body parasites since antiquity. They have often caused poisoning in children, and in cattle and horses (Marsh and Clawson, 1916). *Staphisagriae Semina* (Stavesacre), the ripe seeds of Delphinium Staphisagria, are used locally against pediculosis capitis or pubis, in the form of the 10 per cent Ointment, or as the Fluidextract diluted with 8 to 10 parts of soap liniment or bay rum. It must not be used if the skin is broken. It causes considerable local irritation, and sometimes eczema (Lewin)

◆

VERATRINE (CEVADINE)

Various species of veratrum (green and white hellebore), cevadilla, zygadenus and other liliaceous plants contain mixtures of related alkaloids. These are esters of definite bases and acids, related to aconitine both in structure and action, to digitalis and to solanum alkaloids. They produce multiple effects to which a common key has not yet been found (review, O. Krayer and Acheson, 1946). "*Verat'rine*" is a mixture of alkaloids, extracted from "cevadilla" seeds, which owes its activity mainly to cevadine. It must not be confused with veratrum and its active constituent, protoveratrine, since their actions differ in important particulars. Veratrine produces a characteristic prolongation of muscular contraction of considerable physiologic interest. Therapeutically it is rarely used as a counterirritant in neuralgic conditions, and as a parasiticide against pediculi capitis.

The composition of veratrine was studied especially by Wright and Luff, 1878, and Allen, 1896. *The principal* constituent, both in quantity and action, is the crystalline *cevadine*, the methylcrotonic ester of the base cevine. It is *not* present in Veratrum album; traces are said to occur in Veratrum viride, but this is doubtful. The second important alkaloid of "veratrine" is the amorphous *veratridine*, the veratric ester of verine. This is the "veratrine of Wright and Luff." Its effects agree qualitatively with those of cevadine (Boehm and Lissauer). The commercial "veratrine" contains small quantities of at least three other alkaloids: *cevadiline*, *sabadine* and *sabadinine*. All these are but weakly active. *Germerine*, an alkaloid isolated from Veratrum album by Poethke, 1937, acts much like protoveratrine and veratrine, but also produces some sympathetic stimulation by a peripheral action which is sensitized by cocaine and by ergotamine (Haas, 1938).

The action on striped muscle consists in a characteristic modification, so that it responds by a prolonged contraction to a single stimulus. The nature of this contracture is in dispute. It is actively maintained, and is not a tetanus, since electrograms do not show rhythmic oscillations (de Boer, 1927). It is a special type of contraction, which occurs normally in fetal muscle and in the extrinsic eye muscles of mammals, and is probably identical with the "Tiegel contracture" evoked in excitable muscle to a supermaximal stimulus, and also evoked in special conditions, including drugs such as veratrine, and less typically by formaldehyde, glycerol, and so forth. Analogous changes are shown by nerve, but this is not essential to the veratrine contractures, for it occurs also in curarized muscle (*reviews of muscle contracture:* H. S. Gasser, 1930; Bremer, 1932).

The veratrine contracture is now conceived of as repetitive responses, both of the muscle and the nerve, which outlast the stimulus (Krayer and Acheson, 1946), probably by sensitization of the muscle to the potassium ions liberated by stimulation of the nerve (G. Coppée, 1942).

Veratrine in Myasthenia.—Kroll, 1934, claimed beneficial effects, especially when it was administered in conjunction with ephedrine. It may be doubted whether safe doses would have appreciable effects.

Phenomena in Intact Frogs.—When an animal, and especially a frog, has been poisoned with veratrine, it shows striking peculiarities in its movements. It can contract its muscles with ordinary quickness, but it can not recover its former position for some time (v. Bezold, 1866).

Form of the Muscle Curve.—The reason for this behavior can be demonstrated on isolated muscle. Frogs are most convenient for this purpose, but identical phenomena occur in mammalian muscle (Quagiariello, 1913): if a veratrinized muscle is stimulated with a single shock, the ascent of the muscle curve is as abrupt as usual, but the relaxation is greatly prolonged. The muscle remains in what appears to be complete tetanus, but further analysis reveals that the phenomenon is not an ordinary tetanus.

The Contracture Is Not an Ordinary Tetanus.—If the nerve of a normal muscle-nerve preparation is laid on the veratrine muscle, a single shock sent into the latter causes a single twitch of the normal muscle, and not a tetanus as would be the case if the veratrine muscle were in ordinary tetanus (Fick and Boehm, 1872). However, if the veratrine stimulated the whole length of the muscle fibers at once (in contrast to ordinary tetanus, where the stimulation originates from the motor end plates), there would be no difference of potential, and therefore the nerve of the second muscle would not be stimulated, once the shortening of the veratrine muscle is completed. It is therefore not excluded that the veratrine contracture may be a tetanus, but with the site of stimulus production distributed throughout the length of the muscle. Observations on the development of the contracture in dilute solutions point in this direction, a single stimulus producing first a normal contracture, then fibrillary twitching, and finally contracture even in the absence of extraneous stimulation (Lamm, 1912). Cathode ray oscillograms show multiple rhythms. As these do not occur in the motor nerve, they must arise in or beneath the end plates. It has been suggested that these may be interpreted as ganglion cells, which are not normally automatic, but may be sensitized by veratrine (Eichler, 1938). High concentrations of veratrine paralyze all forms of muscle completely (Köllicker, 1856).

The Contracture Is Active.—The muscle is able to sustain a considerable weight throughout its contraction; the prolongation of the curve is therefore not due to a mere loss of elasticity, but is an active process. This is also shown by the facts that the formation of heat and the use of material are increased (Fick and Boehm). The energy efficiency is of the same order as in normal tetanus (Hartree and Hill, 1922), and the formation of lactic acid, and its prevention by iodoacetic acid, the splitting of phosphogen and the production of ammonia are as in ordinary muscular contraction (review, Bremer, 1932). The tension, the height and quickness of contraction, the irritability, the lifting and sustaining power of the muscle are all raised by veratrine (Dreser, 1890). It also lessens the effects of fatigue.

Influence of Conditions.—The effect of veratrine is enhanced by agencies which stimulate the muscle, such as moderate heat. The contracture is diminished by depression of the muscle produced by cold or excessive heat; by fatigue; or by muscular depressants, such as potassium, quinine or ether. Small doses of calcium increase the contracture, high doses remove it (Milheiro, 1926). Bacq, 1939, found that veratrine sensitizes striped and smooth muscle to the effects of K, Na, Rb, Cs, NH_4, and Ba, and believes that most of the effects of veratrine can be interpreted as sensitization to potassium. Dilutions of veratrine down to 1:10,000,000 cause frog's skeletal muscle to be contracted by dilutions of KCl which are ordinarily ineffective, so that veratrine may be used as a biological reagent for potassium ions. Aconitine and delphinine produce a similar sensitization.

Double-Peak Curve.—Veratrine curves generally show two imperfectly fused contractions (v. Bezold): a primary contraction, which occurs with the normal rapidity, but is somewhat higher than normal, and which tends to relax quickly; and a secondary contraction, which occurs more slowly and lasts longer. Overend, 1889, attributed this phenomenon to the different contraction velocity of the white and red muscle fibers, but Cervello and Weiss, 1899, showed that uniform muscles exhibit the same phenomenon. Riesser, 1921, found material differences in the response of the slow red and rapid white muscles of the rabbit, but this does not explain the double-peak phenomenon. Verzàr and Felter, 1914, attributed the action to increased sensitiveness to normal stimuli.

Veratrine acts directly on the muscle substance, for the effects occur after curare (Prevost, 1867), and in the nerve-free end of the sartorius muscle. Pretreatment with acetylcholine, physostigmine or neostigmine also does not alter the typical effects; nicotine enhances it (E. Frey and Weigmann, 1943). However, *veratrine produces analogous changes in the innervation.* If a portion of the motor nerve of a toad muscle is exposed to veratrine, a single shock applied to the nerve results in prolonged tetanic contraction, the after-discharge lasting from less than a second to a full minute (T. P. Feng, 1941). Querido, 1926, reported that the veratrine reaction diminishes with the *degeneration of the divided sciatic nerve,* until with complete nerve degeneration, direct stimulation of the muscle gives only a single twitch. In the *cat,* also, a single shock stimulation of a motor nerve after intra-arterial injection of veratrine, barium or guanidine causes prolonged repetitive discharges which are not affected by curare (Feng and Li, 1941; Acheson and Rosenblueth, 1941).

Other Substances Producing Veratrine Effects.—The prolonged contracture characteristic of veratrine, is by no means confined to this alkaloid, but is also produced by digitalin, helleborein, muscarine, strychnine, by aldehydes (Verzàr and Felter, 1915), and the like, by cold and by strong electric stimulation (Kruse, 1922). This *wide occurrence* signifies that the phenomenon is of fundamental physiologic importance. These measures also prolong the contraction of *cardiac and smooth muscles.*

The Action of Glycerin on Muscle.—The muscles of frogs poisoned with glycerin respond to single stimuli by prolonged contraction, the curve having a superficial resemblance to that of veratrine, but rather more irregular. The glycerin contraction, however, is a true tetanus, due to greater irritability of the muscle substance, the action current of each contraction sufficing to start another contraction. The phenomena occur also after curarization (Santesson, 1903).

Circulation.—The effects are complex. Those on excised hearts resemble those of aconite and digitalis (slowing with increased systole). In intact animals, stimulation of the vagus center predominates at first (marked slowing); later, the fall of pressure from vasomotor depression becomes prominent. Both actions are cardiovascular reflexes, probably arising from the ventricular region of the heart, with their afferent path in the vagus (Jarisch and Richter, 1939).

Mammalian Circulation.—Small doses sometimes cause primary quickening of the heart. With larger doses (0.025–0.05 mg. per Kg.) there is sudden and marked slowing with corresponding fall of blood pressure (Pilcher and Sollmann, 1915). The slowing is greatest soon after the injection, often with marked arrhythmia or temporary arrest. This acute effect is due to reflex stimulation of the vagus center; section of the vagi largely abolishes it, and stimulation of the vagus trunk does not produce further slowing (Busquet, 1907). With divided vagi, large doses may cause primary quickening and generally moderate rise of blood pressure. Cross circulation experiments also show that the veratridine slowing is partly due to reflexes from the heart, lungs and carotid sinus, partly to direct stimulation of the central nervous system (Krayer *et al.*, 1943). The fall of blood pressure is mainly due to the slowing, although some fall may occur independently (Lissauer). The vasomoter center is moderately stimulated by the respiratory embarrassment, even when the vagi are cut. The stimulation does not occur if artificial respiration is maintained (Pilcher and Sollmann, 1915).

Late Effects.—The acute effect soon passes off. The heart then beats with a steady, moderately slowed rate. This slowing is not removed by atropine and is therefore cardiac. The blood pressure falls progressively, occasionally interrupted by spasmodic rise from central vasomotor stimulation. The strength of the heart is not impaired, for it reacts well to compression of the aorta, and beats efficiently just before death. The fall must therefore be vasomotor; accordingly, sciatic stimulation or asphyxia fails to raise the pressure (Lissauer, 1887). The vagus remains excitable. The cerebral vessels are constricted (Dixon and Halliburton, 1910).

In *heart-lung preparations* (dogs), nontoxic doses of veratrine act chiefly on the cardiac muscle, increasing the total output and work (Krayer and Mendez, 1942).

The perfused mammalian heart (Hedbom-Langendorff) shows primary slowing from stimulation of the peripheral vagus mechanism; then irregularity and finally paralysis of the cardiac muscle. The tonus is increased.

Frog's Heart.—The effects resemble those of aconite and digitalis. They involve mainly the ventricle and consist in slowing (no further slowing on vagus stimulation; Busquet, 1907); prolonged systole and increased tonus; sudden change in the rate to one-half; "peristaltic" contractions; and final median standstill. High concentrations cause prompt systolic standstill, with continued shortening. The auricles continue much longer. The same effects occur on the excised and perfused heart (Boehm, 1913). The response to vagus stimulation is abolished (La Grutta, 1928). De Boer, 1917, attributed the slowing and halved rhythm to increase of the refractory period of the ventricle. If the rhythmic pulsations of the heart are suppressed by vagus stimulation, and the muscle is stimulated mechanically, veratrine prolongs the contracture, as in skeletal muscle (Querido, 1926).

Peripheral Action on Blood Vessels.—Veratrine produces powerful constriction, which may be removed by atropine or quinine. These antagonists do not prevent contracture by barium (Kondo, 1919).

Collapse Action.—The impairment of circulation, combined with emetic action, results in varying degrees of collapse, and thereby fall of temperature, analogous to veratrum.

The **respiration** is influenced by the circulatory and convulsive actions, and also directly. It is temporarily arrested during the acute fall of blood pressure, but may be depressed without any change of blood pressure. The respiratory embarrassment is generally diminished by atropine or division of the vagi (Pilcher and Sollmann, 1915). *Bronchial muscles* constrict in intact animals (Dixon and Brodie), but not in the excised trachea (Trendelenburg, 1912). Titone, 1913, observed that veratrine relaxed isolated bronchial muscles.

Convulsions.—These are commonly present in mammals and frogs, and are probably medullary. Rabbits and guinea pigs show convulsive "bucking." *Cerebral functions* are scarcely affected.

Ureter.—Cevadine increases the tonus and contractions of excised ureter (Rossi, 1919).

Tissue Oxidation.—Cevadine inhibits the oxygen uptake of mammalian tissue, but accelerates it in yeast (Bernheim and Bernheim, 1933).

Local Action.—Cevadine is strongly irritant, resembling aconite. Applied to the skin, it produces burning, later a cold sensation and partial anesthesia, with reddening and sometimes discrete vesication. The irritation is especially strong on the abraded skin, 1:100,000 solution producing tingling and "shooting" pain (Sollmann and Pilcher, 1916). On mucous membranes it causes acute catarrh—sneezing, coryza, gastro-enteritis, vomiting, diarrhea, and so forth; sometimes with corrosive lesions. The *vomiting*, however, is mainly central (Eggleston and Hatcher, 1915). In frogs, the secretion of *mucus* from the skin is greatly increased.

Therapeutic Uses.—Veratrine is used locally as counterirritant, in neuralgias and similar conditions, as 2 to 4 per cent ointment. Sabadilla seeds are employed against pediculosis capitis (salve, 1:4; decoction, 5:200). The irritation is severe, and absorption has caused serious symptoms. The internal use of veratrine (against fever), even in milligram doses, has produced gastro-enteritis.

Absorption is rapid; little is known about the *excretion*, but it probably occurs by the kidneys.

Symptoms of poisoning in man resemble those of aconite poisoning: burning in mouth, spreading to stomach; increased salivation, vomiting, diarrhea, abdominal pain; anxiety, headache, giddiness; pupils dilated; pulse slow and feeble, later irregular; weakness, twitchings in muscles. Death by respiratory and circulatory collapse. Consciousness preserved till the end. Post mortem, often intestinal ecchymoses. In *nonfatal doses*, the symptoms are slow in disappearing, and *slow poisoning* by continued small doses is on record: two patients became weak and thin, suffered from bloody diarrhea, insomnia, disturbance of the intellect, and delirium. The *treatment* is the same as in aconite poisoning. As the veratrine is believed to be rapidly excreted through the urine, it is well to administer hot tea as a diuretic.

Assay.—The gastrocnemius of frog, or leech muscle, may be used, with observations of details to differentiate it from aconitine, colchicine and quinine (Hummelsheim, 1933).

Veratrine is a mixture of alkaloids obtained from the seeds of Asagraea officinalis. Very slightly sol. in water (1:1760); freely sol. in alc. (1:2.8). Its internal use is not advisable, but it has been given in doses of 2 mg. Externally, it is applied as ointments of 2 to 4 per cent. *Maximum dose*, 5 mg.

Zygadenus (Death Camas), Liliaceae, a poisonous plant of western stock ranges, owes its toxicity to veratrine bases. It contains at least sabadine, sabadinine and veratralbine (Slade, 1905). The actions of the Zygadenus alkaloids were studied by Mitchell and Smith, 1911. The literature is given by Marsh and Clawson, 1915.

Andromedotoxin is a N-free neutral principle, isolated by Plugge from *rhododendron* and similar plants. It seems to belong to this group. Species of rhododendron have been used as medicine by the Chinese. Their actions have been investigated by H. P. Chu and How, 1931.

Kalmia, Mountain Laurel and Sheep Laurel are important as stock poisons (Crawford, 1908). Kalmia angustifolia was studied by Waud, 1940. It prolongs the contraction of skeletal muscle, slows the frog heart (not prevented by atropine), constricts bronchial muscle (relaxed by epinephrine, not by nitrite), stimulates the movements of small intestine (not antagonized by epinephrine), and has no effect on the uterus.

◆

VERATRUM

Vera'trum Viride and Album (Green and White Hellebore) seem to be mere varieties (the green American, the white European), with practically identical actions and composition. They owe their activity mainly to the alkaloid *protoveratrine*. A number of other related but less active alkaloids are present (Cramer, 1915). The effects of protoveratrine, and therefore of veratrum, are qualitatively similar to those of cevadine, but the characteristic muscular and irritant actions of cevadine are insignificant in protoveratrine. The most important effects of veratrum are on the medulla, and especially on the circulation, resulting in vagus stimulation, slowed pulse, fall of blood pressure, sweating, "collapse action," and reduction of temperature. It has been employed as a "cardiac depressant," especially in eclampsia, but it is obsolete. Protoveratrine is more toxic than cevadine, approaching aconitine; but the prompt evacuation of overdoses by emesis (central) renders veratrum relatively safe.

Constituents.—The most important alkaloid of Veratrum album, although not the most abundant (0.03 to 0.08 per cent), is *Protoveratrine* (Salzberger, 1890). The other alkaloids are: *Jervine*, 0.1 per cent, weakly active; traces of *Rubijervine* (almost inactive); the inactive *pseudojervine* or protoveratridine, which is probably a decomposition product; the glucoside veratramine; and veratroidine and veratrabline, which are probably mixtures of amorphous bases. Traces of cevadine have been reported in V. viride, but are doubtful.

Black Hellebore, Helleborus niger, is in no way related to veratrum. Its active principle, helleborein, belongs to the digitalis group.

Experimental Effects on Respiration and Circulation.—The typical effects of intravenous injection of Veratrum Viride consist in brief but marked depression of the respiration, slowing of the pulse, and lowering of blood pressure. These effects are largely prevented by section of the vagi, and do not recur if further doses of the Veratrum are injected. Repeated injections generally produce marked rise of blood pressure, especially if the vagi are intact. The effects are probably due to protoveratrine (H. C. Wood, Jr., 1906; Cramer, 1915; Pilcher and Sollmann, 1915).

Sensory Actions.—Dried Veratrum or protoveratrine is irritant, provoking sneezing, and other effects, but in solutions the irritant effects are slight. These have a marked anesthetic action, lasting forty-eight hours, on the cornea (Eden).

General Symptoms in Mammals.—The first effects are nauseant and emetic, often so severe as to obscure other symptoms. Of these, the respiratory changes are characteristic, especially in rabbits. They consist in periodic dyspneic attacks, culminating in convulsions of a medullary type. The respiratory disturbance is probably due to the combined influence on the respiratory and other medullary centers, circulatory changes and muscular exhaustion. In the intervals the respiration is regular. *Death* occurs late, with the circulation fairly preserved and consciousness present to the end (Eden).

Collapse Action.—The combination of the central, circulatory and muscular depression, nausea and dyspnea, results more or less in collapse. This and the profuse sweating lower the *temperature*, proportional to the general symptoms (Eden).

Effects of Therapeutic Doses on Man.—Full doses constantly produce a slowing of the pulse to about 62 per minute (irrespective of the original rate), and generally a fall of systolic and diastolic blood pressure of about 35 mm. The slowing and fall are proportional to the dose. Electrocardiograms show no effect (Collins and Hanzlik, 1918). The blood flow in the arm is markedly lowered by therapeutic doses (Hewlett, 1917). Respiration is not disturbed. Headache, gastric burning, nausea and vomiting may set in, but come after the depression of the circulation, and are therefore not its cause. The effects last for several hours. Large doses (4 cc. of 10 per cent tincturewithin half an hour) may produce more serious and lasting collapse, with a pulse rate of 40 or 30, suddenly returning to normal after eight or nine hours.

Veratrum Poisoning.—Although protoveratrine is highly toxic, veratrum is vomited so promptly that death is rare even with large doses (Wood). It has, however, been reported after 1 to 2 Gm. of the powdered White Hellebore (which is used as insect powder), and in enfeebled patients from a teaspoon of the Tincture. The *symptoms* are burning, vomiting and diarrhea, dysphagia, collapse, paralysis or light convulsions. For treatment, the stomach should be emptied by warm water or lavage, and the collapse treated along the usual lines.

Therapeutic Uses.—Veratrum is probably the most active and reliable *cardiac depressant,* and was formerly much used to slow and soften the pulse and lower the blood pressure, especially in eclampsia and other conditions of high blood pressure. F. E. Whitacre *et al.*, 1947, claim that it relaxes the angiospasm which appears to be a chief factor in eclampsia. Pesci, 1906, claimed that it lowers the blood pressure by 7 to 50 mm., slows the pulse, increases diuresis and lessens uremia. Haultain, 1914, made similar claims, but J. R. Willson, 1944, reports that the fall of blood pressure markedly diminishes the urine output and depresses urea clearance in hypertensive toxemias of pregnancy. H. Goldblatt *et al.*, 1942, found it of no value in experimental renal ischemia. It was used for the same purposes, and to lower the temperature, in the early stages of sthenic fevers (pneumonia) and other acute infections. The effects are probably mainly due to the cardiac slowing from vagus stimulation and to the nausea. Veratrum with other cardiac depressants has gone out of fashion. It is contraindicated in asthenic conditions (cardiac weakness, general debility, typhoid, and so forth.

Response in Pathologic Conditions.—Collins, 1916, observed the most marked effects in cases of hypertonus, the systolic pressure falling more than the diastolic. Little or no response was obtained in arteriosclerosis, paroxysmal tachycardia or heart block.

Administration.—Veratrum is given in repeated doses—1 cc., 15 minims, of the Tincture (N.F.) every half hour or hour, till the skin becomes moist, the pulse slower and slight nausea is present. It may then be stopped. The desirable range is 3 to 4 cc. (Collins and Hanzlik, 1918). Caution is necessary if a total of 4 cc. is exceeded. If vomiting should appear before the other effects, 5 to 10 drops of Tr. Opii are administered with each dose of Veratrum. Repetition of the dosage does not inhibit the action (as occurs with intravenous injections in animals).

Bio-Assay.—Commercial preparations vary considerably in activity. As the drug contains a number of active principles, its efficiency cannot be estimated by alkaloidal assay. The determination of the minimum fatal dose for frogs or guinea pigs is a convenient method. It averages about 2.3 mg. of drug per Gm. of frog, and 0.24 mg. per Gm. of guinea pig (Pilcher, 1917). Rowe, 1925, proposed mice, as more rapid and accurate. The M.F.D. is ¼ mg. per Gm., intraperitoneally.

PROTOVERATRINE

The *actions* of protoveratrine and its derived alkaloids have been reinvestigated by Krayer *et al.*, 1944. The effects of protoveratrine, as described by Eden, 1892, are similar to those of veratrum. In mammals, moderate doses by vein produce temporary fall of pressure, absent if the vagi have been cut. This action is short, the pressure rising rather suddenly 40 to 50 mm. above normal, with increase of pulse rate, and inexcitability of the vagus. The rise is probably due to vagus paralysis. This is also of short duration. With repeated injections, the vagus paralysis becomes permanent, and the primary fall of pressure is absent, there being instead a small rise. *Toxic doses* produce cardiac arrhythmia, with periods of stoppage and corresponding changes of blood pressure. The rate in the intervals is at first rapid, then falls with the blood pressure. The vasomotor center becomes paralyzed.

Frog's Heart.—The effects are mainly depressant: the systoles are somewhat prolonged, but the tone is scarcely increased. Soon the ventricular rate is reduced to half, as with cevadine, aconite or digitalis; but this is interrupted by short periods of total arrest of the ventricle or auricles, apparently due to exhaustion of the muscle. Finally the heart stops in diastole, with relatively small doses (Boehm, 1913).

Motor System.—In frogs poisoned by protoveratrine, the reflexes disappear early. This paralysis is largely *central,* for it occurs also if the poison is excluded from the muscles by ligature. However, there are also *peripheral effects:* the muscles may respond normally to a single stimulus or contract even somewhat more quickly and efficiently; but they fatigue rapidly (Eden, 1892). The prolonged contraction characteristic of cevadine is indicated faintly, if at all, under ordinary conditions; but it may be elicited in excised muscles if precautions are taken against fatigue (Boehm, 1913). The nerve trunks are paralyzed only by concentrated solutions; the negative variation is said to be prolonged.

Jervine.—The effects also resemble those of veratrum, but the quantity of this alkaloid in the drug is too small to have any noticeable effect on circulation (Wood, Jr., 1906). With effective doses, the heart rate is first slowed, then rapid. The blood pressure falls progressively, presumably by depression of the cardiac muscle and vasomotor center. The respiration fails simultaneously (Wood, 1874).

Rubijervine.—Wood, 1874, found that "veratroidine," which was probably an impure rubijervine, acted mainly on the respiratory center, with some cardiac depression. Its quantity is also too small to be important.

Veratrum Viride, N.F. (Green or American Hellebore), is the dried rhizome and roots of Veratrum Viride. The dose of the 10 per cent *Tincture* is 1 cc., 15 minims. Till 1900 the Tincture was 40 per cent. Norwood's Tincture was supposed to be a saturated solution of the fresh root. *Veratrum Album* (White Hellebore) is probably a mere variety of the former, growing in Europe. It is used in the same doses.

◆

APOMORPHINE

Apomorphine is an artificial alkaloid, formed by dehydrating morphine through concentrated mineral acids. The removal of the molecule of water is the result of vigorous reactions that profoundly affect the structure (Pschorr). The actions of the base that is formed differ radically from those of morphine. It does not cause narcosis; its chief effect is emesis, by direct stimulation of the vomiting center, with prolonged and severe nausea which may result in collapse. Small doses are sedative and hypnotic; larger doses cause excitement, convulsions and death by asphyxia. It produces direct depression of excised cardiac and skeletal muscle. Apomorphine is the preeminent centrally acting emetic, especially useful for hypodermic administration in poisoning. The prolonged nausea is disagreeable, and the depression may be dangerous.

Absorption.—Apomorphine is readily absorbed from all mucous membranes. Emesis is produced by applying a few milligrams to the conjunctiva of a dog; also from application to the urethra, vagina, and the like (Macht, 1917).

Fate.—The greater part appears to be destroyed. None is converted into morphine (Bamford, 1930).

The Emetic Action of Apomorphine Is Central.—The specific emetic action of apomorphine was announced by Gee, 1869, the year of the discovery of the substance by Matthieson and Wright. The emesis is promptly produced by small doses, with little preliminary nausea. The fact that there is no evidence of gastric irritation (Gee, 1869), and that apomorphine is more effective hypodermically than by mouth (Siebert, 1871), indicates that its emetic action is not a reflex from irritation of the pharyngeal or gastric mucosa, as is the action of most emetics; but that the apomorphine emesis must result from a central action, a direct stimulation of the hypothetical vomiting center in the medulla. The crucial proof was brought by Eggleston and Hatcher, 1912, who found that the typical phenomena associated with vomiting can be produced by the injection of apomorphine into animals whose entire alimentary canal had been removed, from the cardia to the anus. These eviscerated animals show the retching, the vomiting movements and the expulsion of mucus from the mouth and esophagus. Direct application of the apomorphine to the esophagus or pharynx does not produce vomiting. Emesis occurs if a small quantity of apomorphine (0.0001 mg. per Kg.) is applied directly to the floor of the fourth ventricle, in the region of the vomiting center (Thumas, 1891). Most other emetics also produce vomiting when applied to this region, and so do strychnine, histamine, choline and epinephrine (Weiss and Hatcher, 1923). This response does not occur if the sensory nuclei of the vagus have been destroyed. Hatcher and Weiss, 1923, believe that apomorphine and presumably the other emetics merely lower the threshold of the center to reflexes ordinarily not emetic.

Siebert, 1871, gave emetic doses of apomorphine to dogs daily for six weeks, and found *no signs of inflammation* at autopsy. Eggleston and Hatcher found that dogs require by vein only 1/25 of the oral dose, and vomiting occurs in one-half the time. Only traces of apomorphine are excreted into the stomach, even after enormous hypodermic doses (Bamford, 1930). With locally acting emetics vomiting does not occur *if both vagi are divided* (Openchowski, 1889), but this does not prevent apomorphine emesis (Siebert, Harnak and others). Magendie found apomorphine effective after replacing the stomach by a pig's bladder.

Antiemetic Drugs.—Apomorphine vomiting is not affected by local sedatives (bismuth and the like). but is prevented by narcotics. With chloroform and chloral, full narcotic doses are needed; but with morphine and its esters, small, non-narcotic doses suffice. Papaverine is ineffective (Ruth, 1913); also atropine. Calcium chloride. intravenously, inhibits the emesis for several hours, and also antagonizes apomorphine in some other directions (di Mattei, 1927).

The *movements of the stomach in emesis* were investigated in cats by the x-ray method (Cannon, 1898). The same events follow apomorphine and mustard; the first effect is total inhibition of the tone of the cardial portion, which becomes a flaccid bag. The pyloric end is shut off by a deep contraction ring. The contents are then expelled by sudden contraction of the diaphragm and abdominal muscles. As the expulsions are repeated, the gastric walls tighten around the remaining contents. Kratinoff and Sack, 1927, who observed the gastric movements under apomorphine in dogs with fistulae, and in decerebrate cats, reported that active gastric and intestinal movements precede the contractions of the abdominal muscles and diaphragm.

Susceptibility of Different Animals to Emetic Action.—Animals incapable of vomiting (rabbit, rat, guinea pig. horse, cattle, and so on) do not do so under apomorphine; but many animals which vomit more or less readily in response to local irritants are also completely insusceptible (pigs, birds, frog) or relatively insusceptible to apomorphine emesis (the cat requires about fifty times more per body weight, hypodermically, than the dog). Man and dog are the most susceptible. Continued administration does not establish tolerance (Siebert). Insusceptibility to the emetic actions does not imply tolerance of the other central actions of apomorphine, to which all animals are susceptible.

Recalcitrant Stage.—Excessive doses of apomorphine are not so effective as moderate doses in producing emesis, and may render the animal completely recalcitrant to the emetic action (Eggleston and Hatcher).

Clinical Dosage.—For emetic effect, 5 mg. (1/12 grain) or at most 10 mg. (1/6 grain) of the crystallized hydrochloride, in ½ to 1 cc. of water, should be given hypodermically, and repeated in fifteen minutes if necessary. As a nauseant expectorant, it is inferior to ipecac, but may be used by mouth, in syrup of citric acid, in doses of 2 to 10 mg. (1/30 to 1/6 grain) for adults; ½ to 2 mg. (1/120 to 1/30 grain) for children. This dosage does not cause depression. L. J. Needler, 1944, reports that 3 to 6 mg. injected hypodermically promptly arrest attacks of *paroxysmal tachycardia*, restoring the normal ryhthm during the nausea, with relaxation after emesis.

Onset and Duration of the Emetic Action.—In man, the hypodermic injection of 5 to 10 mg. (1/12 to 1/6 grain) of apomorphine produces severe nausea and vomiting within ten or fifteen minutes. By mouth, twice this dose is uncertain. The emesis may be repeated several times. The nausea is intense and is likely to persist longer than with the reflex emetics, since the apomorphine is not removed.

The **phenomena of nausea** are common to all emetics. They consist in a feeling of sickness, lassitude and weakness; pale skin; increased secretion of sweat, saliva, mucus and tears; sensation of excessive heat; increase of respiration and pulse rate; fall of blood pressure. *During the emesis proper*, the contraction of the abdomen raises the blood pressure spasmodically. This contraindicates emesis in apoplectic patients and the like.

Circulation and Respiration in Nausea and Vomiting.—Traube, 1867, described initial fall of pressure, with slow vagus pulse, succeeded by quickened pulse toward the end of the emetic action. Brooks and Luckhardt, 1915, and Miller, 1915, found emesis accompanied by marked disturbances of the circulation and respiration. There is sometimes a period of elevated pressure; but at the moment of emesis, the heart is usually inhibited, with sudden severe fall of blood pressure. This is interrupted by periods of great oscillations. These great and sudden changes may rupture blood vessels, which would resist more gradual changes of equal degree. *The changes are somewhat different in the two types of vomiting.* (1) Rapid projectile type, with short nausea: during the nausea, the blood pressure is slightly raised, the pulse rate increased, its amplitude diminished. During the vomiting, the pressure falls sharply with practically complete arrest of the heart, or arrhythmia. The respiration is suspended. After the expulsion, rapid recovery occurs to normal. (2) Slow, labored type, with more marked nausea, and so forth: during the nausea, there is deep breathing and salivation. During violent retching, the blood pressure and the intrathoracic pressure oscillate greatly. The pulse is slow and irregular. During the vomiting, the changes are as described. The slowing and fall of blood pressure are due to inhibiting vagus stimulation, since they are prevented by atropine. The oscillations are indirect results of the muscular efforts, and are generally eliminated by curare (Harnack, 1874). *The stimulation of the salivary centers* was studied by V. E. Henderson, 1910.

Accidents in the Therapeutic Use of Apomorphine.—Apomorphine nausea may produce considerable depression, varying in degree in different individuals. It is characterized by muscular debility, and rarely collapse (Harnack, 1908). These may precede or follow the emesis, and are especially liable to occur in the rare cases in which the emesis fails: in pulmonary and cardiac disease; in debilitated patients and in children. The collapse is preceded by irregular respiration, anxiety, vertigo and fainting. During the collapse, the patient may be unconscious and pass into early death. These cases are exceptional, but their possibility should be borne in mind. It is believed by some that the accidents are often due to impurities, so that only freshly made solutions of the crystallized alkaloid should be used, never of the amorphous.

Other Central Actions.—If apomorphine is given in larger doses it produces a series of *excitant effects*, especially in animals which do not vomit (Harnack, 1874). At first there is great restlessness, gnawing, excitement and terror. The gnawing is not seen with rabbits from which the hemispheres have been removed, so that it must be of cerebral origin (Morita, 1915). The respiration is quickened (even under chloral narcosis), but regular. Apomorphine disturbs *heat regulation*, so that animals do not respond to fever by polypnea and shivering (Magne, 1914). With doses larger than are used in man there are ataxia and then violent irregular *convulsions*. These interfere with respiration, and the animal dies in asphyxia. Death occurs also if the convulsions are suppressed by chloral, but then requires a dosage twenty times as high. Frogs exhibit the same phenomena. Hattori, 1910, found that the reflexes from the spinal cord and brain are increased. Apomorphine produces *hyperglycemia* in well fed rabbits (Campbell and Morgan, 1933). The effects on the *intestinal* movements and tonus are variable, in unanesthetized dogs with Thiry-Vella intestinal loops (Gruber, Haury and Drake, 1939).

Hypnotic Action of Apomorphine and Use in Acute Alcoholism and Hysteria.—Small, nonemetic doses (2 mg.) act as a safe and certain hypnotic, effective even in delirium; natural and refreshing sleep occurs usually in five to twenty-five minutes (J. C. Douglas, 1899; Coleman and Polk; 1902). Other observers (Rosebrugh, 1908) report similar results; the tendency, however, has been to use doses (5 mg.) which produce an emetic action. This perhaps aids the therapeutic effect by breaking into the fixed ideas of such patients. The sleep occurs in a few minutes after emesis. Hypodermic administration secures by far the best results.

Local Application.—Harnak, 1874, showed that this paralyzes *cardiac and skeletal muscles* in frogs. The depressant action on the rhythmicity of the heart was studied by Navratil, 1928.

***Apomorphine Hydrochloride, U.S.P.**, is prepared from morphine by the abstraction of one molecule of water. The official is a definite chemical substance with four benzene rings. The preparations of different manufacturers differ more or less in composition and activity (Harnak, 1909). Minute, white or grayish-white, glistening prisms; odorless; acquiring a greenish tint upon exposure to light and air. Must be rejected if it at once imparts an emerald-green color to 100 parts of distilled water. Sol. in water (1:50) and in alc. (1:50). Dose, expectorant, 1 to 2 mg., 1/64 to 1/32 grain; emetic, by hypodermic injection, 2 to 8 mg., 1/32 to 1/8 grain; maximum, 20 mg., 1/3 grain. *Apomorphine Hydrochloride Tablets*, U.S.P.; usual size, 5 mg.

Old solutions of apomorphine acquire a deep green color, indicating decomposition. The emetic action may not be affected by this change in some samples, but it is lost in others (Harnack, 1874).

Chloromorphids are formed in the manufacture of apomorphine if the action of the hydrochloric acid on the morphine is not carried sufficiently far. They are, therefore, a frequent contamination of commercial apomorphine. They are chemically analogous to acetylmorphine, being formed by the substitution of Cl for the OH group of morphine. Their pharmacologic actions are similar to those of acetyl-morphine (heroin), namely, exaggerated morphine effects, with greatly increased toxicity, paralysis of respiration, and an antiemetic action (Harnak and Hildebrandt, 1911). These investigators hold these impurities responsible for the failure of emesis and the collapse.

Apocodeine is derived from codeine. It is not a definite compound (as is apomorphine), but consists of mixtures, varying in composition according to the methods of manufacture (Small and Lutz, 1932). Different samples vary in potency, but their actions are similar (Krayer, 1926). Dixon, 1903, reported that it paralyzes successively the nerve endings of the vagus, vasomotors, other smooth muscle, striped muscle and cardiac accelerator, as well as the nerve centers, but its action does not seem to be absolutely specific. Magnus, 1905, found both stimulant and paralyzant peripheral effects on peristalsis. It has been used as expectorant, emetic, hypnotic and cathartic (Fraenkel).

ASPIDOSPERMA (QUEBRACHO)

The bark of Aspidosperma Quebracho-blanco contains several alkaloids with similar actions: fall of blood pressure, increased heart rate, clonic convulsions with muscular weakness, and a great and persistent increase of the rate and depth of respiration. The lungs are markedly hyperemic (Harnack and Hoffmann, 1884; Wood, 1910). These actions are partly central, partly peripheral. Wood, 1908, attributed the respiratory effect to intense irritation of local areas of the lung, which is observable at autopsy. The alkaloid quebrachine is mainly responsible for this effect. One of the alkaloids, aspidosamine, produces emesis; the others only nausea, with its usual accompaniments. Cow, 1914, found that larger doses paralyze the nerve cells of the autonomic system, brain and spinal cord. Still larger doses paralyze the vagus, sympathetic and motor endings, similarly to nicotine and curare. Death occurs by paralysis of the respiratory center when the motor nerves still respond to stimulation.

Hesse claimed to have isolated six alkaloids; but of these only two are well characterized, namely, aspidospermine and quebrachine, the latter *identical with yohimbine*. The others were probably impure mixtures and cleavage products (Ewins, 1914).

Aspidosperma has been used as a respiratory stimulant in dyspnea and asthma, but its usefulness is doubtful. Its irritant action on the lungs and the circulatory depression should be borne in mind. The dose of the fluidextract is 1 to 4 cc.; of the amorphous aspidospermine (a crude mixture), 0.06 to 0.1 Gm.; of the crystalline (true aspidospermine chloride), 5 to 30 mg., at first every hour or two, then less frequently (S. Solis-Cohen).

IPECACUANHA AND EMETINE

Ipecac, the root of a Brazilian plant, contains several alkaloids, of which two, emetine and cephaeline, produce local irritation and nausea and emesis, by central and local action. Large doses have specific effects against *amebic dysentery*. These will be discussed with other amebicides (see Index). The systemic actions (central and cardiac depression; stimulation and depression of smooth muscle) do not occur when the drug is administered by mouth, since little is absorbed.

The **nauseant and emetic actions** are produced much more slowly than with apomorphine. In man, vomiting occurs only after one-half to one hour. The drug is therefore more useful as a nauseant expectorant than as an emetic. *As expectorant*, the Syrup is employed (1 cc.). An infusion, used as a gargle, has been recommended to avoid irritation of the stomach. *For emesis*, the powdered ipecac may be administered, 0.5 to 2 Gm. in warm water, repeated in half an hour if necessary; or the Syrup (tablespoon for adults, teaspoon for infants, especially in spasmodic croup). It has some advantage over the mineral emetics in that it causes less gastric irritation and less general depression; but its use is practically restricted to the relief of spasmodic croup in pediatric practice, giving a teaspoonful of Syrup of Ipecac every ten to fifteen minutes till emesis occurs.

The location of the emetic action is chiefly central, for vomiting movements occur in eviscerated animals, and it is practically as effective by intravenous as by oral administration (Eggleston and Hatcher, 1915). The response on gastric injection is more prompt, suggesting that the local action facilitates the emetic response. Emetine and cephaeline act alike, except that cephaeline is twice as potent.

Emetine is partly *excreted* into the stomach (Valenti, 1911) and intestine (d'Ornella, 1873).

Irritant Action.—Ipecac irritates all mucous surfaces and may produce conjunctivitis, bronchitis, skin eruptions, asthma, diarrhea, rectal irritation, and so on. Some persons are extremely sensitive to these effects. On the abraded skin, 1 per cent solution of emetine raises a wheal (Sollmann and Pilcher, 1916). Hypersensitive patients also react with urticaria to systemic administration (Savignac and Alivasatos, 1919), or with eczema or asthma. Widal *et al.*, 1922, claimed that these can be desensitized. The *subcutaneous tissue* is but little subject to irritation by ipecac (Zepf, 1903), perhaps because the drug is too rapidly absorbed. Renal irritation occurs rarely.

Use in Dyspepsias.—The gastric hyperemia, produced by small doses, has been used in dyspepsias (a drop or two of the syrup in a teaspoon of water, every fifteen minutes). The benefits are doubtful.

Emetine in Pyorrhea Alveolaris.—The supposed causation of Rigg's disease by endamebae prompted the trial of emetine. Many observers reported good results, but neither these nor the etiology are beyond dispute (Price and Bensing, 1915). Smith and Barrett, and others, found Endamoeba gingivalis constantly present in the lesions, and introduced the local use of ipecac. Bass and Jones, 1915, were especially enthusiastic. They reported the amebae destroyed by hypodermic injections of emetine, 0.03 Gm. daily for three to six days.

Use in Other Parasitic Conditions.—Emetine is the drug of choice against certain *flukes* (Fasciola and Paragonium), 1 mg. per Kg. (to a maximum of 65 mg.), intramuscularly, once daily for a maximum of five days. It has been unsuccessful in syphilis, rabies, trypanosomiasis and bacillary dysentery. Marked improvement was reported for sprue by Schmitter, 1915.

Malignant Tumors.—It was reported that these may disappear after local injection of emetine. However, this is due merely to the caustic action (Lewisohn, 1918).

Systemic effects occur only after hypodermic or intravenous doses. They consist in acute fall of blood pressure, chiefly from cardiac depression, with ventricular fibrillation by large doses (emetine produces diastolic arrest of the isolated frog heart; Moulinier, 1914). Nontoxic intravenous injections lower the carotid pressure, but increase the pressure in the pulmonary artery and vein, and also the pulse rate. Larger doses dilate the pulmonary vessels, but generally less than the systemic vessels. The heart is also depressed. Hypodermic injection does not affect the circulation acutely (Plumier and Clermont, 1919). Most patients under emetine therapy show inversion of the T wave without clinical evidence of myocardial insufficiency (Cottrell and Hayward, 1945).

If the action of toxic doses has lasted any time, the autopsy shows marked *gastro-enteritis* with ecchymoses and even ulcers. There are also hemorrhages into the lymph glands, spleen and kidneys (Kilgore and Liu, 1917). Even fatal doses produce only slight degeneration of renal parenchyma (De la Paz and Montenegro, 1918).

Emetine has been tried in *tuberculous hemoptysis*, the reports being often favorable, but not very critical. The mechanism is not explained. Flandin, 1913, claimed immediate arrest after the hypodermic injection of 40 mg., without unpleasant symptoms. The injection may be repeated in intervals of twelve to twenty-four hours. Nicola, 1914, employing the same dosage as Flandin in hemoptysis, obtained variable results.

Smooth Muscle.—Pick and Wasicky, 1916, pointed out that emetine is related to papaverine in action as well as in chemical constitution. It paralyzes the smooth muscle of the digestive tract, bronchi, uterus and vessels (but small doses stimulate peristalsis). The depressant action is exerted directly on the muscle substance, emetine being mutually antagonistic with barium.

Uric acid excretion is increased by ipecac, as by other gastro-intestinal irritants (Abl, 1913).

Comparative Action of Emetine and Cephaeline.—Emetine is methylcephaeline (Carr and Pyman, 1913). Their actions agree qualitatively; but emetine is the stronger amebicide, while cephaeline is more irritant, more emetic (about twice, Eggleston and Hatcher, 1915) and about twice as toxic (Paul and Cowney, 1901). Emetine was said to be more depressing to the heart, and cephaeline is somewhat hemolytic.

Walters and Koch, 1917, tested *other cephaeline esters*. They found only quantitative differences. *Psychotrine*, the third alkaloid of ipecac, is also chemically related to cephaeline. It has a low toxicity (Walters and Koch). The amount in the drug is small and unimportant. Lloyd announced a colloidal alkaloid ("kryptonine") in ipecac. *Ipecacuanhin* is a crystalline glucosidal constituent (Finnemore and Braithwaite, 1912).

Ipecacuanhic Acid.—A further constituent, ipecacuanhic acid, was, until recently, considered a bearer of the action of ipecac in dysentery, but is inactive. It has the characters of caffeotannic acid (see Index), from which it differs only by one atom of oxygen. They differ from ordinary tannic acid, and are neither antiseptic nor astringent (Kimura, 1903).

PREPARATIONS.—*Ipecac*, U.S.P., is the dried rhizome and roots of Cephaëlis Ipecacuanha or acuminata, containing at least 2 per cent of alkaloids. Walters and Koch, 1917, found that both varieties contain about twice as much emetine as cephaeline. The drug was introduced into Europe about the end of the seventeenth century. It may be administered as the *Fluidextract*, U.S.P.; dose, as expectorant, 0.06 cc., 1 minim, or as emetic, 0.5 cc., 8 minims; or as the *Ipecac Syrup*, U.S.P., 7 per cent of Fluidextract; dose, as expectorant, 0.75 cc., 12 minims; as emetic, 8 cc., 2 drachms. ***Emetine Hydrochloride**, U.S.P., obtained from ipecac or by methylation of cephaeline; it is freely soluble in water or alcohol. Dose, daily, by parenteral injection, 30 to 60 mg., ½ to 1 grain. *Emetine Hydrochloride Injection*, U.S.P., in aqueous solution adjusted to *p*H 3.5; usual sizes of ampuls, 20, 30 and 60 mg. in 1 cc. Care must be used to keep it from contact with the eyes, as it is highly irritant. *Cephaeline* is administered in pills or as powder with sugar in a dose of 5 to 10 mg., 1/12 to 1/6 grain.

◆

THERAPEUTIC USE OF NAUSEANT EXPECTORANTS

Small doses of emetics increase bronchial and salivary secretion and sweat, which is useful in the early, congestive ("dry") stage of colds and in "dry" coughs. The dose should be sufficiently small to minimize general depression and noticeable gastric disturbance, although sometimes this cannot be avoided. The nauseants should be given every two to four hours. For the "abortion" of colds, ipecac is often employed in the form of "Dover's Powder," 0.5 Gm. at night. In the congestive stage, the syrup of ipecac may be used. *Tartar Emetic* may be substituted, but is more depressant, and its continued use may give rise to poisoning. Its expectorant dose is 5 mg. (1/12 grain). Viscid, adherent mucus may be thinned by *Ammonium Chloride* or *Carbonate* (0.2 Gm.), or *Potassium Iodide* (0.2 Gm.), or by the irritant saponin of *Syrup of Senega* (2 cc.).

The **reactions of the salivary center** were studied by V. E. Henderson, 1910. He found that it is readily depressed by *anesthetics* and by *morphine*, even in small doses. *Iodides* and other salts do not cause direct stimulation, but may act reflexly. *Emetine* stimulates both directly and reflexly, as do also *ammonium salts*, but with these the reflex stimulation is the more important. *Antimony* acts only reflexly, *apomorphine* only centrally.

Bronchial Secretion.—J. L. Miller, 1914, could not demonstrate any effect with therapeutic doses of emetine, ammonium chloride or carbonate. Large doses produced an increase, even when administered by duodenum.

◆

LOCALLY ACTING EMETICS

Numerous afferent paths may reflexly stimulate the vomiting centers, but for practical therapeutic purposes only those of the pharynx and gastric mucosa are available. Not every form of gastric irritation results in vomiting—the kind, rather than the degree, of irritation being important. This, and the necessity of avoiding severe local and systemic effects, limits the number of irritants which may be used as therapeutic emetics. However, there is still a wide choice, adapted to the various indications.

Cupric Sulfate and *Zinc Sulfate* act practically alike, provoking the vomiting reflex before there is time for other local irritant action. They are not absorbed (unless the stomach is corroded), and therefore do not lead to systemic effects. Vomiting occurs with certainty in a few minutes. The nausea is therefore short, and the after-depression is small, constituting an advantage over apomorphine. They are especially useful to empty the stomach of indigestible food or poisons (provided that these are not corrosive). Copper sulfate is of especial value in *phosphorus poisoning* if any of the poison is still in the stomach, since the metallic copper is precipitated and forms an impermeable coating over the unabsorbed phosphorus particles. The emetic dose of copper sulfate is 0.25 Gm. in 1 per cent solution; that of zinc sulfate is 1 to 2 Gm. They may be repeated in fifteen minutes if necessary. A teaspoonful of *powdered mustard* in a cup of warm (not hot) water, repeated every fifteen minutes, is a rather uncertain emetic, but a useful emergency remedy in poisoning, when the patient is already disposed to vomit. *Salt water*, or even plain warm water, or tickling of the fauces, may be similarly useful.

Antimony and potassium tartrate (tartar emetic) acts similarly to copper, mainly by a local effect, but its use should be avoided, since it is very depressing. It is fairly easily absorbed, so that 0.2 Gm. has repeatedly proved fatal. The ordinary emetic dose is 30 mg.; and if this is not effective in half an hour, it would be well to give tannin as an antidote. *Emesis as an undesirable side action* occurs with digitalis, squill, apocynum, salicylates, senega and a large number of other drugs. The action may be local or central, often both.

The **site of action of miscellaneous emetics** was investigated by Eggleston and Hatcher, 1915. A drug may be considered to act directly on the center if emesis occurs with smaller doses and more rapidly when the drug is given by vein than by mouth; and if the phenomena of nausea and the motions of emesis occur after the whole alimentary tract has been removed. According to these criteria, they found that the emetic action of most alkaloids is central; namely, apomorphine, morphine, nicotine, lobeline, aconitine, veratrine, pilocarpine, quinine and ergot; as also picrotoxin, digitalis and sodium salicylate. With ipecac, the local action probably contributes to the result.

Therapeutic Use of Emetics.—These are employed chiefly in acute poisoning, if gastric lavage is not practicable. They are not effective in profound narcosis by chloral or chloroform (Harnack, 1874), barbiturates or other hypnotics, morphine, bromide, and so forth. Apomorphine is quite effective in exposing shamming, but involves some risk. Emesis may also be used to empty the stomach in acute indigestion, especially from overeating.

Minor uses, mainly obsolete, are:

To remove solid bodies from esophagus, pharynx or upper air passages. However, according to de la Paz and Garcia, 1916, emesis does not dislodge solid bodies from the trachea or bronchi, but may drive them deeper. Plugs of mucus may be displaced by increased secretion of mucus. Emesis may cut short an attack of *asthma* (Hoover and Taylor, 1915).

To cause *compression of the liver*, for the removal of bile and small gallstones from the gallbladder and ducts. The usefulness of this measure is doubtful; since the intestines are also compressed, the force cannot be very effective, and on the other hand it might rupture a distended gallbladder.

Contraindications to Emetics.—These are mainly due to increase of pressure and to debility, and are as follows: (1) Severe *heart* *defects*, or *aneurysm* of the aorta, since the sudden and violent increase of intrathoracic and intra-abdominal pressure may result in the rupture of these organs. (2) *Atheroma.* The sudden changes in blood pressure are likely to burst a vessel and produce apoplexy. (3) Similarly, they may lead to hemorrhages in *phthisis*. (4) In *advanced pregnancy* abortion may result. (5) Tendency to *hernia*. (6) In all *debilitated conditions* there is danger of collapse. (7) *Caustic poisoning.*

◆

THE PHARMACOLOGY OF TEMPERATURE REGULATION

In warm-blooded animals, departures from the normal temperature disturb a variety of functions more or less profoundly and set off compensating reactions, partly directly and partly through heat-regulating centers of the midbrain, which tend automatically to restore the normal temperature. Heat production and heat dissipation both have a share in this regulation and balance each other. The automatic compensation or regulation is adequate under ordinary conditions and with normal animals, but it may become inadequate if any of the factors entering into it are powerfully altered, and the temperature may thus rise or fall. The changes usually involve several factors, at least secondarily, which vary with conditions. *Heat production* is largely incidental to the ordinary activities of the animal. Voluntary work or involuntary shivering is used in the regulation of temperature; but the regulation by changes in *heat dissipation* is more rapid and generally less disturbing, and is therefore principally utilized. Heat is lost mainly from the skin and respiratory tract, by radiation and conduction, and by the evaporation from the skin and from the pulmonary surface. The relative importance of these channels of heat loss differs in different animals and in the same individuals according to circumstances. In man, the skin is the chief means of regulating the heat loss. *In fever*, the heat regulation is adjusted to maintain abnormal temperatures, so that it appears as if the "pitch" of the centers could be altered by pathological conditions, just as the respiratory center may be narcotized to maintain a higher level of carbon dioxide; and the effects of pyretics and antipyretics have been attributed to lowered threshold and narcosis of the temperature centers. The actual phenomena, however, are more important than the hypotheses.

Direct Application to Heat Centers.—Heat regulation is markedly affected by the direct application of heat, cold or drugs to the region of the caudate nucleus. The temperature is thus *raised* by cold, corrosive poisons, caffeine or tetrahydronaphthylamine ("tetra"); it is *lowered* by heat, chloral, antipyrine or quinine applied to this region (Barbour and Wing, 1913; Prince and Hahn, 1918). Indeed, the drugs are more effective in this way than intravenously. *Direct heating and cooling of the center* have no influence on the febrile reaction to tetra, epinephrine or large doses of cocaine (sympathetic stimulants); but they modify toxin, salt and anaphylactic fever (Hashimoto, 1915). The antipyretic action of antipyrine and salicylate is markedly increased by heat, removed by cold. Heat is effective after quinine, cold is not. Morphine removes the response to both heat and cold.

Heat production may be *increased* by greater activity of the organs, especially by muscular work, or even by increased muscular "tone." The febrile increase of heat production is due partly to shivering, partly to increased activity of the glands, partly to glycogen mobilization by the liver. The "dynamic action" of proteins plays a minor part. Conversely, the production of heat may be *diminished* by reducing metabolism; by quieting the muscular movements with morphine; by lowering their tone with ether, or paralyzing them with curare; by starvation or by depriving an animal of its glycogen; and by reducing the circulation by vasomotor or cardiac depression (collapse), and so forth. The *importance of the chemic regulation* may be judged by the fact that animals become practically poikilothermal when they are paralyzed by curare (Pflueger, 1878) or by high section of the cord; that glycogen-free animals are not rendered febrile by "heat puncture," and the like. Heat may also be supplied directly by physical means, by conduction, radiation, diathermy and insolation.

Heat dissipation is controlled by three factors: (1) *Blood flow* to the skin, acting partly by favoring radiation, partly by increasing perspiration and therefore evaporation. (2) *Air currents*, especially rapid, shallow breathing, which favors evaporation. This is utilized especially by animals, whose fur interferes with evaporation from the skin. (3) The *water affinity of the blood* and eventually of the tissues. All three mechanisms appear to require the cooperation of the supramedullary (midbrain) centers for their adjustment.

The Role of Evaporation.—Water is vaporized from the lungs by the evaporation of the sweat and by direct evaporation from the cutaneous epithelium (Keeton, 1924). The volatilization of 1 cc. of water abstracts 0.6 calories from the body. In man at rest, evaporation accounts for only the smaller part (one-fourth) of the heat loss; but it is the most rapid method of heat regulation and plays the dominant share whenever *extra* heat loss is required; *i. e.*, in compensation against excessive heat production, or against external heat. It is of especial importance in the production and relief of fever.

The *vascularity of the skin* is especially important in man. It plays a conspicuous part in the protection against external heat or cold; against incidental overproduction of heat in muscular work; in the rise and decline of fever, the "chill" and the "crisis"; and in the action of most antipyretic drugs. The vascular reactions may be evoked by direct action on the vessels, by reflexes from the temperature sensations of the skin, and by temperature or other changes in the thermoregulating centers. The sensations that arise in the skin itself often seem the dominant element in evoking and intensifying the regulating mechanisms. The sensation of cold even when it originates in only a limited area of the skin produces general constriction of the cutaneous vessels, as well as shivering. The ischemia of the skin intensifies the sensation of cold and thus causes further constriction. A sensation of heat produces hyperemia of the skin (and diminished muscular tone). The hyperemia feels warm and so produces more hyperemia. The thermoregulating centers, however, appear to be necessary to accelerate or arrest the reaction at the proper level. *Diaphoresis* tends to parallel the vascularity of the skin; but it is also influenced by the central innervation of the sweat glands (and by autonomic poisons), and by the water affinity of the blood and tissues.

The *heat dissipating mechanism of fur-bearing animals* differs considerably from the human (Dill *et al.*, 1933), involving chiefly *polypnea*, panting, as the temperature rises. The degree depends upon the excitability of the thermoregulating center. Light panting increases the ventilation in cats and dogs six to seven times, and it may rise to twenty-seven times the normal. The CO_2 of the blood falls by 40 per cent in light panting, by 55 to 60 per cent in severe. The oxygen saturation is increased (Anrep and Hammouda, 1932). The carotid body takes a part in this regulation: increase of its temperature increases the respiration rate, cooling causes slowing (Bernthal and Weeks, 1939).

The Blood Concentration as a Factor in Temperature Regulation.—Changes of the water content of the blood affect heat loss in several directions. Concentration of the blood decreases its volume and increases its viscosity, and thereby diminishes the blood flow. It also increases the affinity of the colloids for the water, and thus decreases the rate of secretion of perspiration, and of evaporation. The importance of this factor has been emphasized especially by Barbour, who found a marked parallelism between the body temperature and the concentration of the blood (solids or hemoglobin); *i. e.*, the concentration of the blood rises and its water content diminishes, when the temperature is raised by infective fever, cocaine, "tetra," hay infusion or Shiga vaccine pyrexia, with the onset of the chill (Barbour, 1931). The concentration is restored, *i. e.*, lowered, by antipyretics (salicylates, quinine, antipyrine), which, in the absence of fever, have little effect on either the temperature or the blood concentration (Barbour and Herrmann, 1921). Dilution of the blood by the injection of saline (Barbour and Freedman, 1920) or by the administration of glucose (Barbour and Howard, 1920) also lowers febrile temperature, but does not affect normal temperature. Phlebotomy leads to dilution of the blood, and this may be an effective factor in the old treatment of fevers by bleeding. When it is attempted to change the body temperature by external heat or cold, animals protect themselves against the heat by dilution; against the cold by concentration of the blood (Barbour, 1924).

The *water lost from the blood* goes into the tissues, particularly the liver and subcutaneous tissue. The weight of the liver, for instance, increased 3½ per cent in the chill, and most of this was lost when the temperature was restored by antipyrine (Sherman and Barbour, 1935). With the passage of water into the liver, during the rise of temperature, the *liver glycogen* decreases, forming sugar, which helps to hold the water in the liver. This is largely prevented by denervating the liver (Barbour, 1931). In the dilution of the blood volume by antipyretics, this sugar passes into the blood. The shivering of the chill in the onset of fever increases the lactic acid of the muscles, and this draws water into them and accounts largely for their share in the blood concentration (Barbour and Gilman, 1934).

The Changes of Blood Concentration against External Temperature Require the Thermal Centers.—They do not occur if the animals have been rendered poikilothermal by operations on their central nervous system (Barbour and Tolstoi, 1924), and are abolished by ether narcosis (Barbour and Bourne, 1924). The regulation also fails if the external temperature exceeds a certain degree (for dogs, 42° C. in dry air; 33° C. in moist air). These extreme temperatures produce fever and therefore concentration of the blood and dehydration of the tissues (Lozinsky, 1924). The osmotic pressure response to cold is abolished by ergotoxine (Barbour and Gilman, 1934). *Cold applied to the brain base* causes blood concentration and liver hydration; heating of this region has the opposite effects. Heating and cooling the medulla produce the reverse changes (Barbour and Aydelette, 1933).

REACTIONS WHICH RAISE THE TEMPERATURE (PYRETICS)

Increase of heat production or diminution of heat loss tends to raise the temperature; but a significant rise of temperature, *i. e.*, fever, occurs only if the change exceeds the capacity of compensation, either because it is extraordinarily great or because it involves more than one factor or because the temperature-regulating centers do not function normally. This break in compensation may be caused by a number of agencies, acting through different mechanisms. The most important are the bacterial products of infectious fever. These disturb the heat-regulating centers, chiefly to diminish heat loss, but partly also to increase heat production. Injections of foreign protein, of milk or peptone act similarly. Sympathetic stimulants: Epinephrine, ephedrine, cocaine, tetrahydronaphthylamine and methylene blue increase heat production, but they act chiefly by decreasing heat loss, by decreasing the flow of the blood to the skin, and by increasing blood concentration (Barbour and Gilman, 1934). Dinitrophenol and its derivatives produce fever almost exclusively by increased heat production.

Resistance of Birds to Pyretic Agents.—The temperature regulation of birds differs materially from that of mammals, so that hens and pigeons do not develop fever by the administration of most of the agents that are pyretic in mammals (Barelli, 1932). Milk injection has no effect; tetrahydronaphthylamine actually lowers the temperature, averaging 3°, maximum 5.8°, and with high doses the fall persists for several days. Cocaine and caffeine also lower their temperature (J. Bill, 1936). The blood sugar rises as the temperature falls under tetra; also with morphine, barbiturate and urethane; but paraldehyde produces hypoglycemia (Allen and Brill, 1936).

Therapeutic Use of Hyperpyrexia.—Increase of the body temperature is injurious to some of the micro-organisms of infections; for instance, in the late forms of syphilis, especially neurosyphilis, which do not readily yield to chemo-therapy, but are markedly benefited by fever induced through inoculation with malaria (J. Wagner von Jauregg, 1918), or by hot packs or baths which raise the body temperature to 39–40.5° C., 102.2–104.9° F., for some six hours (Epstein and Cohen, 1935). Heat is also effective against experimental syphilitic infection of rabbits (Weichbrodt and Janice, 1919; Schamberg and Ryle, 1926). Hyperthermia has considerable success against gonococcal infections and various forms of rheumatism. It is not known how much of the effect is directly bactericidal, and how much indirectly.

Stimulation and Destruction of the Heat Regulating Centers.—The *"specific" heat production* (as distinguished from that incidental to physiological activity) is under the control of the central nervous system; the muscular tone, for instance, depends on the spinal cord. The rise of temperature produced by puncture of the corpora striata of rabbits ("heat puncture") is due to increased heat production (Richet, 1895), involving especially the hepatic glycogen, since it does not occur in glycogen-free animals (Rolly, 1903). Muscular heat production is not essential, for the temperature rises also in curarized animals (Hirsch and Mueller, 1903). Walbaum, 1913, however, contended that the chief factor is cutaneous vasoconstriction. When the temperature has risen, there is a partially compensating increase of heat loss. The regular course of the fever, which continues for several days, indicates a regulation, which balances the disturbed functions at the febrile level. This may be lowered artificially, by external cold or by antipyretics, but is promptly resumed when these cease to act (Schultze, 1899). High section of the spinal cord destroys heat regulation completely. Ablation of the cerebral hemispheres has little effect. Traumatic or electric irritation of various parts of the midbrain (particularly the corpus striatum, optic thalamus and the ponto-bulbar junction) produces a rise of temperature (Hale White, 1890); but F. Sachs and Green state that faradic stimulation of the caudate nucleus does not produce any temperature changes, in animals or human.

The Ponto-Bulbar "Center."—Tschedschichin, 1866, observed that the temperature rises when a section is made at the junction of the pons and medulla; the same result follows electric stimulation of this region (Heidenhain, 1870) and irritation of various other parts of the midbrain.

Chemical Changes and Adjustments in Hyperthermia by High External Temperature and Other Physical Hyperthermias.—In human subjects, the heat treatments cause loss of *body weight*, great increase of *fluid intake* and therefore little change in *urine volume*, but increase of the *urinary specific gravity* to 1030 to 1035, returning to 1015 to 1020 when the subject becomes accustomed and adjusted to the heat. *NaCl loss* by the sweat is increased, that by urine decreased; these also return toward normal with adjustment. When the adaptation is completed, the blood constituents are practically normal (Talbott, Edwards *et al.*, 1933; high environmental temperature). The prolonged polypnea causes low *CO_2 concentration* in the blood and alveolar air. The pH of the blood rises to 7.6, that of the urine to 8. The *urinary chloride* concentration becomes low. Free HCl disappears from the *gastric juice*. The *lactic acid* of the blood is high and large quantities are lost by the sweat. The *hemoglobin concentration* is increased, and the *oxygen* is more firmly held, so that its supply to the tissues is diminished (Fishberg *et al.*, 1936; short wave fever). The oxygen content of the venous blood is markedly increased in fever therapy (M. Adams and Boothby, 1936).

The **hyperpyrexia of infections** is central, essentially by diminished heat loss, through contraction of the cutaneous vessels (pallor), concentration of the blood, and arrest of perspiration. The heat production is generally increased, so that the basal metabolic rate, in high fever, may be 40 to 50 per cent above the normal, but this is not essential, and does not exceed the limits which are easily compensated in normal animals.

Altered reaction of the cutaneous vessels is characteristic of fever, suggesting disturbed innervation. They are more easily affected by chemical and mechanical irritation (Baeumler, 1873); they constrict more strongly in response to reflexes (Heidenhain); they are likely to undergo alternate contraction and dilatation, with little apparent cause; a slight degree of cooling produces chilliness, and so forth.

Total Nitrogen Excretion.—Increased nitrogen metabolism is a nearly constant feature of infective fevers, but does not run parallel; it may start before or after the rise, and it generally reaches its maximum after the fever has started to decline. It must therefore be an incidental, rather than an essential, feature of the process, and denotes increased tissue destruction, chiefly by the toxic effects of the infective agents. Simple overheating also increases the nitrogen excretion, but relatively much less than in fever.

Gastric Secretion in the Fever of Infectious Diseases.—The acidity, and its response to histamine, are diminished, parallel to the height of the fever. The volume and chloride suffer a smaller decrease (Chang, 1933).

Heat Regulation in Fever.—The febrile temperature generally runs a more or less regular course, implying control and adjustment to the altered conditions. Adventitious changes affect this adjustment, generally in the same direction as in normal animals, but in different degree.

Fever shows the normal daily variations, the rise during the day, and the fall during the night; although these variations may be smaller or larger than normal. Artificial cooling and heating and the administration of antipyretics provoke the same compensatory reactions as in health, though these are less effective. The febrile temperature can therefore be more easily lowered or raised, and the changes are more extensive and more lasting; but when left to itself, the temperature tends to assume its original febrile level. It might be said that the temperature of fever is adjusted to a higher level (Liebermeister).

Water Fever.—Distilled water is liable to become infected with pyrogenic micro-organisms, which produce fever on intravenous injection of solutions made with the infected water. Careful redistillation is needed to insure freedom from these agencies.

The *pyrogens* formed by various micro-organisms are toxic, nondialyzable substances. They do not contain nitrogen and are probably polysaccharides. They are relatively stable in boiling water, but are destroyed by hydrogen peroxide or potassium permanganate (D. H Campbell and Cherkin, 1945).

Yeast Fever.—Fever convenient for therapeutic studies may be produced in rats by hypodermic injection of a 15 per cent suspension of dried yeast, 10 cc. per Kg. of body weight. It reaches its peak of about 1.5° C. in about sixteen hours and persists more than twenty-four hours (P. K. Smith and Hambourger, 1935).

Foreign Protein Fevers.—The phenomena from the injection of milk, proteose, and the like, are similar to those of infectious fevers. *Irritants* may cause fever by the products of tissue decomposition.

Tetrahydrobetanaphthylamine produces central and peripheral sympathetic stimulation and causes a considerable rise of temperature, in which both increased heat (CO_2) production, chiefly by increased muscular movement, and diminished heat loss, chiefly by cutaneous vasoconstriction, appear essential. The action is not through the temperature centers, for it may be produced after these have been destroyed, and is not antagonized by the antipyretics which act on these centers (quinine, antipyrine, salicylates, small doses of morphine) (Feri, 1911), or by those which cause collapse (peptone, histamine, veratrine); but it is suppressed by dilating the cutaneous vessels by nitrites, chloral or barbital (Anan, 1927); or by producing complete muscular relaxation with chloralose (Regniers, 1928), curare, ether or heavy doses of morphine (Mutch and Pembrey, 1911).

The phenomena were extensively studied by R. Stern, 1889 and 1890; Hale White, 1892; S. Anan, 1927, and others. Waser, 1919, investigated its derivatives.

Dosage and Efficiency.—The subcutaneous injection of 0.04 to 0.05 Gm. raises the temperature of rabbits several degrees, the rise starting in an hour and persisting over four hours; but it fails completely in some animals. Dogs and cats react similarly. In man, nontoxic doses do not produce a rise. In guinea pigs it produces a fall of temperature (Glaubach and Pick).

Other Actions.—Aside from the rise of temperature, it produces dyspnea and restlessness, sometimes convulsions. It wakens even decerebrated animals from chloral sleep—while cocaine and caffeine have this effect only on normal animals (Morita, 1915). It also has important sympathomimetic actions (Jonescu, 1909): stimulation of the cervical sympathetic (mydriasis, exophthalmos); a general vasoconstriction involving both cutaneous and systemic vessels (rise of blood pressure), mainly of peripheral origin (Anan, 1927). It has a moderate peripheral dilator effect on bronchioles (Jackson, 1914). Hyperglycemia occurs only with doses that render the animal restless (Corral, 1918). Elliott, 1914, described the rapid production of gastric ulcers in rabbits from hypodermic injection. In dogs, gastric motility and secretion are depressed for a considerable time by pyrogenic substances in doses which do not raise the rectal temperature (H. Necheles, 1943).

Paranitrophenylethylamine produces prompt and marked hyperpyrexia, with a high degree of blood concentration (Barbour, 1934).

Cocaine hyperthermia is probably analogous to the tetrahydronaphthylamine fever, although some differences have been reported. Increased heat production by restlessness and convulsions may play a larger part (Richet and Langlois); but the loss of body fluid is more severe than in B. coli fever (H. G. Barbour, 1926), indicating greatly diminished heat loss. Cocaine fever may be prevented by curare or chloral, but not by the ordinary antipyretics (Mosso).

Methylene-blue hyperthermia is of short duration, the maximum being reached in an hour, and the return to normal in four hours. Quinine is markedly antipyretic, but antipyrine, amidopyrine, veratrine and chloral have little effect (K. Tokieda, 1927). In rats, the rise occurs only if the animals are placed in warm surroundings, 25° C. or higher (Gregoire, 1931).

Atropine hyperthermia may probably be attributed to the muscular excitement and to the suppression of sweat.

Caffeine Hyperthermia.—Large doses of caffeine produce a slight degree of fever (Binz, 1878; Pilcher, 1911). This could be explained by the increased muscular tone and by the dilatation of the intestinal and consequent constriction of the superficial vessels.

Convulsants.—All convulsant poisons (santonin, picrotoxin, strychnine) produce changes in heat regulation. Small doses cause increased heat loss and a slightly smaller heat production. Larger doses cause increased metabolism, through muscular action, and hence increased heat production, which is accompanied by a further increase of heat loss. Paralytic doses diminish the heat production greatly. The *temperature* is changed, accordingly: Small doses tend to lower it; moderate convulsive doses would increase it; paralytic doses lower it greatly. The heat loss is particularly conspicuous in small and young animals; larger animals tend to show a rise of temperature, with moderate doses (Harnack, 1901). In traumatic tetanus, thermic fever and the like, the temperature may rise greatly, usually when there is a general disturbance of heat regulation.

Dinitrophenol and Dinitrocresol.—Alpha 1, 2, 4 dinitrophenol and related nitro derivatives increase the oxidative metabolism and therefore the heat production chiefly by direct peripheral action. The increase may be pushed to twelve times the normal, in intact mammals, higher than with thyroxin. The larger doses raise the temperature to a dangerous or fatal degree. With therapeutic doses, compensatory heat loss by sweating and faster respiration prevents any temperature rise. The increased metabolism, even when double, involves primarily fat, and practically not the proteins or carbohydrates; nor are the protein metabolites materially altered. The fat is oxidized completely, without producing acidosis or ketones (Tainter, Cutting and Hines, 1935). This oxidation of fat has been utilized for the treatment of obesity, but the drug may cause side actions—frequently skin eruptions and neuritis; exceptionally cataract, neutropenia and liver and kidney damage. These are too serious to justify the use of the drug, although the dangers may be minimized by giving large amounts of water, by increasing the dosage only slowly to a moderate rate of weight loss, and by stopping at the first sign of ill effects. Patients with defective liver or kidney function should be excluded. Dinitrophenol is quite ineffective against thyroid deficiency, except as to metabolic rate. It should not be used for therapeutic production of hyperpyrexia.

Chemistry and Related Compounds.—Most of the investigations have been made with alphadinitrophenol 1, 2, 4. The 1, 3, 6, isomer also increases oxidation. The other four isomers slow oxidation and form methemoglobin (Magne, Mayer and Plantefol, 1932). Extensive comparisons with other derivatives were published by Heymans, 1934, and by Tainter and Cutting, 1933. The most powerful stimulator of cellular oxidation was dinitrocyclo-pentylphenol. This, and some of the others, also had a relatively lower toxicity than dinitrophenol and dinitronaphthol for the digestive tract, liver and kidneys. Clowes and Krahl, 1936, found that the nitro radical is not essential for the direct action on oxidation, for this is also produced by halogen-substituted phenols. However, the halogen compounds had no effect on temperature in intact animals.

Nitrophenols generally (but not orthonitrophenol) tend to be reduced in the organisms to aminophenols (E. Meyer, 1905).

Dinitro-orthocresol was advocated as a therapeutic substitute, especially in England (Dodds and Robertson, 1933). It is about five times as potent, and the dosage is correspondingly reduced (0.5 to 1 mg. per Kg. per day). It is open to the same objections, and has no apparent advantage. Acutely fatal doses of 3-5-dinitro-orthocreso produce increased respiration, hyperpyrexia and early respiratory and cardiac failure. Continued feeding does not materially modify growth or food consumption unless the dosage is fairly high (A. M. Ambrose, 1942).

Historical.—The hyperpyretic and toxic actions of dinitrophenol were described by Cazeneuve and Lepine, 1885. Its toxic hazards to munition workers during World War I prompted renewed investigations, including animal experiments by Magne, Mayer and Plantefol (published in 1931 and 1932). They demonstrated correctly the mechanism of the fever and also showed degenerative changes in the liver and kidneys. Meanwhile, Heymans and Bouckaert, 1928 and 1934, had likewise made extensive investigations, including related nitroderivatives. Tainter and Cutting, 1933, and their associates introduced their use against obesity.

Clinical Doses and Effects of Continued Administration.—The sodium salt of dinitrophenol is generally administered in capsules of 0.1 Gm., with meals, beginning with 0.1 Gm. per day during the first week, then 0.2 Gm. per day for several weeks, observing the response, and then increasing in steps of 0.1 Gm., until the dose is stabilized either by the symptoms of excessive heat and sweating, or by the weight loss (aiming generally at 2 or 3 pounds per week). The diet is limited as far as feasible (Bortz, 1934, recommends 700 to 1000 calories), but fluid is consumed liberally. The average of the treatments (Tainter, Stockton and Cutting, 1935) used 300 capsules of 0.1 Gm. during eighty-eight days, at the rate of 0.34 Gm. per day (the longest treatment was for a year, and 0.6 Gm. was the highest daily dose prescribed, and this for a short period only). The increase of metabolic rate varied rather widely for different patients, but was roughly parallel to the dose, averaging 11 per cent per 0.1 Gm. The treatment caused notable losses of weight in about 90 per cent of the patients, generally even when other methods had failed, and this without severe dietary restriction, and in most of the patients without undesirable symptoms. However, a not inconsiderable proportion show toxic effects, usually rather minor, but some serious. The Council on Pharmacy and Chemistry, 1935 (review and bibliography), warned against its uncontrolled administration.

Direct Increase of Tissue Oxidation.—The rise of temperature is chiefly secondary to the increased metabolism, for it is not prevented by extirpation of the heat-regulating centers (dinitronaphthol in pigeons; van Uytvanck, 1934), nor indeed by destruction of the brain or spinal cord, nor by curare (Tainter, Cutting *et al.*, 1933). Oxidation is increased in isolated cerebral cortex of rats (Fuhrman and Field, 1942). It is increased to three or five times in the arrested heart of turtles (Garrey and Boykin, 1935); in the perfused foot of the dog it may be increased more than three times. This may be inhibited by *cyanide;* methylene blue also increases markedly the oxygen consumption in the perfused foot, but cyanide is a less efficient antagonist (von Euler, 1932). Both agents therefore increase oxidation by direct action on the tissue cells (Heymans, 1932), although dinitrophenol, unlike methylene blue, is not a direct oxidant. In sea urchin eggs, cyanide antagonizes the depressant effect of dinitrocresol on oxidation, but the two are additive in suspending cell division (Clowes and Krahl, 1935). Dinitrophenol is not practically effective against cyanide poisoning in the higher animals (Tainter and Cutting, 1933); nor does cyanide antagonize the toxicity of dinitrophenol for animals, but rather adds to the fatality (van Uytvanck, 1931). Dinitrophenol also stimulates oxidation in *yeast cultures*, but higher concentrations inhibit (Field, Martin and Field, 1934).

Central Pyretic Action.—Although there is no doubt as to the direct, peripheral action of dinitrophenol on oxidation, there is also a central action in the same direction, probably on the midbrain and not on the ordinary thermoregulatory center, and this plays the chief role with the smaller therapeutic doses (3 mg. per Kg.) (Siedek, 1934), although with larger doses it is overshadowed by the peripheral action. In harmony with this, the increase of oxidation is potentiated by epinephrine (V. E. Hall and Chamberlin, 1937).

Relations to External and Internal Temperature.—Dinitrophenol (as also the related pyretic agents, tetrahydrobetanaphthylamine and methylene blue) are much more effective in raising the temperature if that of the surroundings is warm (22° C. or over). *If the external temperature is 16° C. or below*, they do not produce increased oxidation and pyrexia, in mammals or birds; on the contrary, they lower oxidation by greatly diminishing or abolishing shivering and eventually cause rapid cooling of the animal. They therefore disturb heat regulation in both directions, so as to exaggerate the detrimental effects of external temperature (Tainter, 1934; Riddle and Smith, 1935; Fuhrman and Field, 1942). External cold has been suggested as probably the most effective treatment of acute dinitrophenol poisoning; it may double the fatal dose (Tainter, 1934). In *hibernating animals*, these pyrogenic agents are more effective than after awakening, when the temperature has risen (Barelli, 1933).

Carbon Metabolism.—The increased oxidation involves both fats and carbohydrates, in the normal proportions (Hall, Fields *et al.*, 1933). Clinically, fat tends to furnish the larger share of the fuel (Tainter, Cutting *et al.*, 1935; decrease of the respiratory quotient). The nitrogen excretion is not increased.

Hyperglycemia.—Ordinary doses of dinitrophenol cause considerable increase of the blood sugar level, in normal subjects, or after injection of dextrose, but not in diabetes (Wishnofsky *et al.*, 1935). In dogs, it is reported to hasten the passage of injected dextrose out of the blood (Ashe, 1935). The lactate concentration of the blood and muscles also tends to rise, while the glycogen of the liver and muscles is markedly decreased (Magne, Mayer and Plantefol, 1933). The hyperglycemia is not due to asphyxia, for it occurs even when the oxygen content of the blood is normal (Hall, Brown and Sahyan, 1933).

Anoxia.—The increased demand for oxygen leads to faster and deeper respiration, and to increased blood flow; the latter has also been demonstrated in the clinical use (H. Freeman, 1934). Apparently it is due chiefly to muscular vasodilatation, and some increase of heart rate and rise of venous pressure, but with little change in arterial blood pressure (Stockton and Cutting, 1934). The oxygen in the venous blood falls, but that of the arterial blood remains fairly normal, and there is no acidosis so long as the respiration and circulation remain adequate. If the oxygen demands exceed compensation, anoxemia and acidosis develop, with cyanosis, piling up of lactic acid in the tissues, leading to early rigor mortis. The oxygen consumption and the respiration are decreased shortly before death. The high fever may culminate in heat rigor, first in the extremities, and finally in the respiratory muscles (Tainter, 1935; Hall, Field *et al.*, 1933).

Comparison with Thyroxin.—Both agents accelerate oxidation powerfully, at least in part by peripheral action, but dinitrophenol acts immediately, while the thyroxin action develops slowly. Dinitrophenol does not remove the phenomena of hypothyroidism other than the basal metabolism and lacks completely the other actions of thyroxin, the tachycardia and the sympathetic anxiety complex of thyroxin overdosage; and the acceleration of tadpole metamorphosis. Dinitrophenol also fails to change the cholesterol concentration of the blood, which on thyroid administration varies with the metabolic rate (Cutting, Rystand and Tainter, 1934). Dinitrophenol does not increase the basal metabolic rate of rats rendered hypothyroid by thiouracil, suggesting that the metabolic action of dinitrophenol requires thyroid hormone (S. B. Barker, 1946).

Acutely Toxic Effects.—Serious acute poisoning is rare and occurs only with gross overdosage (literature: MacBryde and Taussig, 1935). Anoxemic cyanosis and acidosis do not set in as long as the respiration and circulation remain adequate. They are more to be feared in hyperthyroid patients, in whom the increase of oxidation would be additive. Tainter, 1934, showed that dinitrophenol and thyroid administration both lower the resistance to diminished oxygen tension; and conversely, that oxygen inhalation decreases the toxicity of dinitrophenol. The chief danger in acute dinitrophenol poisoning is *excessive hyperpyrexia*, which may culminate in heat rigor, first in the extremities and finally in the respiratory muscles (Tainter, 1935; Hall, Field *et al.*, 1933). In acute overdosage, death generally occurs within twenty-four hours after onset of the symptoms. Postmortem examination has shown degenerative changes in the liver, kidneys and heart muscle.

The *treatment of acute poisoning* comprises gastric lavage with 5 per cent sodium bicarbonate, leaving a large volume of fluid in the stomach; copious intravenous dextrose; cold pack or tub; oxygen inhalation if cyanosed (Tainter). Antipyretics, chloral and barbiturates do not influence the toxic phenomena or the hyperthermia (Tscherkess *et al.*, 1935). Conversely, *dinitrophenol is not an effective antidote* to morphine, chloral, alcohol or barbiturates, although it may temporarily improve the respiration (Tainter and Cutting, 1933). It is not an effective antidote to alcohol (Newman and Tainter, 1936); nor is it effective against cyanide poisoning in the higher animals (Tainter and Cutting, 1933); nor does cyanide antagonize the toxicity of dinitrophenol for animals, but rather adds to the fatality (van Uytvanck, 1931).

Special contraindications to the employment of dinitrophenol are diabetes, and disturbances of the kidneys, liver and heart. Pancreatectomized dogs are hypersensitive to dinitrophenol and die before the usual febrile responses are fully developed. This may be counteracted by the administration of insulin. Dinitrophenol decreases but slightly the hyperglycemia of pancreatic deficiency, and its administration to diabetic patients would therefore be useless as well as dangerous (Tainter, Boyer and De Eds, 1933). Administration of thyroid with dinitrophenol increases the stimulation of metabolism and loss of weight, but the dangers are even greater (Glaubach and Pick, 1934). *Low-fat diet* renders mice more susceptible to the toxic effects of *dinitrotoluene* (Clayton and Baumann, 1944).

Fatal Dosage of Dinitrophenol for Animals.—The minimal fatal dose for 50 per cent of the animals ranges between 20 and 30 mg. per Kg., for various kinds of animals and methods of administration, and therefore presumably also for man; indeed, all the effects in man resemble closely those of equal doses (relative to body weight) in animals (Tainter and Cutting, 1933). The effects of continued feeding to rats of various concentrations are reported by Tainter, 1938.

Toxic Effects from Continued Administration.—Minor side actions, especially skin rashes, are rather common; severe reactions occur only in a small percentage of patients, but they are the more dangerous, because they are unpredictable and develop insidiously after ordinary therapeutic doses have been used for a short or long time without apparent harm. Because the action on metabolism does not increase with continued administration, the earlier users believed that there was practically no risk if a moderate dosage (0.3 Gm. per day) were not exceeded, and if the increase of metabolic rate was kept within reasonable bounds (less than 50 per cent, Dodds and Robertson); but of the patients who took 0.3 Gm. or more for at least six weeks, 23 per cent showed some undesirable effects, especially skin rashes (23 per cent; 2 severe) and peripheral neuritis (18 per cent) (Tainter, Stockton and Cutting, 1935). Such accidents, and the more serious cataract and neutropenia, continued to be reported in the course of ordinary practice; and although the causative relation is not always clear, it must be feared that any effective dosage may develop harmful consequences. The most common *skin reaction* is rather intense itching (with or without erythema) and urticarial or maculopapular eruptions. They generally subside in two to five days after withdrawal, and may or may not recur on resuming the drug. In two cases, there was severe dermatitis of allergic type (Tainter, Stockton and Cutting, 1935). One such case was shown to be allergic by the Prausnitz-Kuester passive transfer test (Frumess, 1934). There may also be swelling of *mucous membranes. Disturbances of smell and loss of taste*, especially for salt and sweet, are common. *Peripheral neuritis* involves especially the legs and feet. It comes on slowly, and clears up three weeks or longer after withdrawal, or may be quite persistent (Nadler, 1935). Long-continued use seems to lead in some cases to *cataract*, even in young individuals (W. W. Boardman, 1935). By 1942, cataract had been reported in 177 persons, often from the ordinary doses and without other untoward effects. The mechanism is not known (W. D. Horner, 1942). Several cases of *malignant neutropenia* have been reported, all from dosages within the supposedly safe limit. Prodromal symptoms of fever, sore throat and headache set in from ten days to four months after starting the drug, and proceed in one to eight days to pharyngitis, cyanosis, stupor, and sometimes death (S. W. Imerman and Imerman, 1936; Goldman and Haber, 1936). Cases of marked *cardiac disturbances* (arrhythmia, bradycardia, sinus rhythm) have been recorded (de Chatel and Motika, 1934). Functional changes in the *liver*, *heart* and *muscles*, and diminished dextrose tolerance, are claimed by MacBryde and Taussig, 1935, for a large proportion of patients who did not show evidence of special idiosyncrasy, but Tainter and Cutting, 1933, found no indication of liver or kidney injury by functional tests; and Schulte, 1937, also failed to find functional or anatomical evidence of liver injury, or opacities of the lens, in dogs that had received rather large doses for half a year. Warthin, 1918, had shown that dinitrophenol may produce toxic hepatitis and jaundice, similarly to picric acid and trinitrotoluol. Increased number of *stillbirths* and increased mortality of the young has been reported for rats receiving fairly large doses (Wulff, Emge and Bravo, 1935).

Cataract occurs routinely in young *chicks* when 0.25 per cent of dinitrophenol (not ortho or para mononitrophenol; W. C. Dietrich and Beutner, 1946) is added to their feed. Fine vacuoles appear in the anterior lens fibers in four to six hours. The posterior fibers show severe degeneration in three to five days (B. H. Robbins, 1944). Rats apparently do not develop *cataract* when large doses of dinitrophenol are fed from weaning till death, which occurred in thirteen months instead of twenty-four months in the controls. Nor did any other organ show histologic changes (Tainter, 1938); nor did cataract develop when vitamin A and riboflavin deficiency was superadded in rats, and ascorbic acid deficiency in guinea pig (Tainter and Borley, 1938); nor did dinitrophenol sensitize rats in any degree to lactose cataract (Borley and Tainter, 1938).

REACTIONS WHICH LOWER THE TEMPERATURE (ANTIPYRETICS)

The temperature may be lowered by anything which diminishes heat production or increases heat loss. As the temperature tends to fall below normal, compensatory reactions are set up, which ordinarily suffice to keep the temperature at the normal level. Indeed, it is difficult to depress the temperature materially below the normal, except by means which effect profound and extensive changes, such as deep narcosis, general vasomotor paralysis or other collapse conditions. It is relatively easy to lower an abnormally high temperature. Accordingly, the practical antipyretics become such only when the temperature is excessive. They have little influence on normal temperature, because their effects would evoke more powerful compensations and partly also because the primary effects themselves are less powerful when they must overcome a normal state, than when they are assisting an abnormal state to the normal. However, the increased response to antipyretics is not confined to high temperatures, but occurs also in infections when the temperature averages but little above normal, such as chronic tuberculosis, osteomyelitis and empyema (Barbour, 1919).

Action of Therapeutic Antipyretics.—The therapeutically available antipyretics act in several ways: The *application of cold* (baths, and the like) results in the direct abstraction of heat; the *chemical antipyretics, antipyrine, acetanilid, phenacetin, quinine, salicylates,* and so on, increase heat dissipation chiefly by mobilizing water, diluting the blood and thus promoting perspiration, aided by dilatation of the cutaneous vessels. Their action is mainly central. *Nitrites* dilate the skin vessels directly. *Aconite and veratrum* probably lessen heat production by slowing the circulation.

Drug changes of normal skin temperature reflect the vascular changes in the skin and are most marked in the extremities, especially the toes. Bierman, 1936, reported: *Marked increase*, by acetylsalicylic acid. *Increase*, by amyl nitrite, alcohol, thyroid administration. *Initial decrease followed by increase, at site of application,* by irritants (iodine and mustard). The increase may last five to ten hours. *Decrease* by pilocarpine (by evaporation of sweat), smoking, caffeine and coffee. Decaffeinated coffee had no effect.

Relation to Heat Centers.—All the antipyretics depress temperature effectively when applied directly to the caudate nuclei. When the central control is excluded, quinine is still antipyretic, while antipyrine and salicyl tend to raise the temperature (Isenschmidt, 1913; Barbour and Denning, 1913).

Therapeutic Use of Antipyretics.—The reduction of hyperpyrexia gives considerable symptomatic relief in fever and rests the patient. It is especially appreciated in the early stages, before adjustment has been reached. For this, it is not necessary to lower the temperature to the normal level, especially as large doses may cause dangerous collapse. Even partial reduction of the fever may be harmful if the febrile temperature is bacteriostatic. Large doses of antipyretics may also interfere with the production of various types of antibodies in animals (Inoye, 1933), but this has not been demonstrated for therapeutic doses.

◆

QUININE, OTHER CINCHONA ALKALOIDS AND OTHER ANTIMALARIAL DRUGS

The bark of the cinchona tree (Peruvian or Jesuits' bark or Cardinal's bark) has a selective effect on malaria, so that a single adequate dose suppresses the plasmodia in the blood. This action is due chiefly to the alkaloid quinine, but is shared more or less by other cinchona alkaloids, quinidine, cinchonine, cinchonidine, and the like, and by most of the numerous chemical derivatives of quinine, and also by certain benzene derivatives, notably quinacrine (atabrine) and pamaquine (plasmoquine), and to a minor degree by several miscellaneous drugs. Its mechanism is not established. Quinine is a general protoplasmic poison, toxic to all cells and to many unorganized ferments and to the brownian movement of colloids. It is especially toxic to ameboid cells, and relatively nontoxic to higher organisms. It is a fairly effective antipyretic, increasing heat loss by hydremia and by dilatation of the skin vessels. It is useful as an analgetic in colds, and in the form of quinine-urea hydrochloride as a local anesthetic. Through its bitterness, it acts as a stomachic tonic. It may stimulate the uterus. Full doses produce "cinchonism," characterized especially by auditory and visual disturbances, which may assume grave proportions with excessive doses. These also cause renal irritation. Very large quantities have sometimes been consumed without serious poisoning, chiefly because the absorption of the drug is limited. Hypersusceptibility and idiosyncrasies are common. Cinchona also contains considerable tannic acid.

Historical.—Until the middle of the seventeenth century, men were quite helpless against the malarial fevers which ravaged the marshy districts of the world. The tree which yields the quinine grew only in South America, and the Indians generally appear to have been ignorant of its effects against malaria. The several accounts of their original discovery are imaginary.

The first that is known of its therapeutic use is the successful treatment, by someone unknown, of a Spanish official at Loxa, Ecuador, Don Lopez de Canizares, in 1630. He suggested its use to the viceroy of Peru, whose wife, the Countess of Chinchon, was cured by it in 1638. (There seems to be some doubt of this account; A. W. Haggis, 1941.) By the next year, the drug was in use in Spain, and in 1640 it began to make its way through Europe. In 1670, large quantities were imported and distributed by the Jesuit fathers. Its use was opposed by many of the scholastically minded "regular" physicians, who considered it inconsistent with the tenets of Galen; but it received the support of the more enlightened, who gave it a practical trial, especially Sydenham, 1675; and of the "pseudo-medics," such as Robert Talbor, physician to Charles II, 1675, who gained fame and substance by exploiting cinchona as a secret remedy. The cinchona was administered as powder, decoction or extract. The discovery of alkaloids in opium by Sertuerner was promptly followed in 1820 by the isolation of quinine and cinchonine from cinchona, by Pelletier and Caventou. Pasteur in 1853 established the relations of the isomers quinine and quinidine, and of cinchonine and cinchonidine. The collection of the bark entails the destruction of the trees. As the use increased, the native trees of the Andes approached extinction, and attempts were made between 1850 and 1860 to establish cinchona plantations in other countries of suitable subtropical climate, especially in the highlands of Java, British India and Ceylon. The first attempts appeared unpromising, the barks being too poor in quinine; until a new variety, the ledgeriana, was raised from seeds collected in 1865, through Charles Ledger, in Bolivia. This proved especially rich in quinine, but was not sufficiently hardy until it was grafted on stocks of Cinchona succirubra. It has been further improved by selective breeding. The plantations of Ceylon and India have been largely abandoned (M. Kerbosh, Proc. Cinchona Anniversary, Mo. Bot. Garden, 1931; this volume also contains other historical papers on cinchona). The cinchona alkaloids remained the only effective means of treating malaria until 1926, when plasmoquine was introduced by Mühlens. This was followed in a few years by atabrine, an acridine derivative, which rivals or surpasses quinine in effectiveness. *The synthesis of quinine* was accomplished by Woodward and Doering, 1944. More than 14,000 synthetic substitutes were "screened" during World War II, and some give promise of being superior to quinacrine (review, E. K. Marshall, 1946).

The **constituents of cinchona** vary, especially quantitatively, in the numerous species and hybrids, and indeed in individual trees and in different parts of the same tree. The alkaloids are contained in the parenchymal cells in all parts of the plant, probably as cinchotannic glucosides. The bark is richest, especially that of the root. The quinine content of the dried bark may attain 13.5 per cent; commercial bark usually contains 4 to 5 per cent, with about $\frac{1}{2}$ per cent of cinchonidine, $\frac{1}{3}$ per cent of cinchonine, and $\frac{1}{6}$ per cent of quinidine. The mother liquor yields a brown extract, *quinoidine*, containing amorphous alkaloids, chiefly dicinchonicine and diquinidine. It is used as an accelerator in vulcanizing rubber. *Totaquine* is a mixture of alkaloid extract from South and Central American barks which do not contain sufficient quinine for effective manufacture. It is potent against malaria. Aside from alkaloids, cinchona extracts contain a tannin, *cinchotannic acid*, with a derivative, *cinchona red*, both glucosides; soluble organic acids (quinic, and so forth); gum, resin, and so on.

The chemical structure of the cinchona alkaloids is built on a uniform pattern, consisting of (1) a quinoline ring, united by (2) a CHOH (secondary alcohol group) to a (3) quinuclidine ring, "loipon," derived from piperidine. T. A. Henry, 1936, concluded that the plasmodicidal action resides in the quinoline nucleus, and that the remainder of the molecule only serves to introduce the quinoline into the plasmodium. Cinchonine may be considered the parent alkaloid. In the natural alkaloids, the hydrogen in the three position of the loipon is replaced by a vinyl group, which may be substituted by alkyls. The hydrogen in the six position of the quinoline may be replaced by hydroxyl or alkyl-oxyl. In quinine and quinidine, the quinoline bears a methoxy, and the loipon a vinyl group. Changes in these groups cause only rather minor quantitative alterations in the antimalarial efficiency; but this is likely to be destroyed completely by changes in the linking CHOH. The asymmetry of this carbon leads to optical isomers, such as (l) quinine and (d) quinidine; (l) cinchonidine and (d) cinchonine; or (l) ethyl hydrocupreine and (d) ethyl hydrocupreidine. Other isomers, namely, quinicine and cinchonicine, are formed by more drastic chemical rearrangement, involving the CHOH linkage, and, therefore, loss of antimalarial activity.

Colloids and Surface Phenomena.—Quinine, like saponin and proteins, tends to concentrate at the surface of solutions, to form rather rigid films (Ramsden, quoted from Bayliss). These interfere with the condensation of other substances at the surface, and therefore hinder catalytic phenomena, inorganic as well as organic. This may explain the decreased metabolism. The surface action is also shown by arrest of brownian movement; and there is a tendency to precipitate colloidal solutions, such as the proteins. Quinine may therefore produce anaphylactoid phenomena. The quinine film presumably diminishes the permeability of the cell. Quinine tends to arrest cell movements, for instance of the white blood cells, infusoria, cilia, spermatozoa, and others, presumably through the rigidity of its film. All these effects render quinine a "general protoplasmic poison," toxic to all kinds of cells; but its toxicity to vertebrates is relatively low, probably because it is largely bound and deposited in insoluble and harmless form.

Ferments.—Interference with ferment action may be seen in many directions, but is markedly selective (Rona and Reinecke, 1921). For instance, the lipases of the serum, pancreas and stomach are poisoned by quinine, but not those of the kidney and liver. The action is much greater in alkaline than in acid solution. The most important enzyme inhibitions are: the oxydases of blood and of protoplasm autolysis (Laqueur, 1906); slowed acidification of shed blood; lessening of the amount of hippuric acid formed when benzoic acid is circulated through the excised kidney. The various digestive ferments are hindered, but not to the same degree. It lessens the glycogenetic function of the liver; *i. e.*, the postmortem transformation of the glycogen into sugar (Hoffmann, 1877). In the therapeutic administration of quinine, the concentration does not rise sufficiently high to hinder the action of oxydase (Johannessohn, 1919). The effects on invertase and on *paramecia* were studied by Rona and Bloch, 1920.

Hemoglobin shows a characteristic change with strong quinine solutions (Marx, 1906). Neither acid hematin nor methemoglobin is formed; vuzin has a similar action (Bijlsma, 1920; Lewin, 1909).

Action on Leukocytes.—A solution of 0.5 to 1 in 1000 is sufficient to inhibit the movements of *leukocytes* on the warmed slide, and a somewhat larger dose causes their disintegration. Phagocytosis is hindered by 0.001 per cent (Hamburger and Hekma, 1908), but stimulated by low concentrations (Manwaring and Ruh, 1907). The depressant action is observed in *intact frogs* in a classic experiment of Binz, 1867. When the mesentery of this animal is exposed, leukocytes in active motion are seen inside and outside the vessel. If quinine is now applied, the movement of the cells outside the blood will be arrested, while those in the blood stream still emigrate. The result is an accumulation of cells about the vessel wall. If the quinine is injected into the vessel, the reverse takes place. The movement of the cells in the blood is arrested, preventing emigration, while those outside do not come into contact with the poison, continue to move away, and leave a clear zone about the vessel. This action does not occur in mammals, since the necessary dose would kill the animal. *In man and mammals,* it causes at first an increase of the lymphocytes, these being pressed into the circulation by the muscular contraction of the spleen and lymph glands. This is followed after an hour by a decrease, and this is again succeeded by rather marked leukocytosis. Continuous administration leads to leukopenia followed by leukocytosis (G. B. Roth, 1912; Johannessohn, 1919). The *opsonic index* is slightly increased in man by doses of 15 grains (T. B. Wilson, 1907).

Local Actions.—Quinine produces some local irritation and anesthesia. When given hypodermically it occasions severe pain, and may lead to *abscess formation.* When given by the stomach, large doses cause *gastralgia, nausea,* vomiting and diarrhea. It also retards the *absorption* of salts, and probably of food. Its excretion through the kidneys may give rise, with large doses, to *albuminuria and hemoglobinuria.* The hemoglobinuria of severe malaria (black-water fever) may be partly due to increased sensitiveness to quinine.

Ulcers.—The sulfate has been used as antiseptic, styptic and stimulant dusting powder on ulcers.

Sunburn Prophylaxis.—Quinine sulfate is protective through its fluorescence, which transforms the ultra-violet rays into longer non-erythemagenic radiations.

Quinine as Anesthetic.—Quinine and its derivatives, when brought in contact with sensory nerves, produce local anesthesia. This is used clinically in the form of the more soluble and less irritant double salts, especially quinine urea hydrochloride. The anesthesia is more lasting than with other local anesthetics; it may persist for several days (Hertzler *et al.*, 1909). It is indeed due to necrosis of the axis cylinders and sheaths

(R. Salm, 1940), with subsequent regeneration. Concentrations above ¼ per cent sometimes produce considerable irritation, edema and fibrous indurations, and above 1 per cent there may be sloughing. Its employment has therefore greatly diminished (E. Mayer *et al.*, 1920), although some clinicians consider these fears exaggerated (E. J. Brown, 1920).

Quinine-urea hydrochloride is injected hypodermically, generally as ¼ per cent, sometimes 1 to 3 per cent. Solutions of 10 to 20 per cent may be used on mucous membranes. Quinine bisulfate, 2 per cent, has also been used in tonsil and throat operations. Data on the *relative anesthetic efficiency* are given by Sollmann, 1918. The anesthetic effect of cinchona alkaloids for the *cornea* was investigated by Morgenroth and Ginsberg, 1912; literature, Bijlsma, 1920. The local anesthetic action of quinine derivatives is proportional to the protoplasmic toxicity (W. E. Dixon and Premankur, 1927).

Double Quinine Salts.—The increased solubility of quinine hydrochloride (3 parts) by antipyrine (2 parts) was announced by Triulzi, 1892, and Santesson, 1897. Gaglio, 1903, and Giemsa, 1908, advised the urethane compound as being less acid and less readily decomposed by boiling, than is the urea salt (Filippi, 1912). It is made with 1 Gm. of quinine hydrochloride, 0.5 Gm. of urethane, and 2 cc. of water.

Antiseptic Action.—Bacteria and yeasts are killed by quinine, but require a higher concentration (2 to 8:1000) than do the protozoa. The efficiency is not materially hindered by serum or pus (K. Taylor, 1915). It is especially potent against pneumococci *in vitro* (O. H. Brown, 1912; Cohen, Kolmer and Heist, 1917), but is surpassed by ethylhydrocupreine (*optochin*). Other hydrocupreine derivatives, eucupine and vuzin, are potent wound antiseptics.

Antiseptic Irrigations.—The following concentrations of quinine hydrochloride are usually employed: cystitis, 0.05 to 0.5 per cent; conjunctivitis, dysentery, 0.5 per cent, gonorrhea, to 5 per cent; hay fever, spray, 1 to 2 per cent.

Wound Infection by Gas Bacillus.—K. Taylor, 1915, recommended dressing with 0.1 per cent of the acid hydrochloride.

Pneumonia.—There is no evidence that quinine reduces the infection; but full antimalarial doses give considerable symptomatic relief (S. S. Cohen, 1911, 1913), presumably through antipyresis and analgesia. It was advised in *Asiatic cholera* (Fullerton, 1896; Ussher, 1906), where it might check the bacteria in the intestinal lumen; but it appears to have been abandoned. Its administration in *rabies* (Moon, 1913, 1915) is useless (Krumwiede and Mann, 1916; Fielder, 1914 and 1916).

Effect on Digestion.—Small doses of quinine (0.05 Gm., 1 grain), taken before meals, act as a stomachic and tonic, but they are probably inferior to other bitters. Larger doses diminish gastric secretion (Klocman, 1912) and interfere with the ferments and with absorption; even small doses when long continued lessen the utilization of food (but the intestinal *absorption of insulin* is increased by quinine; Hanzlik and Cutting, 1941; Driver and Murlin, 1941). Toxic doses stimulate the vomiting center (Eggleston and Hatcher, 1915). Comp. Tinct. Cinchona (5 cc., 1 ʒ) adds the stomachic effect of aromatics and alcohol, and the astringent action of tannin. It may be useful in chronic gastric catarrh.

Quinine on Normal Metabolism and Temperature Regulation.—These are but little affected by ordinary doses, equivalent to 2 Gm. in man. Larger doses lower the temperature, sometimes with a preliminary rise. With toxic doses, the fall is proportional to the collapse.

Heat production and CO_2 production with 20 mg. per Kg. may be slightly increased by restlessness, but this is compensated by increased heat loss; indeed, the latter tends to predominate. Doses above 60 mg. per Kg. lower the heat production, and increase the heat loss (Hardikar, 1925). The *blood sugar level* is lowered in the human, normal and diabetic, by intravenous injection of 0.5 Gm. (A. Loew and Pfeiler, 1927). The *nitrogen metabolism* is not definitely altered even by fairly toxic doses, in man or animals (B. Rosenthal and Lipschitz, 1926). Injections may produce a temporary increase, probably by the local injury. *In vitro or excised organs*, metabolic processes may be altered by quinine, but presumably the concentrations are much higher than those in the circulation. It depresses the *hippuric acid synthesis* in perfused organs, lessens the oxidation of excised muscle (Senta, 1908), and decreases the autolysis of liver pulp (as also eucupine; Rosenthal and Lipschitz, 1926).

Antipyretic Action.—The suppression of malarial fever by quinine is etiologic. However, quinine also reduces other febrile temperatures to normal, analogous to the other antipyretic drugs, *i. e.*, by adjustment of the temperature-regulating centers, primarily through increased heat loss, assisted somewhat by diminished heat production (Virchow, 1927). The increased heat loss is accomplished partly by cutaneous vasodilatation, but probably chiefly by lowering the excessive concentration of the blood, and this in turn by hyperglycemia (Barbour and Herrmann, 1920). The *clinical antipyretic dosage* is 0.3 to 1 Gm., 5 to 15 grains. Because of the cinchonism, and the occasional idiosyncrasies, its use is restricted largely to conditions in which the depressant action of the ordinary antipyretics is especially feared (influenzal pneumonia or cardiac decompensation), and to colds, in which small doses suffice. Like other antipyretics, it is more effective when the temperature tends naturally to fall; the slow absorption delays the response for an hour or two.

Older Views of Antipyretic Action.—It was formerly held that quinine acts radically different from the other antipyretics, almost exclusively by limitation of heat producton (Gottlieb, 1891), through direct decrease of protiin catabolism. This has been contradicted by all modern workers. It was based partly on data obtained by inadequate methods, partly on the unjustified transfer of highey artificial conditions.

Metabolism.—Gaseous metabolism is but little changed by quinine; there may be a small decrease or increase (Hardikar, 1925; Virchow, 1927). The nitrogen metabolism is also unchanged (Hardikar, 1924).

Efficiency Against Experimental Fevers.—Quinine prevents or reduces the hyperthermia of coli injection, and of heat puncture, but not of tetrahydronaphthylamine (Girndt, 1929). It lowers temperature, if the external temperature is high (Lewitzky, 1869), presumably by evaporation; and after high section of the spinal cord (Naunyn and Quincke, 1869), probably by collapse rather than by antipyresis.

Eucupine and *vuzin* are not antipyretic, but tend to raise the temperature by increased protein metabolism (Rosenthal and Lipschitz, 1926).

Use of Quinine in Colds, Headaches and Neuralgias.—Like other antipyretics, quinine has an analgetic effect in these conditions. It is used in doses of 0.05 to 0.2 Gm., 1 to 3 grains.

Administration of Small Doses.—Small doses of quinine sulfate or hydrochloride may be administered in the forms of pills or capsules; or in solution, the taste disguised by glycyrrhiza (no acid must be prescribed with the latter!). The free alkaloid is almost tasteless, and the tannate should be quite so, because of their slight solubility. Their absorption may not suffice for large, but is probably adequate for small, doses. They can be placed dry on the tongue and swallowed with a draught of water.

The *esters of quinine* with various acids are insoluble and therefore tasteless. They pass the stomach unchanged, but are slowly saponified in the intestines, in this way exhibiting a gradual and presumably weak action. They are more easily administered, and produce less side actions, but are not always devoid of cinchonism. They are used in the same doses as quinine, in powder or suspended in liquids. To this type belong *aristochine* (diquinine carbonic ester) and *euquinine* (quinine ethyl carbonic ester).

Central Actions.—The effects are not important, except with toxic doses. They consist in *slow general* paralysis probably preceded by stimulation, but the latter is difficult to make out in mammals. *Frogs* show increased reflex irritability, followed by loss of spontaneous movement, then paralysis of respiration, and lastly of the cord. The effect on spinal reflexes is discussed by Bijlsma, 1920. The depressing effects are much less marked in *mammals*, but *appreciation of pain* is distinctly diminished. Its addition to morphine or urethane does not increase their narcotic effect. *Mental efficiency tests*, in man, showed marked impairment after 1 Gm. of quinine (Muensterberg, 1892).

Respiration.—Therapeutic doses have no definite effect. Toxic doses stimulate the respiratory center. If the vagi are intact, the respiration becomes fast, but shallow and therefore inefficient. If the vagi are divided, the respiratory volume is increased to such an extent as rapidly to lower the alkali reserve of the blood to a fatal level (Sagata and Tatum, 1923).

Skeletal Muscle.—Quinine, quinidine, cinchonine and cinchonidine have similar actions: Dilute solutions cause direct depression with prolonged refractory phase (details under quinidine). Concentrated solutions produce rigor (literature, Bijlsma, 1920).

Small doses of quinine (5 to 40 mg. of the hydrochloride, intravenously, per Kg. in mammals) increase the tension response to single maximal stimuli, in normal, curarized and denervated muscle. Somewhat larger doses diminish the ability to maintain tetanus, by increasing the refractory period. The excitability of the motor end plates is lowered. Physostigmine and veratrine no longer give repetitive responses to a single stimulus. The response to acetylcholine is hindered or abolished (Oesterle and Maaske, 1939; A. M. Harvey, 1939; A. Ravin, 1940).

Quinine promptly suppresses the myotonus in congenital and atrophic *myotonia*, in torticollis, and in "night cramps" of the extremities; the effect usually lasts only so long as the quinine is being administered (0.2 to 0.5 Gm., by mouth, two or three times daily; A. Wolf, 1936; H. K. Moss and Herrmann, 1940). The result is attributed to the curare-like action (Harvey, 1939). The effect may be obtained within three minutes by intravenous injection. *In myasthenia gravis*, quinine increases the asthenic symptoms, sometimes to a dangerous degree. It may be useful for diagnosis of mild cases, in conjunction with the inverse effect of prostigmine (A. M. Harvey and Whitehill, 1937).

Circulation.—The actions of quinine, quinidine and cinchonine, and presumably of the other related alkaloids which have been less studied, are generally similar, but they differ in practical importance. Quinidine should be consulted for details of the cardiac actions used in the control of auricular fibrillation. With quinine, the circulatory effects are important as side actions of its clinical use in malaria; the vascular action and the antagonism with epinephrine may also be discussed in this place. *Moderate clinical doses* by mouth have little if any effect on the heart or blood pressure. Small doses may produce a temporary quickening of the pulse and rise of blood pressure (references, Bijlsma, 1920). Flushing of the skin and the tinnitus indicate some vasodilatation. *Larger doses*, from 1 Gm. up, in man, tend to lower the blood pressure and to depress the heart. The latter becomes marked with doses of 6 to 8 Gm. (Meldolesi, 1926). *Intravenous injections* cause sharp and often dangerous fall of blood pressure, clinically as well as experimentally, the degree and duration increasing with the rapidity of the injection, as well as with the dose (Bramachari, 1922). The fall of pressure involves *several mechanisms*, especially direct cardiac depression; diminished responsiveness of the vagus; direct depression of the vessels, especially in the skin and muscles; and with intravenous injections, presumably flocculation and shock.

The *prothrombin* level of the blood is lowered materially by therapeutic doses of quinine sulfate (0.33 Gm. daily for 6 to 16 days). This may be avoided by the concurrent administration of K vitamin (L. A. Pirk and Engelberg, 1945).

In dogs, intravenous injections of 10 cc. of 0.1 per cent solutions of *quinine, quinidine* or *hydroxyethylcupreine* have no appreciable effects on the heart rate and respiration. The fall of pressure is greater with quinidine than with quinine (Kruse, 1939).

Cardiac Depression.—This consists in diminished tonus, excitability and force, and in prolonged refractory period, with intact or perfused or atropinized heart (Hammet, 1927; see also quinidine). The heart is also rendered progressively irresponsive to vagus stimulation, electrically or by veratrine (Nelson, 1927). Very dilute solutions may stimulate the heart, especially with unfavorable ion mixtures in the perfusion fluid (W. Burridge, 1928).

Vascular Effects.—The flushing of the skin and ears which accompanies the fall of pressure indicates a specialized vasodilatation. Oncometric measurements on animals indicate that this is confined chiefly to the skin and limbs. The observation that the acute quinine fall is less if the aorta has been clamped at the bifurcation indicates that this vasodilatation is the major element in the fall (E. E. Nelson, 1927). The vasodilator action appears to be directly on the vessels, in mammals; for although frog vessels may be constricted by quinine (Biberfeld, 1918), perfused mammalian organs are generally dilated (Tamino, 1927); and they fail to respond, *in situ*, to stimulation of constrictor nerves or to epinephrine (Nelson). The response of perfused kidney vessels to epinephrine is also impaired; on excised arterial rings this may be observed with dilutions of 1:80,000. The constrictor action of barium is not antagonized (Nakano, 1927). Perfusion of frog vessels with quinine also destroys their constrictor response to epinephrine (Stake, 1929, claimed that epinephrine may even become dilator, which is denied by Santesson), and to veratrine, but not to barium (Kondo, 1919).

Antagonism to Epinephrine.—McCarrison and Cornwall, 1919, were the first to report that epinephrine does not effectively antagonize the circulatory depression of quinine; this holds also for quinidine and cinchonine (Arrilago *et al.*, 1921). Conversely, the cinchona alkaloids diminish the pressor response to epinephrine (Clerc and Pozzi, 1920), repeated doses of quinine increasing the interference. This is probably due chiefly to the direct vascular antagonism. The heart is not concerned, for quinine does not prevent the augmented response of the heart to epinephrine (Hammet, 1927; Nelson, 1927); on the contrary, it tends to prevent the epinephrine slowing (Clerc and Pozzi), both by diminishing the rise of pressure, and by rendering the heart refractory to vagus control.

The **use of quinine as abortifacient and oxytocic** has some traditional but rather undeserved reputation. Clinical doses produce little or no effect unless labor pains have started; it is, therefore, ineffective for inducing premature labor. Abortion has sometimes followed toxic doses, but presumably as a manifestation of the general toxicity, rather than through direct uterine action. It has been claimed that the administration of 0.65 Gm., 10 grains, of quinine, preceded by 2 ounces of castor oil, induces labor at term and hastens uterine involution (Bailey, 1926); but if so, it is probably ascribable to the castor oil; for in malarial districts, quinine is administered freely in all stages of gestation, apparently without terminating the pregnancy. It has been claimed that it is successful only if the os is already partly dilated.

Quinine is also administered to intensify weak puerperal contractions (0.25 to 0.5 Gm. every hour, to a total of 1 Gm.; Franz and Katz, 1921); and as a part of colonic ether anesthesia technic, to offset the depression of the ether. Graphic registration shows little if any effects (Dodek, 1932). The effectiveness is not improved by *intramuscular* or *hypodermic injection*, and these may produce sloughing. *Intravenous injection* (0.5 Gm.) has been used, but the risk is scarcely justified. In the *Gwathmey colon anesthesia*, 0.65 Gm. of quinine hydrochloride is added to the ether-oil mixture, with the hope of counteracting the depressant action of ether on the uterus. In view of the poor absorption of quinine from rectal injection, it appears improbable that it could have this action, unless through local irritation. The absorbed quinine passes into the *fetal circulation*, and the fetus is said to excrete it rather slowly (Dilling and Gemmel, 1929).

Experimentally, moderate doses of quinine may stimulate, and high doses depress, the rhythmic contractions and tonus of the uterus, excised and in situ. The stimulant action increases with the excitability of the uterus in the progress of pregnancy, so that 0.5 to 2 mg. per Kg. induce labor in puerperal cats (Schübel, 1928); but the response is highly variable and often absent. Several investigators report that quinine *sensitizes the uterus to oxytocin,* so that only $\frac{1}{10}$ to $\frac{1}{4}$ of the ordinary dose suffices to produce uterine contraction (Schübel, 1931; Legiehn, 1932).

Excised Uterus.—The stimulant action was described by Kurdinowski, and by Kehrer, 1906. The response varies for different animals and increases with pregnancy (Senta, 1912). In general, stimulation or reinforcement of the movements begins with 1:150,000 to 1:100,000. Relaxation and paralysis occur with 1:10,000 to 1:5000 (Lieb, 1914; Stake, 1929).

Antagonism to Epinephrine Stimulation.—Chistoni, 1922, found that high concentrations of quinine (1:5000) suppress the stimulant effect of epinephrine on the excised uterus of pregnant rabbits. This has been confirmed also for lower concentrations of quinine, 1:100,000 to 1:30,000, which are ordinarily stimulant (Langecker, 1926). Quinine may even render the epinephrine depressant (Stake, 1926, 1929). With the virgin uterus of the cat, quinine exaggerates the depressant response to epinephrine (Nelson, 1928).

Other Antagonisms and Synergisms.—Antipyrine and urethane increase the depressant action of quinine; amidopyrine potentiates the stimulation with small, and the depression with large doses (Kubota). Barium stimulation tends to overcome quinine depression (Stake, 1929).

Cinchonine, cinchonidine and *quinidine* act similarly to quinine (T. Stake, 1926). The dextrorotatory isomers are more oxytocic than the levo (Chopra, David and Dikshit, 1928). *Vuzin* and *eucupine* are ineffective (Bijlsma, 1920).

Other Smooth Muscle.—The *spleen* and *intestines* may be contracted. High concentrations (1:5000 to 10,000) may relax the intestines (Biberfeld, 1916). Excised *tracheal muscle* is relaxed (Trendelenburg). Quinine and quinidine dilate the bronchi *in vivo* (literature, Bijlsma, 1920).

Thyroid Gland.—Hyperthyroid patients are markedly resistant to cinchonism. Administration of quinine, 60 mg. per Kg. daily for several weeks, has no effect on the normal thyroid; but produces regressive histological changes in rabbits with compensatory thyroid hypertrophy (not in guinea pigs). In human exophthalmic goiter, treatment with 2 Gm. of quinine per day had no beneficial effects (Bromberg and Gray, 1931).

Quinine Test for Hyperthyroidism.—I. Bram, 1935, reported that the tolerance for quinine is in direct proportion to the basal metabolic rate, and responds with this to treatment. Patients with high B.M.R. may take 2 Gm. of quinine per day for weeks without cinchonism; up to 6 Gm. per day were given. Only 5 per cent of some 4000 hyperthyroid patients reacted with cinchonism, either because they were hypersensitive, or because their goiter was atypical.

Egg Production.—Quinine, when fed to doves, reduces the size of the yolk and albumen of the eggs. This continues for some time after the administration is stopped, and is then followed by a compensatory increase (Riddle and Anderson, 1918).

Cinchonism.—The larger therapeutic doses of quinine produce headache, ringing in the ears, and disturbed vision, a complex of symptoms grouped under the name of cinchonism. These are probably due to a selective action on the vessels of the eye and ear, which can also be demonstrated experimentally on animals. Toxic doses produce *photophobia, deafness* and *blindness,* at first partial, later complete. Similar phenomena occur with salicylates and related drugs, as indeed also with fever itself, and with "colds." Cinchonism is more easily produced in some individuals than in others. It is said that the minor symptoms may be somewhat diminished by bromides. Hyperthyroid patients generally have marked tolerance for quinine, and absence of cinchonism has some diagnostic significance.

Functional changes of vision and hearing set in promptly. Decrease of visual acuity, and especially of dark adaptation, may be demonstrated ten minutes after oral administration of 0.6 Gm. of quinine. Diminished auditory discrimination may be established by tuning fork in fifty minutes, and subjective auditory sensations persist for five to six hours (Lazarev and Balikov, 1930). Macht *et al.*, 1919, claimed that small doses of quinine increase the acuity of hearing.

Quinine amaurosis occurs in some patients from a single small dose, in others only after prolonged administration or after a single large dose (J. N. Evans, 1923). It is characterized by gradual constriction of the visual field, with dilated, fixed pupils. The fundus in most cases shows spasmodic closure of the retinal artery, some dilatation of the veins, intense retinal edema (Harnack, 1912). The retinal ganglion cells and the optic nerve undergo rapid degeneration (Druauld, 1902), presumably by the ischemia. (Amblyopia may occur, however, even when a scleral fistula is made to counteract ischemia; R. Knoblock, 1946.) Most cases recover with some loss of the peripheral field, but in some the blindness is permanent. Nitrites give striking improvement and perhaps hasten recovery (Pelner and Saskin, 1942). *The internal ear* is found congested, post mortem (Kirchner). Congestion of the tympanum was found in some patients who had taken 5 to 10 Gm. of quinine for attempted suicide (Chryssicos and Yanoulis, 1938). Wittmaak (1903) claimed that the aural congestion is not due to quinine, but to death. He demonstrated changes in the cells of the spiral ganglion, by the Nissl stain and is therefore inclined to attribute the auditory effect to a specific toxicity of quinine to these cells.

Major Toxic Actions of Quinine.—With high doses of quinine, the symptoms of cinchonism are accompanied by *difficulty of speech, confusion of ideas and somnolence, followed by loss of consciousness,* alternating with *delirium, coma,* and at times *convulsions.* The *treatment* is by evacuation and symptomatic.

General paresis may appear, preceded by general depression and muscular weakness. The final symptoms are those of *collapse,* due to general paralysis of the central nervous system, and in part also of the heart. The *respiratory center* shows a short primary stimulation followed by more marked paralysis. This latter is the usual *cause of death.* But since the medullary centers are not markedly affected until late, large doses are often survived. The *fatal dose* is usually given as 8 Gm., but 30 Gm. have been recovered from. It is doubtful how much of this really entered the circulation, since the sulfate is rather insoluble, so that a large amount may not have been absorbed.

The *minimal fatal dosage* of quinine for different animals, hypodermically, was compiled by Bijlsma, 1920. The minimal lethal dose of quinine, quinidine and related alkaloids for guinea pigs was reported by Dawson and Harms, 1934.

Visceral Degenerations.—Cornwall, 1920, administered quinine to rabbits, hypodermically or intravenously, over long periods. He found damage to the epithelium of the suprarenals and kidneys, and increased disintegration of red corpuscles in the spleen. These observations require confirmation.

Purpura hemorrhagica is a not infrequent phenomenon of intolerance after large doses (van der Horst, 1918).

Skin Eruptions and Idiosyncrasy.—Scarlatinal or urticarial rashes are not rare after therapeutic doses of quinine, and susceptible individuals may develop dangerous edemas of the mucous membranes and serious collapse. Local reactions are also produced by the application of quinine solutions (1:1000 to 1:10) to the scarified skin of hypersusceptible patients, while normal individuals do not react, so that this may be used as a harmless test of quinine idiosyncrasy. If this is positive, quinidine may be tested, for while the skin reactivity often extends to the other levo cinchona alkaloids, cinchonidine or ethylhydrocupreine, it extends more rarely to the dextro isomers, quinidine, cinchonine, ethylhydrocupreidine (Dawson and Garbade, 1930, 1933).

Desensitization was partly confirmed in the cases of O'Malley and Richey, 1919, with parallel changes in the skin reaction. Further confirmation is desirable. They started with the oral administration of 5 mg. of quinine bisulfate plus 0.5 Gm. of sodium bicarbonate; after one and one-half hours they gave 0.5 Gm. of bicarbonate with 0.1 Gm. of quinine. This was repeated daily, leaving the desensitizing dose at 5 mg. and increasing the second dose by 0.1 Gm. every day.

Absorption.—Quinine is absorbed mainly from the small intestine (MacGilchrist). The absorption is materially hindered by gastro-intestinal irritation, vomiting, diarrhea and the like (Porak, 1918), but not by dysentery (Chopra *et al.,* 1934). The disulfate is absorbed five or six times more readily than the sulfate from isolated intestinal loops (J. C. Andrews and Anderson, 1943).

Fate.—The greater part of the administered quinine is destroyed in the body. The destruction involves usually 60 to 70 per cent and sometimes to 90 per cent of the quinine (Porak, 1918; Hartmann and Zila, 1918). Less than 10 per cent is excreted after intravenous injection (Taggart *et al.,* 1946).

A large part of the quinine is rapidly removed from the blood in the liver, whether it is administered by mouth, or intravenously, or perfused through the excised liver (Grosser, 1908). It is also destroyed *in vitro* by certain liver extracts. An enzyme has been isolated, associated with flavoprotein liver aldehyde oxidase, which oxidizes quinine, its derivatives, and a variety of quinolines, isoquinolines and substituted pyridines (W. E. Knox, 1946). Excision or chloroform injury of the liver decreases the destruction of quinine and so prolongs the blood concentration and increases the urinary excretion (C. E. Anderson *et al.,* 1943). However, G. Chen and Geiling, 1944, report that hepatic injury or blockage of the reticulo-endothelial cells does not materially alter the rate of disappearance of quinine and quinacrine from the circulation. They consider the lungs chiefly responsible for the removal and enzymatic destruction of quinine. Because of the rapid removal, the toxicity on intravenous injection increases materially with the speed of injection (S. Weiss and Hatcher, 1927). A part, however, is not destroyed, but is fixed, for the lungs, liver, kidneys, heart and brain store it in concentrations greater than in the blood (R. A. Hatcher and Weiss, 1926). The distribution of quinine in the tissues of fowl is described by F. E. Kelsey *et al.,* 1943, using a micromethod of Kelsey and Geiling, 1942, quantitative for 0.1 gamma. B. B. Brodie and Udenfriend, 1943, used a fluorescence method for plasma, available also for quinidine. The **photodecomposition** of quinine was studied by Kyker and Cornatzer, 1943.

The concentration of quinine in the blood plasma varies considerably for the same oral dosage. With the daily dosage of 0.3 Gm. it ranges from 0.2 to 0.9 mg. per 100 cc.; with 0.2 Gm. it averages 0.3 mg.; for 0.5 Gm., 0.5 mg.; for 1.5 Gm., 1 mg. (J. V. Taggart *et al.,* 1946). It is necessary to maintain approximately 0.5 mg. for four days to secure the disappearance of the malaria parasites for fourteen days in blood-induced vivax infections; with 0.4 mg. their suppression is only temporary (R. W. Berliner *et al.,* 1946). Concentrations above 1 mg. are highly toxic (Hartmann and Gila, 1918).

With oral administration of a single dose of 0.5 Gm. of quinine dihydrochloride, the maximal concentration, averaging 1 mg., is reached in half an hour; after twenty-four hours it has fallen to 0.15 mg. (Chopra, Roy and Das Gupta, 1931). *A single dose of the principal cinchona alkaloids,* 10 mg. per Kg., to normal individuals gave the following average peak concentration in mg. per 100 cc. of plasma: quinine, 0.3; cinchonidine and quinidine, 0.2; cinchonine, 0.05. The peak is markedly lower if the alkaloids are administered immediately after a meal (E. P. Hiatt, 1944). Similar results are reported by Taggart *et al.*, 1946. They conclude that the low level of cinchonine is probably due to greater destruction.

After intravenous injection, the concentration falls promptly to about the same level as is attained with oral administration (J. P. Morgenroth, 1918; Hatcher and Gold, 1927).

With quinidine, 95 per cent has left the blood within five minutes, 99 per cent within an hour (Weiss and Hatcher, 1927). Chopra *et al.*, 1934, found the average concentration of 1.2 mg. per cent fifteen minutes after intravenous injection of 0.5 Gm. of quinine dihydrochloride in man, which is slightly higher than with the same dose by mouth; but the concentration was not so well maintained for intravenous injection, so that none could be demonstrated in the blood in twenty-four hours.

Intramuscular injection gives about the same concentration, but it is attained more slowly. Chopra *et al.*, 1934, after 0.5 Gm. of quinine dihydrochloride, found that the maximum (averaging 0.95 mg. per cent) was not reached until after two hours. After twenty-four hours, the concentration was 0.2 mg. per cent.

Partition of Quinine between Serum and Corpuscles.—The concentration of quinine within the corpuscles is about the same as in the plasma (O. S. Gibbs, 1928), or smaller, ½ to ⅓ (Ramsden, Lipkin and Whitley, 1918). *In vitro*, the addition of ethyl urethane increases the ratio in the corpuscles (di Mattei, 1930).

Excretion.—Quinine is excreted mainly by the urine, and somewhat by the feces, even after parenteral administration. Traces are found in other secretions, including the milk (Terwilliger and Hatcher, 1934).

With 1 to 2 Gm. per day, the concentration in the urine is about 600 mg. per liter; *i. e.*, more than sixty times as much as in the blood. The amount recovered from alkaline urine is only half as large as from acid urine, owing to reabsorption of the basic alkaloid from the bladder (Haag *et al.*, 1943; J. C. Andrews and Cornatzer, 1944). Quinine is always present in the gastric and intestinal content after hypodermic injection, in man and in animals. Its appearance in the bile and saliva is irregular (Hartmann and Zila, 1918; Bauer *et al.*, 1918; Valdiguié and Lacaze, 1919).

Course of Excretion.—The urinary excretion begins within half an hour, and is practically completed in twenty-four hours (Nishi, 1909; Baldoni). Traces may continue for three days or longer. The feces do not contain it after twenty-four hours (Valdiguié and Lacaze, 1919). The maximum in the urine is reached in four to ten hours, independent of the dose or method of administration. This would indicate that doses should be repeated every three or four hours. The excretion is delayed in severe nephritis and diminished in cardiac decompensation (Porak, 1918).

ANTIMALARIAL DRUGS

Before the discovery of cinchona, the competing civilizations of the world were alike conquered and sometimes extinguished by malaria. The advent of quinine has completely changed the outlook, but the importance of malaria has continuously increased, with the increased crowding of the world, and the need of more intense colonization of the tropics. The disease is said to affect almost constantly 800 millions of people (Müller, quoted from Dawson), and to cause annually two million deaths (Ross; ibid.). The treatment of malaria was revolutionized by the discovery of quinine, but its use remained empirical, lighted only in part by discovery of the malarial organisms, the plasmodia, by Laveran, 1880. The mechanism of its action is still unknown. The vital importance of the malaria problem in the World Wars gave opportunities for more accurate study. New paths of approach were opened by the introduction, through Wagner von Jauregg, of intentional malaria inoculation as a treatment of syphilitic paresis, and by experimental malaria in animals. They led to synthetic antimalarial agents not closely related to quinine; especially to quinacrine, which is actually more effective than quinine. Intensive screening of over 14,000 chemicals during World War II produced several compounds of the 4-aminoquinoline series which appear superior to quinacrine (review R. L. Loeb *et al.*, 1946).

Clinical Success.—Adequate and safe dosage of quinine or of quinacrine produces prompt suppression, although rarely if ever complete eradication of the malaria. Within one to five days, usually three, if quinine is given by mouth, or within one or two days if given by vein, the plasmodia of benign tertian malaria disappear from the circulating blood and with them disappear the febrile paroxysms caused by the developmental cycle and the consequent destruction of the corpuscles. Failure to respond to these drugs, if they have been absorbed, is probably nonexistent, nor is there any acquired resistance or "fastness." The viscera, however, of most and possibly all treated patients continue to harbor some plasmodia which multiply at times to produce clinical attacks, "relapses," sometimes after many months, generally under conditions of strain or lowered general resistance, for an average of a year with falciparum infections, two years with vivax, ten years with quartan (J. Hayman, 1946). Relapses occur in a third to half of the vivax infections, much less frequently with the falciparum. Each relapse decreases the liability to further relapses.

Recurrences do not occur in persons inoculated with infected blood, nor in natural inoculation if there has been no therapy. Quinine and quinacrine appear to kill the trophozoites completely, the sporozoites only partly (M. F. Boyd, 1940, 1942). The surviving plasmodia have been greatly modified, especially as regards their rate of multiplication. In acute attacks this is such that the survival of 4 per cent of the parasites would suffice to reproduce the original number by the time of the next cycle. The "cure" checks this multiplication in two directions: A part of the plasmodia propagate into the sexual forms which cannot multiply until they have passed through the mosquito. These are, therefore, harmless to the patient, but render him an infective carrier. Another part of the plasmodia remain asexual, but their multiplication is not sufficiently vigorous to overwhelm the normal destructive mechanisms; at the same time, the sluggishness of these plasmodia appears to render them resistant to destruction by quinine as well as to the natural protective agencies, so that a rather stable balance is established. If this is temporarily upset, multiplication resumes, the patient is self-reinfected, and the typical ague attacks set in; and with this, the plasmodia recover their susceptibility to quinine treatment, although often not quite in the same degree, *i. e.*, chronic malaria is less amenable to quinine. This is not due to adaptation to the drug, for it also occurs if the earlier attacks were not treated. It is a common phenomenon of protozoan infections.

The tendency toward later relapses is less if the original treatment was early, intensive and prolonged for some time after the symptoms had been suppressed, as already noted by Sydenham. Excessive dosage, however, may do more harm than good to the patient; and prolonged treatment tends perhaps to hinder the development of the natural mechanisms which build up a lasting defense more effectively than does chemotherapy. The Malaria Commission of the League of Nations (Third and Fourth General Reports, 1933 and 1937) therefore recommends merely to treat the individual attacks, which generally become progressively milder until the disease is practically extinguished, rather than to prolong the chemotherapy beyond the symptoms, as was the usual practice. This policy applies also to quinacrine.

Susceptibility of Plasmodia Species and Their Developmental Cycles.—Quinine and quinacrine are nearly equally effective against the circulating trophozoites and other asexual forms of the vivax and quartan plasmodia, which are responsible for the febrile paroxysms. Adequate doses also destroy most of the sexual gametocytes of these species, which develop between the attacks and infect the mosquito (M. F. Boyd, 1944). Quinacrine is more effective than quinine against falciparum (malignant tertian). Neither drug precludes vivax relapses; pamaquine decreases recurrence materially if administered for ten days, not if confined to two days (Hayman). Totaquine (mixed cinchona alkaloids) is not suitable for falciparum. The *timing of the administration* with reference to the attack is practically immaterial (Maxcy, 1928). Pamaquine in safe doses has relatively little effect on the asexual forms and does not modify the clinical course, but it devitalizes the infecting stage of the falciparum, and renders most patients noninfectious (Boyd).

Visceral Foci.—When the plasmodia are introduced by a mosquito they disappear almost instantly from the circulating blood, lodge in the reticulo-endothelial system, and do not reappear in the circulation until several days, when they have multiplied to overflow. These exo-erythrocytic foci are also centers for late relapses and probably for sexual development. Antimalarial drugs do not reach these "visceral centers" in sufficient concentration to be effective. Injection of malarial blood does not at first involve the reticulo-endothelial system, and is, therefore, much more amenable to treatment. Falciparum owes its high mortality to the rapid multiplication of the parasites and rapid destruction of the blood cells. A sticky substance agglutinates them and obstructs the circulation, so that most of the plasmodia are in stagnant capillaries where drugs do not penetrate (E. C. Faust, 1945).

The mechanism of action of the antimalarial drugs has not been established; it is perhaps through interference with metabolic processes necessary to development and multiplication of the plasmodia, somewhat analogous to "antibiotic" agents (review, E. K. Marshall, 1944).

The multiplication of Plasmodium knowlesi is suppressed by the same concentration of quinine and of quinacrine *in vitro* as *in vivo*, indicating that these substances act without "intervention" of the body (E. G. Ball, 1946). The effect of quinine is not due to direct *lethal* action on the plasmodia, for *in vitro* this is not materially greater than with nonspecific drugs, and the concentrations of quinine required to kill the plasmodia are much higher than those which exist in the blood in quinine treatment. Nor has it been possible to demonstrate that quinine stimulates the production of specific or nonspecific antibodies; nor is the action due either to an antipyretic or to a colloidoclastic reaction, for other agents which produce these effects are not specific against malaria. Quinacrine, on the other hand, is directly fatal to the plasmodia.

Blood Concentration and Parasite Count.—If the action were directly parasiticidal, the number of plasmodia in the circulating blood should fall lowest when the concentration of the drug is highest. This is not so with *quinine*, according to observations on rhesus monkeys infected with Plasmodium knowlesi (R. N. Chopra, Ganguly and Roy, 1935). The highest concentration of *quinine* obtainable by intravenous injection without too severe toxic effects does not reduce the number of parasites or cause their degeneration until after some hours, when the concentration has already fallen; and a single dose of quinine, no matter how large, is effective if the number of parasites is low, less than 100,000 per cubic millimeter. If the treatment has been successful, nearly all the parasites disappear, and the few that remain multiply but slowly and feebly, although practically no quinine remains in the blood. The action therefore appears to be indirect. With quinacrine (Chopra *et al.*, 1936), the number of parasites begins to fall as soon as the concentration of the drug rises, so that there is probably a direct lethal action on the plasmodia, but the full effect is not reached for some twenty-four hours, so that there is probably also an indirect action. However, as further indication of direct action, a single dose of quinacrine is effective even if the parasite count is high, above 500,000 per cubic millimeter; and the remaining parasites, when they reappear in the peripheral blood, multiply at the same rate as in the original attack, and result in death.

The *experimental inoculation of malarial blood* in the treatment of paresis, introduced by Wagner von Jauregg, 1918, offered an immediate test for direct antiplasmodial action. In this treatment, the patient receives a subcutaneous or intravenous injection of 5 cc. of the blood of a patient with benignant tertian, removed at the height of the paroxysm. After a latent period of above five days, this induces typical malaria, which may be arrested at any time by relatively small doses of quinine. Kirschbaum, 1923, found that incubation of the malarial blood for twenty-four hours, with an equal volume of quinine hydrochloride, 1: 5000, in isotonic saline or dextrose, does not destroy its virulence, although this quinine concentration is at least ten times greater than the clinical peak concentration. On the other hand, incubation with neoarsphenamine for three to six hours destroys the virulence. It has been objected that these conditions are not physiological (Giemsa, 1927), but this renders the resistance to quinine only more remarkable, and speaks strongly against direct plasmodicidal action. The experiments were confirmed by Yorke and MacFie (Maxcy, 1931), and extended by S. P. James *et al.*, 1927, to the sporozoites of the mosquito: infection followed the injection of blood serum containing quinine, 1: 5000, in which infected anopheles had been teased and left in contact for fifteen minutes. Evidently, concentrations of quinine much higher than can exist in the blood do not kill the plasmodia directly. Administration of quinine to malaria-infected canaries interferes with the normal growth and development of the parasites (E. M. Lourie, 1934). *Quinacrine* is directly plasmodicidal, so that blood of monkeys heavily infected with Plasmodium knowlesi loses its virulence when digested twenty-four hours with an equal volume of quinacrine solution, 1: 25,000 (Chopra *et al.*, 1936). The atabrine becomes firmly bound by the parasites (F. M. Peter, 1935).

Direct Injury of Plasmodia by Quinine under Extreme Conditions.—Laveran, 1880, the discoverer of the plasmodia, observed that their *motility on a slide* is arrested by quinine, 1:1000. However, this concentration is a hundred times greater than occurs clinically. Many substances not antimalarial are fatal to plasmodia in lower concentrations.

Many observers, for instance, Lo Monaco and Panichi, 1899, observed *degenerative changes in the plasmodia* of quinine-treated patients. This shows that the parasites have been injured, but not whether by direct action. Bass, 1922, found that incubation of *cultures of plasmodial blood* with quinine, 1: 9000, for five hours appeared to check the development and alter the stainability of the plasmodia as compared with controls, but the objection of abnormal concentrations holds against these observations, as against those of Laveran; and as with these, similar effects are produced by many substances which are not antimalarial. It has also been suggested that the parasites are killed by a decomposition product of quinine; but all the known decomposition products are much less effective than quinine. Giemsa, 1927, reviewing the theories, inclines to a direct plasmodicidal action in the *capillaries*, where quinine is adsorbed and concentrated on the endothelium. It was suggested that the surface affinity of quinine may cause its *adsorption* on the surface of the corpuscles (Morgenroth, 1918; O. S. Gibbs, 1928), to form a resistant film which would hinder the penetration of the merozoites, and so prevent the completion of the cycle; this is not supported by direct evidence. *Blocking of the reticulo-endothelial system* with trypan blue decreases the effectiveness of quinine, pamaquine and quinacrine in avian malaria (Kritschewski and Demidowa, 1935).

The *blood picture and the spleen are not affected in normal individuals* by antimalarial doses of *quinine*, by mouth or by vein. Patients with chronic malarial splenomegaly who respond favorably to quinine, react with transient leukocytosis, especially of the large lymphocytes and monocytes, with coincident reduction in the size of the spleen and increase of erythrocytes (with intravenous injection, the red count may be temporarily diminished by hemolysis). These changes are absent if the quinine is not successful against the infection, indicating that there may be a causal relation. Pamaquine causes a temporary increase of lymphocytes, but a sharp fall of the monocytes, and does not contract the spleen (Hughes and Shrivastava, 1930).

Toxicity for Paramecia.—Before the discovery of plasmodia, C. Binz, 1868, surmised that malaria was due to protozoan parasites, which could be killed by quinine, since he found that this is highly toxic to infusoria *in vitro*. Paramecia have been widely used as a presumptive index of antimalarial action (C. Binz, 1869; G. Grethe, 1896), but no definite relation has been established; in fact, substances with a paramecia toxicity as high as quinine are totally devoid of antimalarial action (U. N. Brahmachari *et al.*, 1930). Incidentally, dilute solutions of quinine, or brief contact with concentrated solutions, stimulate the multiplication of paramecia. The toxicity is materially greater in light than in the dark (M. Feiler, 1928). Continued exposure to low concentrations increases the resistance to quinine; the susceptibility is restored by small doses of sodium arsenite, which have no apparent effect when used alone (Neuschloss). Pamaquine, strychnine, aconitine and solanine, like quinine, stimulate growth and division in low concentrations (10^{-12} to 10^{-21}), and depress in somewhat higher concentrations (10^{-12} to 10^{-5}). Keeping the cultures in the dark greatly decreases the toxicity of solanine as well as of quinine, but has no effect on the pamaquine and the other drugs (Feiler, 1928, 1929). Colpidium cultures tolerate a maximum concentration of 1:2000 acutely, but if adapted by *gradually increasing amounts*, tolerance to a concentration of 1:300 is established (O. Harnisch, 1926).

Amebic Dysentery.—Quinine is used by rectal irrigation. Its administration by mouth (2 Gm. per day) is sometimes effective, but less certain than emetine (Brooks. 1914). Slow rectal injection of 1 or 2 liters of 1:2000 to 1:1000 solution has been advocated for local action (W. Fletcher, 1924).

Treatment of Malarial Paroxysms.—Quinacrine and quinine are both fully effective in suppressing and treating the clinical attacks of benign tertian and quartan malaria. The febrile attacks are suppressed within thirty-six hours, and the trophozoites disappear from the blood, generally by the third day. Quinine reaches effective plasma concentrations sooner than quinacrine, which is partly fixed in the tissues; but this can be practically compensated by higher initial dosage (Findlay and Stevenson, 1944). Quinacrine is probably the less toxic drug under these conditions, but both drugs are subject to toxic side actions, which may enforce the choice. The preferred routine during the war consisted of 0.2 Gm. of quinacrine hydrochloride with 1 Gm. of sodium bicarbonate and a tumbler of water every six hours for five doses, followed by a 0.1 Gm. tablet three times daily after meals for six days. If quinacrine is not tolerated, *quinine* or *totaquine* is given, 1 Gm. three times daily before meals for two days, followed by 0.6 Gm. three times daily for five days (J.A.M.A., 1945, *128*:1101; M. F. Boyd, 1944).

Intramuscular injection of quinacrine may be used if vomiting interferes with oral administration; 0.2 Gm. in 5 or 10 cc. of water into each buttock (total, 0.4 Gm.). Two additional injections of 0.2 Gm. may be given six to eight hours apart, changing to the oral administration as soon as the drug is retained.

Intravenous administration of quinine is indicated if the patient is in *coma*, or if the blood film shows high population of falciparum; injecting *very slowly* (in not less than thirty minutes) 0.6 Gm. of quinine hydrochloride in 300 cc. of normal saline. Hanzlik and Cutting, 1945, recommend addition of 1 mg. of epinephrine. This may be repeated in six to eight hours if necessary; or, preferably, an intramuscular injection of quinacrine may be given immediately after the quinine.

Pamaquine naphthoate, 90 mg. with 2 Gm. of quinine daily for ten to fourteen days greatly decreases the incidence of relapse in vivax malaria. The two drugs together apparently accomplish the eradication of the plasmodia when neither is effective alone (D. R. Talbot, 1943; R. W. Berliner *et al.*, 1946). A smaller dosage, 10 mg. three times daily after meals, has been administered during the last five days of the ordinary quinine treatment or begun two days after quinacrine was stopped, and continued for five days, to prevent spread to mosquitoes It should be stopped if untoward symptoms develop. This dosage is toxic to the gametocytes, but not to the asexual forms, and therefore has no effect on the attack. It should not be administered at the same time as quinacrine, as their toxicity is additive.

Therapeutic malaria induced in paresis by the injection of blood from patients carrying a vivax strain, or by mosquitoes infected from such patients, is peculiarly amenable to quinine, so that the administration need not be continued beyond three dyas (Yorke and MacFie, 1924). *Oxophenarsine hydrochloride* (*Mapharsen*) is effective against therapeutic malaria. A single intravenous injection of the antisyphilitic dosage generally terminates the paroxysms, but three or four injections are given to obviate recurrence (D. Goldman, 1938). Tertian malaria resistant to quinine alone may respond promptly to one injection of 40 mg. of oxophenarsine hydrochloride. It is advisable, however, to follow this with four injections of 40 mg. at weekly intervals (W. H. Stewart, 1945). Intensive bismuth therapy, especially with thioglycollate, checks therapeutic malaria, but does not eradicate it (W. F. Schwartz, 1939). *Sulfanilamide* is somewhat effective against mild malaria attacks (J. H. Williams, 1941); as is also *methylene blue.*

Screening of antimalarial agents utilizes the malarias of birds and apes. The results cannot be transferred directly to man, as the efficiency for different plasmodian species is not necessarily parallel. Several species of parasites should be used. The comparative potency is expressed as multiples of the effective dose of quinine or quinacrine or other established drug (review, E. K. Marshall, 1942; 1946). Bird malaria especially has been used to study the relation of chemical constitution to action (Giemsa *et al.*, 1926; Hegner *et al.*, 1930; *Quinacrine*, P. Tate and Vincent, 1934; *Pamaquine*, Hegner and Manwell, 1927; Lacorte, 1927).

Quinoline compounds with diethyl-amino alkaline chains in the 8 position are both schizotropic and gametotropic; those in the 4 position are only schizotropic (Galperin).

Relapses should be treated as they arise, generally less energetically than the original attack. They become progressively milder by the development of natural defense mechanisms.

Relapses may be provoked by stress and strain and overfatigue. Plasmodia may sometimes be mobilized by epinephrine, 0.5 cc. of 1:1000 hypodermically. This defers, but does not prevent, recurrence and is not recommended.

"*Blackwater fever*," attacks of serious *hematuria* following on spontaneous intravascular hemolysis, may occur during quinine treatment of a relapse of falciparum malaria, after repeated previous attacks treated with quinine without hematuria. It also occurs with quinidine and cinchonine (Leverani, 1929), and with pamaquine (Earle *et al.*, 1946), but rarely, if ever, with quinacrine.

Quinine hemolysis evidently involves sensitization. Quinine is not hemolytic for normal blood. The affected erythrocytes hemolyze when transferred into a normal individual, and normal red cells injected into a sensitized individual hemolyze as quickly as the patient's red cells (H. Foy *et al.*, 1945). It is interpreted as involving two factors: (1) increased fragility of the erythrocytes to lysolecithin; and (2) a circulating hemolysin (H. Most and Meleney, 1944). The parasitized cells develop greater mechanical fragility (S. C. Shen *et al.*, 1946). C. McGuire, 1945, suggests that the liver is involved in the sensitization, as many subjects have amebic liver injury

Suppressive Treatment.—Vivax malarial attacks do not develop while appropriate doses of quinine or quinacrine are taken. They do not prevent the infection, but the parasites do not multiply in the visceral foci sufficiently to produce clinical symptoms. If the medication is suspended at any time, multiplication resumes and progresses, and a "delayed primary attack," often more or less atypical, develops in several weeks or months, most frequently between the third and ninth week (I. M. London *et al.*, 1946). It can be controlled by quinacrine, 1 Gm. in divided doses on the first day, followed by 0.3 Gm. daily for six days (H. Most and Hayman, 1946). The deferment may be convenient temporarily, and does no harm, but the vivax infection will rarely be cured until the attack is permitted to develop. Falciparum infection is suppressed indefinitely after medication is discontinued (O. R. McCoy, 1945; M. F. Boyd, 1944).

Quinacrine appears to be more effective than quinine and is generally better tolerated. Nausea generally disappears when its use is continued. The maintenance dosage is a tablet of 0.1 Gm. daily, at the evening meal. This dosage requires two or three weeks to establish a full plasma concentration; it is, therefore, advisable to begin the administration one to four weeks before the expected exposure. If quinacrine is not tolerated, *quinine sulfate*, 0.5 to 0.65 Gm., may be taken daily at the evening meal. Cinchonism from this dosage is not serious with most people, and decreases with use. There is no evidence of the production of drug-resistant strains (A. Missiroli, 1939).

Drug eradication of malaria from a locality by curative or prophylactic treatment is practically impossible with the present drugs; but systematic periodic blood examination and treatment with quinacrine or quinine, followed by pamaquine, materially lowers the incidence (Gorgas Memorial Laboratory Annual Report, 1941).

Experimental infection of syphilitic patients with vivax and falciparum sporozoites is prevented by administering 160 mg. of pamaquine naphthoate on the day preceding and for five or six days after the inoculation. Smaller doses and shorter periods are ineffective (H. A. Feldman *et al.*, 1946).

Oral administration of quinine is to be preferred; absorption is sufficiently prompt so that the saving of time by parenteral injection is not significant. The next paroxysm is likely to occur in any case; but the attacks should be suppressed by the third or fourth day with quinine, by the sixth or seventh with atabrine. Quinine should be given before meals. Experiments with bird malaria indicate that divided doses are more effective and less toxic than the same amount in a single dose (Sergent and Sergent, 1921; H. Beckman, 1944). The absorption is more prompt if the quinine is given in solution, the sulfate being dissolved with a slight excess of dilute sulfuric acid to prevent precipitation in the mouth by the alkalinity of the saliva. Tablets or capsules of quinine sulfate (not more than 0.3 Gm., 5 grains each) practically avoid the bitterness and are adequate, except perhaps on the first day. Old pills made with ordinary excipients may give but little absorption. For children, the dosage may be reduced in proportion to body weight, and the sulfate may be suspended in syrup of chocolate or of yerba santa. The tasteless quinine esters (euquinine and aristoquine) require hydrolysis by the acid of the digestive tract and are, therefore, less effective than the soluble salts of quinine, especially in hypochlorhydria (Biginelli, 1928). Cinchona preparations are less effective than quinine salts, and adequate doses contain so much tannic acid that they may upset the digestion. *Totaquine* is considerably cheaper than the purified quinine (P. F. Russel, 1935). *In case of idiosyncrasy*, quinidine or cinchonine may be tried.

Parenteral administration should be used only when the oral is impossible, in coma, vomiting, or high pyrexia. In such case intramuscular quinacrine should be preferred, since quinine is irritant and poorly absorbed from intramuscular injection and may cause sudden death when administered intravenously.

Intravenous injection (introduced by G. Baccelli, 1890) initiates the action more promptly, especially in moribund patients. Its final effectiveness is no greater, however, since the concentration in the blood drops in a few moments to the same level as with oral administration (S. Weiss and Hatcher, 1929; Chopra *et al.*, 1934). On the other hand, the intravenous injection produces exaggerated cinchonism and involves serious risk of acute and sometimes fatal circulatory collapse, as also local irritation. In view of these objections, it should be used only in moribund patients with algid collapse. A single intravenous dose of 1 to 2 Gm. of quinine and urea hydrochloride in 10 cc. of water, injected *very slowly* may clear conditions sufficiently to continue with oral administration. Quinine dihydrochloride presents more danger of flocculation, but has been used, 10 grains (0.65 Gm.) in 100 cc. of normal saline injected by gravity, or in 20 cc. by syringe, with great caution, stopping the injection (at least temporarily) if collapse develops. In emergencies, ampuls containing the above dose in 20 cc. of saline may be used, with a syringe, but with even greater caution and slowness. Care must be taken that the solution does not infiltrate the walls of the vein or the subcutaneous tissue, else sloughing or fibrosis may result (L. S. Dudgeon, 1919). Idiosyncrasy is generally a definite contraindication. Circulatory embarrassment enjoins extra caution; so also does the recent use of large doses of quinine.

Acute Side Actions of Intravenous Quinine Injections.—More or less cinchonism is the rule, setting in during the injection, with bitter taste, ringing in the ears, blurred vision, mental confusion and vertigo. These increase with the rapidity of the injection, but are usually not dangerous. They attain their maximum in three to ten minutes, then gradually subside for several hours. The blood pressure falls acutely, clinically as well as in animals, especially with rapid injections of concentrated solutions (Brahmachari, 1922; R. McCarrison and Cornwall, 1919). Concentrations of 1:150 are dangerous (MacGilchrist); immediate death has been reported (see Eggleston, 1917). On the other hand, even 10 per cent solutions have been injected without serious effects (A. D. McLean, 1917). More or less fall of pressure is probably present in all cases, but it is usually of short duration. The degree and duration depend partly on the speed of injection, partly on the patient. The mechanism is by cardiac depression, and probably also by colloid flocculation. The onset of collapse is indicated by profuse sweating, dilation of the pupils, staring expression and twitching of the facial muscles. Epinephrine is used as antidote.

Intramuscular injections (quinine dihydrochloride, 1 Gm. in 10 cc.; or quinine-urea hydrochloride, 2 Gm. in 5 to 10 cc.) are not absorbed more rapidly than the oral doses, and they cause considerable local irritation, especially if they are made too near to the sciatic nerve (Sicard *et al.*, 1917).

Rectal injections of quinine give but little absorption, and solutions of ½ to 1 per cent are so irritating that they are not retained over twenty minutes, and are followed by inflammation. Colonic irrigation with 1 or 2 liters of 1:2000–1000 solution of quinine sulfate or hydrochloride may be used in *amebiasis.*

Antimalarial Action of Other Cinchona Alkaloids and Quinine Derivatives.—The clinical evidence, reviewed by Dawson, 1930, indicates that the common cinchona alkaloids, quinine, quinidine, cinchonine and cinchonidine, are practically equivalent in equal dosage, nor is one seriously more toxic than the others. The greater experience with quinine, however, should cause this to be preferred, except in idiosyncrasy, when quinidine or cinchonine may be substituted. Of these, quinidine comes nearest to quinine (Sanders and Dawson, 1932), and it may be even more effective in malignant malaria. Its systemic toxicity is about a third higher. It is administered as the sulfate, 0.65 Gm., 10 grains daily.

The *plasma concentration,* milligram per liter, required to suppress blood-induced vivax malaria is: quinine, 5; quinidine, 0.9; cinchonidine, 2; cinchonine, less than 0.1. The effective oral dosage, however, does not show much difference (Zubrod *et al.*, 1946).

Cinchonine and **cinchonidine** produce clonic and tonic convulsions, located below the optic thalami. They are more depressant to the heart than is quinine (Albertoni, 1882). Their cardiac actions were studied by Chopra *et al.*, 1928, and various pharmacological actions of cinchonidine by Provinciali, 1932 and 1938. They are similar to quinine.

Quinamine differs quantitatively from quinine. It is less toxic for bacteria and protozoa, markedly more tonic for the uterus, and is a more potent local anesthetic (Chopra and David, 1927).

Cinchonamine.—This is more toxic than quinine (F.D., 75 mg. per Kg. of dogs or cats). It produces salivation, hallucinations and epileptoid cerebral convulsions. It has little effect on blood pressure (Ellrain).

Totaquine, the mixed alkaloids of cinchona bark, is clinically practically as potent as the same dose of quinine (National Research Council, 1944; J.A.M.A., *125*:977).

Quinicine and Cinchonicine.—When quinine or cinchonine is heated with acid, the linking CHOH is hydrolyzed to CO, the two H's being transferred to the adjacent C and N of the loipon, forming an imide group and breaking the benzol ring. These compounds were discovered by Pasteur in 1853 and named by him quinicine and cinchonicine. Chemists, impressed by exaggerated estimates of the toxicity of quinicine, suggested that the toxic actions of quinine are due to the formation of quinicine by the gastric acidity, and that this formation in mixtures of quinine with organic acids would constitute a dangerous incompatibility. These fears are quite unfounded, both because quinicine (quinotoxine) is not much more toxic than quinine itself, and because only insignificant traces of it can be formed at ordinary temperatures even with organic acids, and still less with mineral acids (Biddle, 1912; Ad. Kaufmann). Incidentally, the formation of these compounds is indicated by black discoloration.

There need be no fear of prescribing solutions of quinine and dilute mineral acids, although organic acids should be avoided. Discolored and precipitated solutions should not be used, since they would be deficient in the therapeutic qualities of quinine.

The yellow or green *discoloration of quinine solutions* on aging or sterilization is produced by oxidation products, catalyzed by the presence of traces of copper (Bachstetz and Cavallino, 1934). The change would scarcely be sufficient to affect the actions.

Miller and Rhode, 1895, proposed to change the names to *quinotoxine* and *cinchotoxine*. The change has been largely adopted, but seems confusing and unjustified. The toxicity is not very high; and practically the same name, *quinatoxine*, had previously been applied by Ostermayer, 1884, to a quite different substance, diquinoline dimethylsulfate. This produces curare actions (Hoppe-Seyler, 1880; Durdufi, 1889).

Actions of Quinicine (Quinotoxine).—Bachstetz and de Caro, 1932, reported that the MLD for rats is a fourth that of quinine; for mice, one-half. Hildebrandt claimed that it is not convulsive, that it has a digitoxin effect on the frog heart, and that it raises the blood pressure slightly. Biberfeld found the toxicity for mammals low (lethal dose, 15 mg. per Kg. by vein; 200 mg. hypodermically, corresponding to about ½ ounce in man). In this large dose it produced convulsions. It did not have a digitoxin effect on the exposed frog heart, but depressed it like quinine. It also depressed other smooth muscle, produced local anesthesia similarly to quinine, but was not antipyretic.

Actions of Cinchonicine (Cinchotoxine).—The toxicity of this is also low. Hildebrandt found the hypodermic lethal dose as 150 mg. per Kg. for mice (equivalent to 10 Gm. for a man). The same dose of cinchonine was not toxic. Hunt obtained about the same number for cinchotoxine (310 mg.) as for quinine (370 mg.). Rabbits seem considerably more susceptible (Biberfeld, M.F.D. hypodermic, 10 mg. per Kg.; Fraenkel, F.D. hypodermic, 30 mg. per Kg.; Hildebrandt, cat, F.D. hypodermic, 20 mg. per Kg.). Death is preceded by violent convulsions. Hildebrandt described a slight rise of blood pressure. Biberfeld found depression of the circulation. Fraenkel observed on the exposed heart, first strong contractions, then diastolic arrest.

Ultraviolet Radiation on Toxicity of Quinine and Quinidine.—Macht and Teagarden, 1923, reported that these alkaloids are more toxic to rats exposed to the sunlight or to the quartz lamp, than to those kept in the dark. Quinine was more toxic than quinidine. The radiation, without quinine, had only a slightly stimulant effect on the muscular activity. *Exposure of quinine solutions to ultraviolet rays* apparently produces chemical changes by which it is rendered more toxic to paramecia *in vitro*, and also more effective against canary malaria (G. Roskin and Romanowa, 1929).

PREPARATIONS.—The ordinary salts of quinine are white, odorless and intensely bitter. They are *incompatible* with alkalis and other alkaloidal precipitants, and with salicylates, benzoates and tartrates (*not* with iron salts). Solutions containing free organic acids deteriorate slowly. *Average dose of all quinine salts:* 1 Gm., 15 grains, daily; individual doses vary from 0.06 to 0.6 Gm., 1 to 10 grains.

Quinine and Urea Hydrochloride, a double salt of quinine hydrochloride and urea hydrochloride, corresponding to about 62 per cent of anhydrous quinine. Freely soluble in water (1 Gm. in 1 cc.) with strongly acid reaction. *Quinine and Urethane Injection*, U.S.P., in water for injection, approximately 2 parts of quinine hydrochloride to one part of urethane. Usual size, 0.25 Gm. of quinine hydrochloride and 0.125 Gm. of urethane in 2 cc. *Quinine Bisulfate*, U.S.P., $Qu.H_2SO_4.7H_2O$, freely soluble in water (1 Gm. in 10 cc.) with strongly acid reaction. *Quinine Dihydrochloride*, U.S.P., Qu.2HCl. Freely soluble in water (1 Gm. in 0.6 cc.) with strongly acid reaction. *Quinine Ethylcarbonate* (*Euquinine*); fleecy crystals, only slightly soluble in water and practically tasteless. **Quinine Hydrochloride**, U.S.P., $Qu.HCl.2H_2O$. Soluble in water (1 Gm. in 16 cc.) with neutral reaction. Average dose, oral, 0.6 Gm., 10 grains; intramuscular, 0.2 Gm. **Quinine Sulfate**, U.S.P., $Qu._2H_2SO_4.2H_2O$. Fleecy white crystals, acquiring brown tint when exposed to light. Very bitter. Sparingly soluble in water (1 Gm. in 810 cc.), with neutral reaction. *Quinine Sulfate Tablets*, U.S.P., usually contain 0.12, 0.2 and 0.3 Gm. (2, 3 and 5 grs.). *Tinctura Antiperiodica* (Warburg's Tincture) contains 1.5 per cent of quinine hydrochloride, 0.3 Gm. per tablespoonful, with rhubarb, aloes and aromatics. Used in India against malaria. *Cinchonine Sulfate*, $(C_{19}H_{22}N_2O)_2H_2SO_4.2H_2O$; differs from quinine in being dextrorotatory and can sometimes be used successfully in persons who have an idiosyncrasy to quinine; white, lustrous crystals; soluble in water (1:60). Dose, 0.15 Gm., 2½ grains. *Totaquine*, U.S.P., a mixture of alkaloids from the bark of Cinchona species, containing not less than 10 per cent of anhydrous quinine, and about 75 per cent of total cinchona alkaloids. Yellowish to pale brown powder. Almost insoluble in water. Average dose, 0.6 Gm., 10 grains. *Totaquine Capsules*, U.S.P., and *Totaquine Tablets*, U.S.P.; usual sizes, 0.12, 0.2 and 0.3 Gm. *Cinchona*, N.F. (Peruvian Bark), the dried bark of various species and hybrids of Cinchona, known in commerce as Red or Yellow Cinchona, which yields not less than 5 per cent of Cinchona alkaloids (6 per cent, of which not less than one-half is quinine and cinchonidine, B.P.). Dose, 1 Gm. (0.6 to 4 Gm.), 15 grains (10 grains to 1 drachm). *Comp. Tincture of Cinchona*, N.F., 10 per cent of cinchona flavored with serpentaria and bitter orange peel. The B. P. is colored red with cochineal. Dose, 4 cc., 1 drachm.

QUINACRINE

Quinacrine (*atabrine, atebrin, mepacrine*), invented by Mauss and Mietzsch, 1933, is an alkyl-amino-acridine derivative with the same side chain as pamaquine. Its antimalarial use was discussed in the preceding section. Like quinine, it acts chiefly on the trophozoites. Its *efficiency* both against vivax and falciparum malaria is generally superior to that of quinine, both for suppression and for clinical treatment. Widespread clinical attacks of falciparum were practically eliminated by its use in the U. S. Army, and deaths from malaria have become extremely rare (C. S. Livingood and Dieuaide, 1945). The therapeutic dosage is usually well tolerated. The *skin* is colored yellow, starting in about a week and persisting for two or three weeks after administration is discontinued. The color is due to the drug, not to bile. The action by mouth occurs so promptly that parenteral administration is rarely necessary. If vomiting prevents oral administration, the doses may be injected by rectum or intramuscularly. Intravenous injection should be avoided, as it involves more risk, especially in view of the slow excretion.

Quinacrine is also effective against *giardiasis*. Administer 0.1 Gm. (1½ grains) by mouth three times daily for five days; then an interval of five days before it is repeated (Morrison and Swalm, 1939). Promising results have been reported in *spotted typhus* (P. van Meerendonk, 1942).

Fate.—Quinacrine is quickly *absorbed* from the intestines, but its *plasma concentration* rises slowly. It is *excreted* by the urine and somewhat by the bile. The urinary excretion starts within fifteen to sixty minutes, but proceeds slowly, a considerable part being retained in the tissues, including the skin.

With the clinical dosage continued for forty-five consecutive days, the *excretion by the urine*, which becomes intensely yellow by the third to fifth day, gradually increases to 6–11 per cent of the daily dose. After the last dose the excretion declines; in fifty-five days it is less than 1 per cent of the original dosage (F. E. Kelsey *et al.*, 1944). Part of the excreted drug is unchanged, part exists as acridine derivatives, varying in different animal species (Scudi and Jelinek, 1944).

The *plasma concentration* of quinacrine rises gradually from the beginning of the treatment and falls slowly on ending. Repeated doses eventually attain an equilibrium (never more than 1 mg. per 100 cc.; Scudi and Hamlin, 1943), about the end of the fourth week, and then continues practically constant as long as the dosage is maintained (J. A. Shannon *et al.*, 1944). A week of constant dosage reaches about half of the eventual level. The equilibrium level can be attained in two weeks if the dosage is doubled in the first week. On discontinuing administration of ordinary doses, the level falls to half in two weeks. Moderate doses of sodium bicarbonate or of alcohol do not affect the quinacrine level (P. K. Smith, Gallup and Cain, 1946).

The *tissue concentration* (fluoroscopic method; L. C. Craig, 1943; J. M. Mason, 1943) is highest in the liver, intermediate in the spleen, kidneys and bone marrow (Scudi and Hamlin, 1943; J. W. Jailer, 1945). It is also found in the brain (Fernando and Wijerama, 1935), and passes into the fetus (F. K. Oldham and Kelsey, 1945). In the liver it is diffusely distributed through the parenchyma, not especially in the Küpffer cells (Jailer, 1945). The amount in the liver may reach 6 per cent of the total dosage; nearly 5 per cent may be recovered from the bile (Annegers *et al.*, 1943).

A characteristic brilliant yellow fluorescence of the finger and toe nails, when illuminated by the Wood light, develops when quinacrine has been taken for a considerable time, as in prolonged suppressive routine. It begins to disappear in three to six months after discontinuing, but some may remain up to a year. The skin, hair and teeth do not have the fluorescence (Ginsberg and Shallenberger, 1946; Kierland *et al.*, 1946).

Toxic effects are not often a serious factor in oral administration of quinacrine, being less than with quinine; that of American manufacture is no more toxic than the original product (O. W. Barlow *et al.*, 1945). It does not produce auditory or visual disturbances; even prolonged administration does not diminish activity of vision in air pilots, except in rare instances (E. A. Abbey and Lawrence, 1946). Nor does its use for ten months produce significant changes in the liver and kidney function or in the blood (B. G. Macgraith, 1945). It does not affect the uterus, so that it may be used safely in pregnancy (N. Sapeika, 1934). The yellow color of the skin should not be a serious drawback. Its intensity is an individual peculiarity, not related to the duration of the administration (E. A. Abbey and Lawrence, 1946).

The most common side effects are dizziness, headache and rather mild *gastro-intestinal disturbances*, nausea, vomiting, sometimes diarrhea, starting several hours after administration.

They occur in a considerable proportion of subjects, especially with suppressive treatment, but decreased materially when the dosage was reduced from 0.2 to 0.1 Gm. (P. H. Long, 1946). They often disappear in a few days if the drug is continued and may generally be prevented by dilution and sodium bicarbonate.

Mild excitement occurs occasionally. More severe psychoses appear exceptionally toward the end of a week of energetic oral, not with suppressive, treatment (J. W. Field, 1943; Sheppeck and Wexberg, 1946); or after intramuscular injection (P. Wilkinson, 1944): erethismus, volubility, confusion, occasionally mania. They return to normal in about a week without treatment.

Hepatitis and other serious complications are rare even when suppressive treatment is continued for a year.

A few patients develop *chronic dermatoses*, lichenoid or eczematous, which may progress to exfoliative. They are more common with larger doses, and yield rather slowly on withdrawing the treatment. A few deaths from exfoliative dermatitis and hepatitis have been reported (C. M. Agress, 1946).

Edema of the corneal epithelium has been reported (F. M. Reese, 1946). It disappeared in three weeks after withdrawal, without permanent damage.

Livingood and Dieuaide, 1945, urge that the routine dosage should not exceed 0.7 Gm. weekly for suppression, or 2.8 Gm. in seven days for treatment; and that administration should be discontinued on the appearance of atypical lichen planus, unexplained chronic eczematoid dermatoses, exfoliative dermatitis, severe leukopenia, agranulocytosis and aplastic anemia, acute hepatitis or toxic pyschoses reasonably attributable to the drug.

Hypodermic or intramuscular injections of quinacrine hydrochloride are irritant and may produce necrosis (F. Hawkins, 1944). *Intravenous injection* of quinacrine is not justified. It may produce accelerated or slowed (gasping) respiration, circulatory collapse and death; or vomiting, fever and psychoses.

Industrial exposure to quinacrine dust gives a high incidence of irritation of the exposed mucous membranes, and especially of dermatoses of varying severity. Local deposition of the dye in the cornea may interfere with vision, but this clears after withdrawal from exposure (O. W. Barlow, Gorham and Bedell, 1946).

The acute toxicity of quinacrine for animals is rather low, and the effects not characteristic. It is a local irritant. Large doses produce gastro-intestinal irritation and cerebral stimulation. Rats show delayed passage of food through stomach and intestines, with gastric hypersecretion and hypertonus (Oxford Malaria Research Unit, 1944). Intravenous injection causes transient fall of blood pressure. It protects the heart against chloroform-epinephrine ventricular fibrillation (K. I. Melville, 1946). Perfusion of 1 to 1.5 mg. per liter through dog heart-lung preparations impairs the contractility of the heart muscle, increases venous pressure and diminishes cardiac output (L. H Smith and Stoeckle, 1946). There is little direct effect on the autonomic organs. The excretion is slow and imperfect as in man (G. Hecht, 1933; De Langen and Storm, 1934).

Continued administration to rats over extended periods produced no perceptible effect on weight or othersiwe with 25 mg. per Kg. daily; 40 to 65 mg. retarded growth (Hegsted *et al.*, 1944). Large oral doses (800 ppm in the diet) cause generalized yellow discoloration; large necrotic foci in the liver, with regenerative changes in the remaining liver tissue; fibrosis and focal necrosis in the cardiac and skeletal muscle; hyperplasia of bone marrow and leukocytosis; marked changes in the adrenal cortex, reticulo-endothelial system and kidneys, death by myocardial fibrosis and liver injury. The toxicity is increased by fasting, diminished by high protein and low fat diet (O. G. Fitzhugh *et al.*, 1945; H. Siegel and Mushett, 1944; Scudi *et al.*, 1944).

***Quinacrine Hydrochloride**, U.S.P.; *Atabrine di-Hydrochloride, Mepacrine Hydrochloride*, B.P.: a yellowish crystalline powder, of bitter taste. Soluble in water (1 Gm. in about 35 cc.), with acid reaction. Average dose, 0.1 Gm., 1½ grains. *Quinacrine Hydrochlordie Tablets*, U.S.P.; usual sizes, 50 and 100 mg., ¾ and 1½ grains.

CHLOROQUINE

Chloroquine, N.N.R., "SN7618," is the most promising of several 4-amino quinoline series drugs that appear superior to quinacrine and quinine in effectiveness against the erthrocytic forms of vivax and falciparum plasmodia. Its potency is about three times that of quinacrine. A single dose per week secures suppression. Acute attacks are terminated in one or at most two days, and falciparum is cured. With vivax it lengthens the interval between treatment and relapses considerably more than does quinine or quinacrine. It does not prevent infection. It is well tolerated, does not produce cinchonism, gastro-intestinal derangement and does not discolor the skin or cause serious dermatites. Its absorption, cumulation and fate resemble those of quinacrine (synoptic report, R. F. Loeb, Clark *et al.*, 1946).

Fate.—Chloroquine, 7 - chloro - 4 - (4 - diethylamino-1-methylbutylamino) quinoline, is practically completely *absorbed* from oral administration. The *urinary excretion* is slow, but rather more rapid than that of quinacrine. The *blood concentration* is somewhat higher than with quinacrine of the same dosage. Considerable amounts are *deposited in the tissues*, proportional to the dose, and distributed similarly to quinacrine. It is concentrated in the nucleated cells, especially in the liver, spleen, kidneys, lungs, and leukocytes to 200 or 300 times its plasma concentration; very little in nervous tissue. The greater part is *destroyed* in the body, as is quinacrine, only 10 to 20 per cent being recovered from the urine; the urinary output is increased by acidification and decreased by alkalinization of the urine. When administration is discontinued, it disappears slowly, the concentration in body fluids falling by about a third in a week.

The toxicity for experimental animals is about the same as with quinacrine, by oral administration, acutely or continued. The intravenous toxicity is somewhat higher for chloroquine.

Clinical side effects in the treatment of acute attacks are mild and transient headache, visual disturbances, pruritus, gastro-intestinal symptoms. Continued use of 0.5 Gm. weekly for eleven months does not produce any serious symptoms or impair general health.

The *dosage* for suppression is 0.3 Gm. once each week. For acute attacks, Most, London *et al.*, 1946, recommend one tablet of 0.3 Gm. when the diagnosis is established by blood smear, repeating this in four hours and on each of the following three mornings, making a total of five tablets (1.5 Gm.) during four days.

It is marketed as **Chloroquine Diphosphate** (*Aralen diphosphate*).

PAMAQUINE NAPHTHOATE (PLASMOQUINE, PLASMOCHIN, AMINOQUIN)

This butylamino quinoline derivative is somewhat effective against the erythrocytic forms of vivax and falciparum plasmodia, but its potency against these is limited, even with maximum tolerated dosage (J. V. Taggart *et al.*, 1946). It acts chiefly on the gametocytes and may be used when these continue in the blood after quinine or quinacrine, to diminish the liability to relapse and to render the patients noninfective to mosquitoes. The administration was discussed in a previous paragraph. It is generally but not invariably successful in these objectives, although it is rather toxic.

Historical.—Plasmoquine was the first substance, outside of quinine and its immediate derivatives, shown to possess distinct antimalarial properties. Its synthesis by Schulemann, Schönhöfer and Wingler, and its introduction as an antimalarial agent by Mühlens and Fischer in 1926, was the achievement of a systematic search for quinine substitutes by the I. G. Farbenindustrie, involving well over a thousand compounds (review, J. H. Williams, 1942).

Fate and Excretion.—The excretion is slow. Considerable amounts are destroyed in rabbits, much less in cats and dogs (Le Heux and von Wijngaarden). Quinacrine interferes with the destruction and therefore increases its plasma concentration to several times the control level. This accounts for the increase of toxicity (T. J. Kennedy *et al.*, 1946).

Clinical Toxicity.—Restricted doses do not produce tinnitus or nausea, but large therapeutic doses may be seriously toxic. Death has occurred with 0.4 and 0.6 Gm. (Cordes, 1927). The individual susceptibility is not predictable, except that it is increased by quinacrine. The usual symptoms are headache and giddiness, cyanosis by methemoglobinemia (Fischer and Weise, 1929), nausea and vomiting, jaundice, sometimes severe abdominal pain, collapse in the more serious cases (J. B. West and Henderson, 1944). Convalescence is protracted. *Hemolytic anemia* occurs in about 5 per cent of the patients, after three to five days of therapy, sometimes gradually. It has no relation to the plasma level or to the presence of malaria or fever. It generally clears promptly on withdrawal (D. P. Earle *et al.*, 1946), but it may hamper recovery from malarial anemia. *Granulocytopenia* is frequent in patients with high dosage. It gradually returns to normal on withdrawal. Other leukocytes are not affected (Zubrod, Knowlton *et al.*, 1946).

Toxicity to animals varies with the species, cats being especially sensitive. Acute circulatory collapse predominates with rabbits; cats and dogs succumb more gradually to methemoglobinemia (Le Heux and van Wijngaarden, 1929). Tskimonauri, 1931, reported that therapeutic doses (0.3 mg. per Kg.) raise the blood pressure and stimulate the respiration. Larger doses lower the pressure and produce dyspnea. The heart was relatively resistant. Eichholtz, 1929, found that intravenous injection of 2 to 3 mg. per Kg. results in A-V block. Pamaquine is not directly antipyretic, for coli fever in rabbits is affected only by toxic doses (Girndt, 1929). The uterus is probably not affected by therapeutic doses. Higher concentrations stimulate, and toxic doses depress (Epstein, 1933). Oral administration to dogs for three to six days induces ocular symptoms, enophthalmos, miosis, relaxation of nictitating membrane, suggesting central depression of sympathetic tone (Moe and Seevers, 1946).

PREPARATIONS.—*Pamaquine naphthoate, Plasmoquine, Plasmochin, Aminoquin Naphthoate*: a yellow powder, practically insoluble in water, nearly tasteless, but with a local anesthetic effect when placed on the tongue. *Dose*, 10 to 30 mg. per day, as pill or capsule.

8-aminoquinolines related to pamaquine hold out promise of curing vivax malaria (R. F. Loeb, Clark *et al.*, 1946). **Pentaquine,** "SN 13,276," 6-methoxy-8-(5-isopropylaminoamylamino)-quinoline is more potent and less toxic than pamaquine, and in conjunction with quinine it appears to cure Southwest Pacific vivax malaria.

Certuna, α-dialkylamino-oxyquinnyl butane, has a clinical gametocidal action similar to that of pamaquine (Kikuth, 1938).

Paludrine ("4888"), an isopropylbiguanide derivative synthesized by Curd and Rose, 1945, is reported to effect clinical cure of vivax malaria, without serious side effects (A. R. D. Adams and Macgraith, 1945).

QUINIDINE

Quinidine, one of the cinchona alkaloids, is the dextro-isomer of quinine, the latter being levorotatory. The actions of the alkaloids agree qualitatively, but quinidine is rather less effective against malaria. Both alkaloids lower the contractility of skeletal and cardiac muscle, and lengthen the refractory period, but with quinidine the depression of contractility is less, and the prolongation of the refractory period relatively greater. It is a valuable agent for controlling auricular fibrillation, especially when this is not due to anatomic lesions.

The *fate* of quinidine is similar to that of quinine. When it is administered by mouth, the capillaries of the liver remove a part from the blood and hold it adsorbed (Bellet, Ravdin and McMillan, 1933). With intravenous injection about 95 per cent leaves the blood stream in five minutes, and 99 per cent within an hour (S. Weiss and Hatcher, 1927).

The effects on skeletal muscle throw light on the mechanism of the cardiac actions: Immersion in quinidine solution (1:25,000) lengthens the refractory period, so that the muscle does not respond to rapid stimulation by the usual tetanus, but by a relatively slow, independent rhythm of contractions followed by a complete relaxation (J. G. Brody and Sollmann, 1923). Such a rhythm would be more favorable to the performance of external work, such as pumping, than the continued tetanus, which consumes more energy, but dissipates it as heat. The latter is essentially the condition of the fibrillating auricle.

Quinidine also suppresses the physostigmine twitching of skeletal muscle in cats (S. Weiss, 1926); it slows markedly the rate of fibrillation of the tongue after hypoglossal section. (This approximates the rate of auricular fibrillation. It is quickened by strophanthin; Buchbinder, 1930). The force of the contractions of the muscle tends to be depressed by quinidine, although not so much as by the quinine; but this is largely compensated by the rest in the refractory pause. Quinidine, quinine, cinchonine and cinchonidine act essentially alike upon striped muscle, but with quantitative differences of practical importance (Brody and Sollmann, 1923; Santesson, 1892; Secher, 1915).

Effects on Normal Heart.—Effective doses of quinidine (or quinine) prolong the refractory phase and thereby slow the conduction and the rhythm. The slowing permits greater filling of the heart, so that the amplitude is increased (Bodo, 1928). The carotid sinus reflexes are diminished or abolished, in man (by 2 Gm.; Nathanson, 1934) as well as in animals (Vercauteren, 1932). *Brief fall of blood pressure* is a constant characteristic of the *intravenous injection* of quinidine, but is apparently quite independent of the cardiac effect and possibly a flocculation phenomenon. The pressure in the pulmonary artery rises with small doses, but with large doses it falls more than the systemic blood pressure does. *Toxic doses* impair the heart, producing sinoauriculo or auriculoventricular block or ventricular fibrillation, or gradual inhibition of the whole heart; the auricles usually cease after the ventricles.

Analysis of the Cardiac Actions.—Intravenous injection of therapeutic doses (5 to 10 mg. per Kg,. corresponding to 5 to 10 grains in man) into normal animals (especially dogs) produces the following effects (Th. Lewis *et al.*, 1922; H. M. Korns, 1923; D. E. Jackson *et al.*, 1922; Cohen and Levy, 1921).

Prolongation of the refractory period, by 50 to 100 per cent. This explains the other phenomena in a large part, if not altogether.

Depression of excitability, i. e., higher threshold of stimulation; greater resistance to extrasystoles; disappearance of extrasystoles (the latter discovered for quinine by Starkenstein, 1907); relief of aconitine and barium irregularities. The decreased excitability is largely a manifestation of the increased refractoriness.

Slowing of the rhythm, sometimes after a temporary acceleration. The rate of the atropinized heart (135 to 190) may be slowed by 30 to 80 beats per minute. This also results from the refractoriness.

Increased amplitude of excursions (16 to 100 per cent), due to greater diastolic filling which results from the longer diastolic pause; therefore, also the result of the lengthened refractory state. The systolic volume is not altered by these doses.

Inconstant effects on the T wave; frequently reversed and changed in volume.

Slowed conduction, auriculoventricular, and also within the auricular and within the ventricular muscle. Toxic doses may produce a 2:1 auriculoventricular block.

Inconstant alterations in the response to vagus stimulation.—Jackson *et al.* found the response generally increased. Lewis *et al.* found little effect on the response of the sinus rate, but the decrease of A-V conduction normally produced by vagus stimulation was materially smaller under quinidine, and in some cases vagus stimulation produced even an increase of conduction. This "vagus" reversal was studied by Dale, 1922, who considered it analogous to the effect of nicotine and curare, and distinct from that of atropine.

For blocking cardiac inhibition by maximal vagus stimulation in dogs, quinidine is twice as potent as cinchonidine and cinchonine, and three times as potent as quinine, referred to plasma concentrations (Hiatt, Brown *et al.*, 1945).

The *frog heart* is depressed by quinine (Santesson): the heart is slowed by 1:50,000 solution and weakened in its contraction; its effectiveness is consequently diminished. The slowing occurs after atropine, and is therefore muscular. A 1:5000 solution kills the heart in a few minutes. Segments of the apex of the ventricle also respond by weakened contractions, and increased refractoriness is shown by higher resistance to tetanization (Sasaki, 1921). In strong solutions the dextrorotatory cinchonine and quinidine are less depressant than the levorotatory quinine and cinchonidine (McK. Cattell and Cattell, 1926).

Turtle Heart.—Electrically driven segments of the auricle and ventricle respond to quinidine chiefly by increased threshold for electric stimulation. The conduction of the muscle is raised. The refractory period is not materially altered in these preparations (Wedd *et al.*, 1942). In intact hearts, all the cinchona alkaloids diminish the amplitude and frequency, ending in diastolic arrest. The levo-bases (quinine and cinchonidine) are more toxic than their dextro-isomers (Fredericq and Terroine). W. S. Love, 1926, reported that both quinidine and strophanthin cause a slight shortening of the refractory period in the intact turtle heart. On this basis, Lewis and Drury, 1926, interpreted the prolongation of the "effective refractory period" under quinidine, strophanthin and veratrine as concerned with the spreading of the impulse rather than with local recovery of excitability.

Perfused Mammalian Heart.—F. B. Hofmann, 1920, found considerable increase of the resistance of the auricles to electric extrasystoles and fibrillation under quinidine. It also lowered the force of the contractions, without much change in rate. Larger doses abolish the contractions and render the muscle inexcitable. Further studies were made by Boden and Neukirch, 1921.

Quinidine against Auricular Fibrillation.—The lengthening of the refractory period is utilized clinically to combat auricular fibrillation (Th. Lewis, 1922; Clerc and Pezzi, 1922; H. M. Korns, 1923). Quinidine gradually slows the high rhythm of the auricles, and in about half the cases this terminates in a sudden cessation of the fibrillation and return to the normal heart rhythm. While the auricular oscillations are slowing, the ventricular contractions increase in regularity, but also in rate, toward a 1:3 or 1:2 rhythm, until the normal rhythm is restored. This may be attained in one to three days, sometimes with only a total of 0.6 Gm. of quinidine. The normal rhythm may then persist indefinitely without medication. In other cases the quinidine medication must be maintained continuously day and night; and in others again the quinidine fails to break up the fibrillation.

Mechanism of Quinidine in Auricular Fibrillation.—The prolonged refractory state tends to render the auricular muscle incapable of maintaining the rapid rate characteristic of fibrillation. It also tends to break up the circuits of auricular excitation which Garrey, 1914, and Lewis, 1921, considered the mechanism of the rapid rate; for the wave of excitation would die out when it found the muscle inexcitable on completing the circuit; and with the cessation of these stimuli, the sinus rhythm would resume its pace-making function. The auriculoventricular block resulting from the excessively numerous stimuli would diminish; partly because fewer stimuli arise and partly because the refractoriness of the bundle would also be increased by the quinidine, so that it would not be affected by the majority of the stimuli. The stronger and more regular impulses set a pace that the ventricles can follow; at first, imperfectly, *i. e.*, with a partial block. So long as fibrillation persists, this blocked ventricular rhythm would be faster than the more completely blocked rate that obtained before the quinidine; but the ventricular rhythm would be much more regular, and much more efficient for the propulsion of the blood. When the circuit of fibrillation or the unfavorable cycle of rapid rate:short refractory period, is broken and the normal length of the pendulum of strong refraction and strong contractions is reestablished, the latter tends to perpetuate itself automatically. If the original cause of the fibrillation persists, it may reproduce the fibrillation when the quinidine has been excreted, and continuous administration may be necessary. In nearly half the cases quinidine is unsuccessful. It is conceivable that the conduction may sometimes be so much slowed that the excitability of the muscle is restored before the circuit is completed, notwithstanding the prolonged refraction; but the failure may sometimes be due to failure to reach and maintain an adequate dosage, because of fear of the dangers of the drug. Failure is most frequent in cases of long standing, with marked cardiac insufficiency. The most favorable cases are those of short duration or of paroxysmal type.

Administration.—Quinidine sulfate may be administered in capsules or tablets. The susceptibility of the patient is tested by a dose of 0.2 Gm., which is repeated in two hours. If there are no bad effects, the regular dosage is started on the following day, with 0.2 to 0.4 Gm. three to five times per day, generally not exceeding 2 Gm. per day. If no benefit follows within three days, quinidine is generally considered unsuccessful and its administration is stopped. In case of complete success, the drug may be omitted, and readministered on recurrence. The maintenance dose is about 0.25 Gm. per day. If toxic manifestations occur, it should be discontinued. Prolongation of the Q-T interval furnishes a criterion of quinidine action. With 0.2 to 0.35 Gm., the full action is attained in one and one-half to three hours (also with intramuscular injection). It fades in eight hours. Administration at two hour intervals gives cumulation (Sagall *et al.*, 1943).

Previous digitalization may perhaps increase the chances of success and diminish the danger of accidents. It prevents the ventricular tachycardia that sometimes occurs in quinidine therapy (T. Lewis *et al.*, 1922). Quinidine is more depressant and toxic to skeletal muscle when this is overloaded and fatigued. Presumably this holds also for the heart, and would be counteracted by digitalis. On the other hand, digitalis would reinforce the beneficial lengthening of the refractory period. Conversely, quinidine counteracts the "toxic irregularities" of digitalis (C. C. Haskell, 1928; Kwit and Gold, 1934). It is well to observe that the two drugs produce prolonged refraction and slowed conduction by absolutely different mechanisms: the digitalis by the increased force of the preceding contraction, the quinidine by the slowing of the restorative metabolism.

Accidents.—In susceptible individuals, quinidine may produce phenomena similar to those of quinine hypersusceptibility, *i. e.*, nausea, vomiting, convulsions, palpitation, headache, faintness and flushing. Occasionally, but rarely, quinidine may change auricular fibrillation to more serious irregularities, intra-auricular block, ventricular tachycardia and fatal ventricular fibrillation. The frequency of fatal incidents in auricular fibrillation is no greater with than without quinidine (Viko, Marvin and White, 1923; H. L. Smith and Boland, 1939). Cumulation need not be feared, since quinidine is rapidly excreted.

Other cinchona alkaloids have the same effect in auricular fibrillation, and are interchangeable with quinidine within a limited range, but their action is not so potent, regardless of dosage (H. Gold, Modell *et al.*, 1946).

Synthetic substitutes have been studied for cardiac actions by G. S. Dawes, 1946.

Ventricular Fibrillation.—Mautz, 1936, found quinidine effective in reducing cardiac irritability in surgical operations on the heart. Wégria and Nickerson, 1942, 1943, showed that it raises the fibrillation threshold to faradization and to epinephrine.

Use in Other Cardiac Irregularities.—R. W. Scott, 1922, found the continued administration of quinidine completely successful in arresting and preventing *ventricular tachycardia.* Pezzi and Clerc, 1930, reported favorable clinical effects from quinine against extrasystoles, paroxysmal tachycardia and auricular fibrillation. They administered 0.5 Gm. by mouth, two or three times per day. J. H. Wyckoff and Otto, 1926, found quinine ineffective in patients who responded to quinidine. Quinidine was effective in preventing attacks of *paroxysmal auricular tachycardia,* both spontaneous and induced by epinephrine (H. L. Otto and Gold, 1926). This may require larger doses, but 2 Gm. of the sulfate per day generally suffice, and may be continued for weeks without evidence of injury; however, as much as 4.8 Gm. (0.6 Gm. every three hours) is sometimes needed. It does not slow the rate of *sinus tachycardia,* including that of *thyrotoxicosis;* but it is effective against auricular fibrillation in this condition (P. S. Barker *et al.*, 1943).

PREPARATIONS.—***Quinidine Sulfate,** U.S.P. (Quinidin. Sulf.), $(C_{20}H_{24}O_2N_2)_2.H_2SO_4.2H_2O$, occurs as needle-like white crystals, very bitter, soluble in water (1:100). Average dose, 0.2 Gm. *Quinidine Sulfate Tablets,* U.S.P.; usual sizes, 0.1, 0.2 and 0.3 Gm., 1½, 3 and 5 grains.

HYDROCUPREINE DERIVATIVES

The alkyl derivatives of hydrocupreine were found by Morgenroth to have a high bactericidal efficiency, even in the presence of protein; and at the same time a relatively low toxicity to the tissue cells. They were therefore proposed as tissue antiseptics, both for local and systemic application. The germicidal power varies specifically for different bacteria. Ethylhydrocupreine ("optochin") is especially toxic to pneumococci; while higher homologues, such as "eucupine" and "vuzin" are more efficient against pus organisms. The effects of various new derivatives on *pneumococci in vitro* and on guinea pigs were reported by Gundel and Seitz, 1933. Eucupine and vuzin were introduced by Morgenroth, 1917, as wound antiseptics. Enthusiastic reports were published, especially in the German army. They were also employed in pleural empyema; but their use has not spread. Their pharmacologic actions agree in most respects with those of quinine. The literature is reviewed by Bijlsma, 1920, and Bruhn, 1919. Eucupine is iso-amyl hydrocupreine (the alkyl replacing the first C_2H_5 in the quinoline); and vuzin is iso-octyl hydrocupreine.

ETHYL-HYDROXYCUPREINE (OPTOCHIN)

This drug has a special toxicity for *pneumococci* (Morgenroth and Halberstaedter). It is successful against experimental pneumonia in mice, but much less successful in man (Moore and Chesney, 1918). Its application is further limited by the fact that efficient doses are liable to produce retinitis and blindness. It appears to be of some value locally in pneumococcic infections of the eye.

Ophthalmic Use.—Optochin hydrochloride is used locally as antiseptic, irritant and anesthetic in conjunctivitis, and on ulcers, especially ulcus corneae serpens. A fresh 1 or 2 per cent solution is applied, at first every two hours (Bedell, 1920). The first instillation is painful, but this is followed by *local anesthesia,* lasting one-half hour or longer (Morgenroth and Ginsberg, 1912 and 1913). Weaker concentrations are ineffective; 1 per cent does not cause permanent damage, but stronger solutions injure the cornea. Subconjunctival injections of ½ to 1 per cent also produce local injury (R. Schneider, 1920).

Bactericidal Action on Pneumococci.—*In vitro,* the drug inhibits the growth of pneumococci with a concentration of 1:800,000 in serum; it kills them with 1:400,000 (Wright, 1912). The action is slow with low concentrations, and increases in speed with the concentration. Serum reduces the activity to ⅕ or ⅒ (Cohen, Kolmer and Heist, 1917). Solutions in blood are even less active than those in serum; but the entire blood is more active than the serum separated from it, since the corpuscles take up a higher percentage of the drug (Morgenroth, 1918). All strains of pneumococci, as also some streptococci, are inhibited *in vitro* by concentrations of 1:100,000; whereas other streptococci, meningococci and gonococci require 1:10,000-5000. However, transition races are occasionally found. Quinine requires much higher concentrations. Optochin also increases greatly (potentiates) the efficiency of antipneumococcus serum (H. F. Moore, 1915).

Phagocytosis.—Optochin (and quinine) accelerate the phagocytosis of pneumococci (Cohen *et al.*).

Experimental Pneumonia.—Morgenroth, 1911, found optochin more effective than quinine against trypanosome and pneumococcus infections of mice. With these, optochin is effectively prophylactic in 90 per cent, and curative in 50 per cent of the experimental infections (Morgenroth and Levy; Engwer, 1912). The serum of rabbits is bactericidal after hypodermic doses of 0.1 Gm. per kilogram, which are well tolerated. Larger doses are usually toxic. Oral administration is not so effective (Moore, 1915).

Blindness occurs frequently, even with the ordinary therapeutic doses, such as 1.5 Gm. per day. Fraenkl, 1915, obtained some degree of amblyopia in 10 per cent of his series. The disturbance of vision generally starts abruptly and is usually severe, often progressing to complete amaurosis. The pupils are maximally dilated. If the drug is stopped, the vision usually improves, after a few days, but sometimes only after months; and even in the more favorable cases there remains more or less restriction of the visual field, central scotoma and impaired color vision (literature, A. Adler, 1916).

The *pathology* is similar to that from quinine (literature, Adler, 1913; experimental, Hirschfelder, 1915).

Other Side Actions.—The susceptibility to these varies greatly in different individuals. Temporary cinchonism and vomiting are frequent (Seifert, Nebenwirk, 1915).

Administration.—The daily dose of 0.024 Gm. per Kg

(1.5 Gm. per 60 Kg.) should be divided so that a fraction (*i. e.*, 0.15 Gm.) is taken every two and one-half hours, to maintain a constant concentration in the blood. There is a slight accumulation, and the drug should not be continued more than three or four days. The vision should be carefully tested throughout.

Other Infections.—Izar and Nicosia, 1914, used it against malaria because the cinchonism is shorter than with quinine. Levy, 1912, also claimed a curative effect against Streptococcus mucosus.

Hay Fever.—Hacke, 1919, reported good results from swabbing with 1 per cent optochin hydrochloride. Confirmation is required.

The **pharmacologic actions** correspond qualitatively with those of quinine, but are more toxic. Intravenously, optochin is more depressant to the heart; the blood pressure, however, falls less than with quinine, since there is also vasoconstriction (Smith and Fantus, 1916; Doeschate and Laeuwen, 1917). The antipyretic efficiency of optochin is smaller (Smith and Fantus). It has but little inhibitory action on the emigration of leukocytes (Ikeda, 1916).

Fate.—The alkaloid disappears rapidly from the plasma after intravenous injection. It persists longer and in greater amount in the corpuscles (Boecker, 1915).

PREPARATIONS.—*Ethylhydrocupreine Hydrochloride*, N.F., *Optochin*. Very soluble in water (1:2).

◆

ANTIPYRETIC ANALGETICS

Certain groups of pyrrole, benzene, aniline and quinoline derivatives are antipyretic, increasing heat loss in fever, mainly by mobilizing water, like the nonspecific action of quinine. They also relieve the discomfort of "colds," and the pain of headache, dysmenorrhea, neuralgias, neuritis and rheumatic conditions, but they are not very effective against acute traumatic pain. They are often harmless, but may develop toxic reactions with little or no warning, and some are subject to allergy. This group of drugs includes the pyrazolon derivatives, antipyrine and aminopyrine; the paramidophenol derivatives, acetanilid and acetophenetidin (phenacetin); the salicylates and the quinoline derivative cinchophen.

The **antipyretic action** is discussed under Temperature Regulation (see Index). In general, the extent of the antipyretic action increases with the dose of the drug from the smallest effective dose (0.2 Gm. for acetanilid, 0.5 to 0.7 Gm. for antipyrine or acetophenetidin), until the normal temperature has been reached. Up to this point there is little danger of a direct collapse action. But if the dose necessary to secure this result is exceeded, the toxic effects set in. The *full antipyretic* dose may be stated as 0.5 Gm. (7 grains) of acetanilid; 0.8 Gm. (10 grains) of acetophenetidin, 1 Gm. (15 grains) of antipyrine.

In beginning the treatment, this dose has to be repeated once or twice, with an hour's interval, until the desired fall is secured. After this, the single dose is repeated whenever the temperature begins to rise. Four or five doses are required per day to keep the patient practically fever free. The action does not persist after the drug is excreted. With single doses the antipyretic effect reaches its maximum in about two hours, and then declines gradually, so that the febrile level is practically restored in eight hours (Gottlieb, 1890). *Synergism by magnesium* with the antipyretic action of this group was reported by Barbour, Winter and Richey, 1930.

Undesirable side actions are rather common, especially when full antipyretic doses are used. Susceptibility to these differs. *Sweating* and *chills* are part of the temperature regulation. Nausea and other phenomena of *cinchonism* are necessary concomitants of full salicylate dosage (salicylism), but are exceptional with the others. Sodium salicylate rarely has other material side actions, but it may produce temporary renal irritation. Large doses of acetanilid may cause *cyanosis*. *Skin eruptions*, including generalized erythema, urticaria and angioneurotic edema, occur especially with antipyrine and aminopyrine. Free salicylic and acetylsalicylic acid tend to produce *gastric irritation* and acidosis and may require to be guarded by alkalis. Collapse may occur, with weak and irregular pulse, dyspneic or shallow respiration, pale or cyanotic skin, cold sweat, disturbed consciousness, subnormal temperature, and death by circulatory failure. The collapse action is strongest in the "mother substances"—aniline, quinoline, phenetidin, phenylhydrazine, and phenol—and generally in the members of the antiseptic group; so strong, indeed, that the action of these cannot be safely controlled. Of the more usual antipyretics, acetanilid produces probably the strongest direct collapse effects; then comes antipyrine, then acetophenetidin, then salicylates. Direct collapse, however, is rare if the dosage is kept within reason. Sometimes it is due to the reduction of the febrile temperature, "unmasking" a preexisting febrile collapse. Caution is necessary in the use of all antipyretic measures in asthenic fevers. Menstruation also favors the development of collapse. *Allergic reactions* of various kinds may occur, including edema of the mouth and respiratory passage (asthma), especially with acetylsalicylic acid; malignant *neutropenia* with antipyrine and aminopyrine; and *hepatitis* with cinchophen. They will be considered under these drugs. The *treatment of acute poisoning* by overdoses of the antipyretics is by evacuation and stimulants, heat, and so forth. The **analgetic action** is secured by relatively small doses, such as acetylsalicylic acid, acetophenetidin or aminopyrine, 0.3 Gm., 5 grains; acetanilid, 0.2 Gm., 3 grains; acetylsalicylic acid, 0.3 Gm., 5 grains; sodium salicylate, 0.6 Gm., 10 grains; repeated in three hours, if necessary. If these doses fail, larger doses are usually also ineffective, except in rheumatic fever, where the dosage must be pushed to salicylism. The *mechanism of the analgesia* is obscure. It may occur without dulling of consciousness, nor do antipyretics reinforce the actions of ordinary narcotics to a marked degree (Lomonorsoff, 1911). The appreciation of tactile sensations or of traumatic pain is but little dulled. The effect on headache may be due to relief of intracranial pressure by mobilization of excess water, as in the antipyretic action; it may be imagined that something of the kind takes place in the relief of neuralgia.

Analgetic efficiency may be measured in man by the amount of heat radiation necessary to produce pain when applied to the skin of the forehead. This threshold is raised by analgetic drugs to a certain limit. The following are the average doses required to produce the maximal analgesia of which the drug is capable, and the average per cent by which this raises the pain threshold: Dilaudid, 3 mg., or metopon, 6.6 mg., or morphine sulfate, 30 mg., each *100 per cent;* codeine phosphate, 60 mg., *50 per cent;* ethyl alcohol, 30 cc. or trichlorethylene inhalation, *40 per cent;* acetanilid, acetophenetidine or acetylsalicylic acid, or aminopyrine, 0.5 Gm., *35 per cent;* evipal, 0.5 Gm., *20 per cent;* caffeine or quinine or ergotamine, *none.* Combinations are merely additive. Higher doses increase the duration, but not the degree of analgesia. The appreciation of heat as such is not decreased by salicylate. *Suggestion* with a placebo may raise the threshold by 30 per cent. *Prejudice,* anxiety and doubt may make acetylsalicylic analgesia practically ineffective (H. G. Wolff *et al.,* 1940, 1942, 1943). By a similar method (D'Amour and Smith) applied to rats, the analgetic potency in comparison with acetylsalicylic acid (= 1) is: aminopyrine, less than 0.6; acetophenetidin, 0.8; antipyrine, 2.0; acetanilid, 2.6; sodium salicylate, 3.6; salicylamide, 7.5 (E. R. Hart, 1946).

Psychologic Experiments on Man.—Quinine, antipyrine and acetophenetidin in doses of 1 Gm. produce marked impairment in mental efficiency tests (Muensterberg, 1892). Analgetic doses (0.025 to 0.5 Gm.) do not impair neuromuscular coordination, as judged by the "tapping test," but they retard the reaction time (Macht *et al.,* 1918).

Sensations other than pain are not materially affected by therapeutic doses of analgetics (acetylsalicylic acid, opiates, alcohol, barbiturates; Wikler *et al.,* 1945). *Cutaneous sensibility,* when tested with bristles, shows only slight and questionable changes. Some experimenters report increased threshold (Martine *et al.,* 1915; Hale and Grabfield, 1923; P. K. Smith, 1937); but Mullin, 1937, found no significant effect on cutaneous tactile and pain sensation, not even when headache was relieved. The *acuity of hearing* is decreased by the salicylates, but rather increased by small doses of other antipyretics, including quinine (Macht *et al.,* 1920). The discrimination of musical pitch appears to be diminished by all.

Addiction to antipyretic analgetics would not be expected in normal individuals, as these drugs do not produce appreciable effects unless headache or other aches are present. In most cases, the habitual use is prompted and maintained for the relief of pain, headache or menstrual distress. It may develop toxic symptoms, especially cyanosis with acetanilid and acetophenetidin; but it is a superficial habit rather than a firm addiction, and withdrawal does not cause marked reaction. A few individuals feel euphoria, and these may develop addiction, with considerable reaction (restlessness and excitement, sometimes maniacal) on abrupt withdrawal (Payne).

Proprietary headache powders usually contain from 50 to 70 per cent of acetanilid or acetylsalicylic acid, or mixtures of these, often with caffeine, bromides, ammonium carbonate or sodium bicarbonate. The caffeine and bromide may reinforce the analgetic action. Mixtures of acetophenetidin, acetylsalicylic acid and codeine are said to be somewhat less toxic than would correspond to the sum of their components (S. Loewe *et al.,* 1927), but this requires confirmation. The alkalis were supposed to increase the solubility, but do not do so (Puckner, 1906). It was also claimed that all these drugs diminish the toxicity, but even caffeine lacks this effect (E. D. Brown and Moorehead, 1925). The indiscriminate use of the powders by the laity has repeatedly produced acute and chronic poisoning. The use of aminopyrine in such powders, which is especially dangerous, has greatly diminished. When the new Food and Drug Regulations became effective, the sale of acetanilid in the United States decreased from 986,000 to 427,000 pounds between 1937 and 1939, while the sale of acetylsalicylic acid increased from 2,500,000 to 5,300,000 pounds.

Synergism with Hypnotics.—Small doses of the antipyretic analgetics, including quinine, augment somewhat the sedative effect of hypnotics and perhaps conversely (Starkenstein, 1925; Loewe, 1927; Steinmetzer, 1928). Mixtures of aminopyrine and various barbiturates had a considerable vogue before the casual connection of aminopyrine to granulopenia was realized. The practical advantage of such combinations is probably not great. Pohle and Nietschmann, 1938, believe that the analgetic action is weakened, not potentiated.

Barbiturates decrease the acute toxicity of amino pyrine by a third (C. L. Rose, 1935), but aminopyrine does not confer protection against barbiturate (Pohle and Nietschmann, 1938).

PYRAZOLON DERIVATIVES: ANTIPYRINE (PHENAZONE) AND AMINOPYRINE (PYRAMIDON)

These are feeble bases, readily soluble in water (antipyrine, 1:1; aminopyrine, 1:18), differing in this respect from the acetanilid group. Antipyrine is used chiefly as antipyretic, and aminopyrine as analgetic (see the preceding section). The discrimination is perhaps merely traditional. Aminopyrine is about three times as potent as antipyrine. Its tendency to malignant granulopenia makes its use unsafe. Two to 5 per cent solutions of antipyrine are employed in the mouth and throat and in cystoscopy, and 0.4 per cent on the conjunctiva, for mild local anesthesia. This is preceded by smarting.

The **antipyretic action** has been discussed in the preceding sections on antipyretics (see Index).

Heat loss is considerably increased in normal animals, and the increase is several times greater in fever (Gottlieb, 1891). Calorimetric data show a moderate compensatory increase of *heat production*, more marked at normal temperature than in fever. The metabolism data are contradictory (review, S. Weber, 1904). Excessive doses (0.75 Gm. in rabbits) diminish heat production, presumably by incipient collapse. The *nitrogen metabolism*, with therapeutic doses and normal temperature, shows generally no change or some fall. Large doses often increase the nitrogen excretion, especially in man. In fever, therapeutic doses decrease the excessive nitrogen metabolism. Therapeutic doses with normal temperature produce no change or some decrease of *carbon dioxide metabolism*. Larger doses (2 to 3 Gm. of antipyrine for man) produce a small but unmistakable decrease in both gaseous exchange and nitrogen excretion (incipient collapse?). The effect on carbon dioxide metabolism is also inconstant in fever. Therapeutic doses may somewhat increase or diminish the CO_2 excretion, or leave it practically unchanged. *After the fall of temperature has set in*, the carbon and nitrogen metabolism are commonly lowered. This may be ascribed to the removal of the hyperpyrexia, for metabolism is naturally less active at the lower temperature. Antipyrine, and especially phenacetin and acetanilid, decrease the arterial oxygen; the CO_2 is less changed (Piccini, 1912). The *respiration of excised muscle* is not affected by antipyrine (in contrast to quinine and salicylate) unless high concentrations are used (Senta, 1908). The oxygen uptake of rat tissue is diminished by 20 to 30 per cent when aminopyrine, M/4500, is added. Antipyrine is inactive (Bernheim, 1939).

Side Actions.—Large doses of antipyrine and its derivatives produce collapse effects essentially identical with those of the acetanilid group which may result in considerable fall, even of the normal temperature, proportionate to the metabolic rate (Githens, 1925). These drugs have less effect than acetanilid on blood, but are much more likely to cause skin eruptions.

Antipyrine Eruptions.—With susceptible individuals, these occur promptly even after small doses; in the form of round or oval erythematous somewhat pigmented patches, which may become bullous. When the drug is discontinued, these are replaced by pigmented areas, which become rapidly congested if another dose is taken (H. MacCormac). It has been claimed that the hypersusceptibility may be desensitized by small doses (Widal and Vallery-Radot, 1920).

Fate.—Antipyrine and aminopyrine are eliminated largely unchanged by the urine (Jonescu, 1906), partly as glycuronate, which reduces Benedict's reagent, but does not ferment with yeast (Enkelwitz, 1935). Traces are excreted by the sweat (Tachau, 1911) and sputum (Hofbauer, 1915). The urine volume is generally decreased. Occasionally the urine is blood-red, and green in reflected light (Penzoldt). Aminopyrine urine contains several derivatives, including rubaconic acid, which gives a red color to acidified urine (Halberkann and Fretwurst, 1940).

PREPARATIONS.—*Aminopyrine*, U.S.P. (Amidopyrine; Pyramidon), occurs as a white, crystalline, odorless powder; soluble in water (1:18) and alc. (1:1.5). Dose, 0.3 Gm., 5 grains, generally administered in tablets and only once a day. *Aminopyrine Tablets*, U.S.P., usually 0.3 Gm. ***Antipyrine** (Phenazone), is a white, crystalline, odorless, slightly bitter substance; sol. in water (1:1) and alc. (1:1.3). Incompatible with nitrites (Sp. Aeth. Nitrit.), tannins, calomel and sodium salicylate. Average dose, 0.3 Gm., 5 grains; maximum dose, 1 Gm., 15 grains; in solution, powders or capsules.

AGRANULOCYTOSIS: ITS CAUSATION BY AMINOPYRINE AND OTHER DRUGS

Agranulocytosis, agranulocytic angina, malignant neutropenia, or granulopenia, is a syndrome of blood changes, systemic symptoms and local lesions in the mouth and sometimes other mucous membranes. It often begins with severe pharyngitis and ulceration of the mucous membranes of the mouth and throat as in Vincent's angina, but with a different etiology and blood picture. The characteristic feature is a marked decrease of the polymorphonuclear neutrophile leukocytes, without significant decrease of the red blood cells and hemoglobin. There is marked prostration, and if the agranulocytosis becomes complete, the outcome is always rapidly fatal (four or five days), often by an intercurrent infection, presumably through loss of resistance. The mortality in untreated cases is nearly 75 per cent. The condition was first described as a clinical entity by W. Schultz, 1922.

Causation by Drugs.—R. R. Kracke, 1931, and Madison and Squier, 1933, noted that most cases of agranulocytosis were connected with the use of *aminopyrine* or its compounds, generally either in large doses or over long periods. Although this occurs only in a small proportion of its users, and therefore requires a special susceptibility, the causal connection is definitely established.

The incidence of agranulocytosis was highest when this drug was most widely used (Kracke and Parker, 1934); it has waned in the United States since the use has become restricted, and it has practically disappeared in Denmark, where aminopyrine is no longer sold (Kracke, 1938). Cautious administration of aminopyrine to susceptible individuals produces the disease at will (Sturgis, 1935; Dameshek and Colmes, 1936; Benjamin and Biederman, 1936). Kracke, 1938, estimated that about 80 per cent of the clinical cases are due to aminopyrine or its compounds.

Most of the remainder are due to other drugs, chiefly to dinitrophenol, arsphenamine, sulfanilamide and "novalgin" (a derivative of aminopyrine); more rarely to acetanilid, acetophenetidin, cinchophen, quinine, organic antimony compounds, and gold salts. A few cases probably occur without drugs. Barbiturates apparently do not cause it. The *hypersusceptibility* may develop suddenly after short or long usage (Holten, 1937). Once developed, it appears to persist indefinitely. It probably belongs to the group of conditioned toxicoses, which Landsteiner and Jacobs, 1935, suggested may be due to alterations induced in some tissue protein which render this antigenic. The bone marrow and blood appear to be rather subject to such reactions, as seen also in thrombocytopenic purpura, hemolytic anemia, pancytopenia and leukemoid reactions (Fitz-Hugh, 1938). The *susceptibility of animals* to the neutropenic action appears to vary as widely as that of man.

Kracke and Parker reported that the administration of these drugs to rabbits produces injury of the bone marrow, with decrease in the neutrophils, thrombocytes and blood platelets. Similar effects are produced in dogs (Butt *et al.*, 1939), but they require much greater doses, so that their identity with the clinical phenomenon is not certain. Interference with the normal leukocytic response to nucleic acid injection has been reported in rabbits treated with antipyrine and other drugs suspected of producing clinical leukopenia, with doses that did not lower the number of leukocytes in normal animals (Climenko, 1935); but the dosage was still far beyond the therapeutic range. D. K. Miller and Rhoads, 1937, reported that the bone marrow changes occur with smaller doses of aminopyrine in dogs with dietary insufficiency ("black tongue" diet). On the other hand, Stenn, 1935, found no change in the blood picture of numerous guinea pigs, rabbits and monkeys, kept for over eight months on aminopyrine, with doses so large as to cause diarrhea, stupor, malnutrition and some fatalities. The changes caused by hemorrhage, starvation, infections or benzene poisoning, were not modified by aminopyrine. Filo, 1937, reported that aminopyrine produces hemolytic and regenerative anemia in guinea pigs, with increase of reticulocytes, normoblasts and leukocytes, including granulocytes.

Pathology.—The blood changes start before the fever and necrosis of the mucous membranes, so that they are not caused by these. The primary lesion appears to be a "maturation arrest" ("anakmesis") in the bone marrow, which is filled with young granulocytes and is poor in mature cells (Darling *et al.*, 1936; Fitz-Hugh, 1938). Stenn, 1935, described degeneration of the myeloid cells. Parker and Kracke, 1936, reported that *glutathione* is depleted in leukopenic patients and animals and suggested that this agent may play an important part in regulating bone marrow activity, and that its deficiency may be the starting point of leukopenia (review, W. Dameshek, 1936).

Kracke and Parker found *quinone* ($C_6H_4O_2$) and *hydroquinone* especially active in rabbits. These occur among the products of decomposition of the benzol derivatives in the body, and these writers suggest that the different neutropenic liability depends on the facility with which these decomposition products, especially hydroquinone, are formed.

Treatment of agranulocytosis has been attempted by transfusion, and by stimulating the bone marrow through injection of pentonucleotide; but severe cases generally die in spite of this treatment, and light cases recover spontaneously. The most promising approach is through bacteriostatic agents, penicillin and sulfonamides. The grave dangers of agranulocytosis enjoin great care in the use of aminopyrine, especially in analgetic mixtures, which are likely to be taken in excess. It should be used only on patients of known tolerance, and then only in small doses and for short periods. It should be stopped immediately if pharyngitis develops, or if the neutrophils decrease.

PARAMINOPHENOL DERIVATIVES (ACETANILID, ACETOPHENETIDIN)

The antipyretic and analgetic actions and uses of these *"coal tar antipyretics"* are discussed in preceding sections. They are effective, but the antipyretic doses are liable to produce undesirable side actions, and their use is believed to entail some danger of circulatory collapse, especially with acetanilid, but this is rare. Their continued use against headaches may cause chronic poisoning, especially cyanosis. These drugs are relatively insoluble, and are therefore used as powders or tablets. Their taste is not seriously objectionable.

Structure and Antipyretic Action.—The large number of antipyretic benzene derivatives differ quantitatively in their actions, with definite relations to their chemical structure. Salicylate, acetophenetidin and acetanilid are the most useful representatives, and the others may well be spared. Manufacturers introduced almost numberless antipyretics; but the number of really new and valuable products is small. The great mass of this material consists of insignificant variations in the established products.

The antipyretic action resides in the benzene ring, but benzene (C_6H_6) itself is not antipyretic, because it cannot readily enter into reaction with the body cells; this capacity of reacting may be given to it by substituting for one of its [H] atoms an [OH] group, as in phenol, C_6H_5OH; or still more strongly by an NH_2 group, as in aniline, $C_6H_4.NH_2$ (phenylhydrazine, $C_6H_5NH.NH_2$ being stronger); or by both as in paramidophenol, $C_6H_4OHNH_2$.

These aromatic alcohols and amides are called the "mother substances" of the antipyretic drugs. They are strongly antipyretic, but they also produce collapse. Before they can be used in practice, this collapse action must be diminished. This may be done by replacing the [H], either of the [OH] or of the [NH_2], by other radicals; the reduction of toxicity is greatest if the substitution is made in the NH_2. These substituted compounds act only after the mother substance is liberated from them in the body. Their action is therefore more gradual, less violent, and more easy of control. The reduction of toxicity is greatest if the substituted radical is an alkyl; less if it is an acidyl. If several H atoms are substituted, the toxicity is less if both an acidyl and an alkyl radical are introduced, than if both radicals be of the same kind. The toxicity and the therapeutic qualities *both* diminish with the size of the introduced radical. The most useful is the ethyl (C_2H_5) or acetyl (C_2H_3O) radical; with the methyl or formyl group, the toxic action is too great; with larger groups, and particularly with aromatic groups, the compound becomes so resistant that the therapeutic action is reduced almost to nothing. These laws must be modified if the compound is decomposed in the stomach with liberation of the mother substance. The radicals must be introduced into the ring by substitution; the mere addition of acid radicals, forming salts, does not modify the properties of the original substance. Therefore aniline acetate ($C_6H_5.NH_2.HC_2H_3O_2$) preserves the original toxic action of aniline; whereas this is greatly weakened in acetanilid ($C_6H_5.NH.C_2H_3O$). The substitution of an H by I, Br or Cl, does not modify the antipyretic or toxic action of the original substance. *Para-acetylaminophenyl urethanes* were reported by Cox, Eikler and Shriner, 1931, to be rather feebly antipyretic and not hypnotic.

Fate.—The antipyretics are rapidly absorbed and excreted. Acetanilid, acetophenetidin and their derivatives are mainly oxidized to paraminophenol (Hinsberg and Treupel, 1894), which is probably the form in which they produce their actions (A. G. Young and Wilson, 1939). This is excreted in the urine, chiefly as paired compounds with sulfuric and glycuronic acids. In man, acetanilid is oxidized to para-acetyl aminophenol (Mörner, 1889). It gives the "indophenol reaction" in the urine.

Notwithstanding its limited solubility, *acetanilid* is absorbed practically completely by rabbits even with oral administration of 700 mg. per Kg. of body weight, corresponding to about 45 Gm. for man (Stanton and Agricola, 1937). Its absorption was also complete in monkeys receiving by mouth 100 to 400 mg. per Kg. daily for nine to eighteen weeks (P. K. Smith, 1940).

The oxidation of acetanilid to paraminophenol by *tissue suspensions* was studied by H. O. Michel *et al.*, 1937.

Therapeutic Uses.—The antipyretic and analgetic actions and dosage are discussed in a preceding section. Acetanilid and acetophenetidin are administered in solid form as powders, capsules or tablets. They occur as white crystalline powders, of a warm, not unpleasant taste.

Acetanilid was introduced clinically as antipyretic by Cahn and Hepp, 1886, The antipyretics have been used in *diabetes insipidus*, but they are not very effective. The *antiseptic action* of the antipyretics is not very potent, but they are sometimes used as antiseptic, astringent and *hemostatic dusting powders* (acetanilid; or antipyrine in 5 per cent sterilized solution). They are less poisonous and less irritating than iodoform; but toxic effects have been reported from the application of acetanilid to wounds. Acetanilid is a potent inhibitor of certain *enzyme systems* in the body (F. Bernheim, 1943).

Leukocytosis was believed to be produced by antipyretics, but Gehrig, 1915, found no effect. The migration of leukocytes from the inflamed mesentery of frogs is inhibited by antipyrine (Ikeda, 1916). Phagocytosis *in vitro* is also unaffected (Arkin, 1913).

Circulation.—The general circulation is but little affected by ordinary doses. They may slow the heart indirectly by reducing the temperature; this has sometimes been misinterpreted as cardiac depression.

The *cutaneous vessels* are dilated; the *intracranial vessels*, after a short dilatation, show a more persistent constriction, similar to that from caffeine or alcohol (E. Weber, 1909). Hirschfelder, 1915, described dilatation of the pial and retinal vessels, from acetanilid, antipyrine, amyl nitrite, caffeine, and alcohol. This tends to raise intra-ocular pressure, enjoining caution in glaucoma (Wessley, 1915). With *toxic doses*, the heart is first accelerated, and later slowed, by direct action upon the heart muscle. Strips of terrapin's ventricle are slowed and arrested by acetanilid (Carr, 1910). The *vasomotor center* is not affected by moderate doses (with the exception of the part controlling the cutaneous vessels). The *blood pressure* depends solely upon the cardiac action, being at first increased and later diminished. In doses producing collapse there is paralysis of the vasomotor system, and consequent fall of blood pressure.

Striped Muscle.—Immersion in acetanilid solution (1:5000) diminished the direct and especially the indirect excitability of muscle (Macht, 1919). Muscle immersed in dilute antipyrine solution preserves its excitability much longer than when immersed in Ringer's fluid (J. G. Brody, unpublished).

Narcosis.—Goldfish immersed in acetanilid solution, 1:2500, undergo deep narcosis, which is reversible for several days. This effect has not been noted with paraminophenol or with salicylates (Sollmann).

The **toxicity** is rather low, even with acetanilid. The clinical phenomena have been discussed. Fatalities have been reported from 0.6 to 50 Gm. (P. J. Hanzlik, 1940), but are exceptional with the lower doses. In a variety of *animals*, marked prostration, cyanosis and dyspnea begin with about 200 mg. of acetanilid orally per kilogram of body weight. Even with 800 mg. per Kg., half of the animals recover. This would correspond to about eighty times the ordinary therapeutic dose. The blood of animals dying of acetanilid does not contain sufficient abnormal pigment to account for the death (P. K. Smith, 1939; Lolli *et al.*, 1943).

There is *no evidence of cumulative action*, for daily administration of 200 to 400 mg. per Kg. to rats or monkeys over ten to eighteen weeks does not produce significant changes in growth, hemoglobin concentration, blood count and leukocyte count. Indeed, some tolerance develops, both to the depressant and to the analgetic effects. With daily doses of 500 mg. per Kg., there is impairment of growth or loss of weight and a significant decrease of blood count without change in the leukocytes (Helms, 1933; P. K. Smith and Hambourger, 1936; Stanton and Agricola, 1937; P. K. Smith, 1940). *Withdrawal* does not cause any "abstinence symptoms" (*i. e.*, no increase of discomfort erethismus in rats, Stanton and Agricola; monkeys, Smith, 1940).

Influence of Sodium Bicarbonate on the Toxicity of Acetanilid.—Conflicting results have been reported. The results of P. K. Smith, 1936, indicate a moderate decrease in toxicity (about 25 per cent), when two molecules of bicarbonate were administered with each molecule of acetanilid.

Clinical chronic acetanilid poisoning may occur from the continued use of acetanilid headache powders, generally over some years. The patients show a peculiar cyanosis, sometimes with the histologic blood changes of pernicious anemia; marked leukocytosis; cardiac weakness; progressive mental and physical debility. Methemoglobin may also appear in the urine (D. D. Stewart, 1905). *Anemia* may be severe, with hyperplasia of the bone marrow, but with rapid recovery on withdrawal (Meulengracht and Lundsteen, 1939). An individual predisposition is probably necessary to produce marked chronic acetanilid poisoning: A series of ten human subjects who took 4 grains (0.25 Gm.) of acetanilid three times daily for sixteen weeks showed no significant changes in blood, urine, or in renal and hepatic functions (Helms, 1933). The persistent use tends in itself to produce headache, thus establishing a vicious cycle. The *withdrawal of acetanilid* rarely causes abstinence symptoms, but S. Payne, 1935, reported craving and restlessness for a few days, and excitement, sometimes quite maniacal, allayed by small doses of the drug.

The *cyanosis* occurs constantly in animals poisoned by large doses of acetanilid or acetophenetidin. Clinically it is inconstant, but generally it develops gradually with continued use of these drugs, sometimes within a few days, increases progressively for weeks and fades slowly during two weeks after withdrawal. Unsaturation of 2 to 28 per cent of the hemoglobin of many persons using acetanilid was reported by W. D. Paul and Clark, 1935. Its mechanism is disputed. The blood may contain some methemoglobin and sulfhemoglobin within the corpuscle, involving generally 2 to 5 per cent of the hemoglobin; but several observers have failed to demonstrate either sulfhemoglobin or methemoglobin in their clinical cases, or even decrease of oxygen binding power, and are inclined to attribute the cyanosis to colored products of the oxidation of paraminophenol (Lundsteen *et al.*, 1938; Meulengracht and Lundsteen, 1939; A. Leslie, 1939).

The *acute blood pigment changes* were studied by P. K. Smith, 1939, in rats, comparing ⅔ M.F.D. of acetanilid, and equimolecular amounts of acetophenetidin, aniline, paraminophenol, sulfanilamide and sulfapyridine. All formed appreciable amounts of methemoglobin and sulfhemoglobin. Methemoglobin and sulfhemoglobin were in about equal amount with acetanilid and acetophenetidin; methemoglobin predominated with aniline and sulfapyridine; sulfhemoglobin with sulfanilamide. Paraminophenol produced less abnormal pigment than the other compounds. Methemoglobin formation occurs readily in dogs on oral administration of acetanilid, 0.1 to 0.3 Gm. per Kg. of body weight (T. R. Kruse and McEllroy, 1927). The acetanilid and acetophenetidin methemoglobin increases with the dose as a sigmoid curve. Cats appear the most sensitive species; man is about half as much, dog a fourth, rat a twenty-fourth, rabbit and monkey very little. Continued administration to man led to little or no cumulation of methemoglobin (D. Lester, 1943). Para-aminophenol and beta-phenylhydroxylamine also have sigmoid curves of methemoglobin formation (Lester *et al.*, 1943). Ortho-aminophenol is more potent than the para in forming methemoglobin. *Nitrosobenzene* is less potent than hydroxylamine (C. Petersen, 1941). *Alcohol* is reported to increase methemoglobin formation by aniline in cats (W. Heubner and Schwedtke, 1936). D. Snapper, 1925, reported that *sulfhemoglobin* is formed in patients or dogs receiving acetanilid or acetophenetidin, if hydrogen sulfide is being absorbed from the intestinal tract, by administering sulfur by mouth, or in digestive disturbances with intestinal putrefaction (Harrop and Waterfield, 1930).

Methemoglobin formation in shed blood proceeds more weakly than it does in the body. The relation of the methemoglobin formation to the chemic constitution of benzene derivatives was investigated by W. Heubner, 1913. It is much more pronounced in the mother substances, aniline, phenylhydrazine, and the like; it is stronger with acetanilid than with the other antipyretics. Paraminophenol forms a reversible oxidation-reduction system with its quinimine, $C_6H_4.O.\ NH$, which acts as a catalyst. Phenylhydroxylamine is not catalytic, but oxidizes irreversibly to azoxybenzene (W. Heubner *et al.*, 1923). *Lactophenin* produces *icterus* in over half of the patients, usually on the ninth to twelfth day of its use. It is probably of the retention type rather than hemolytic (Hanssen, 1916).

The monograph of Martin Groves (Hillhouse Press, New Haven, 1946) gives an extensive *bibliographic review* of acetanilid.

Preparations.—***Acetanilid,** U.S.P. (Acetanilidum; Antifebrin; Phenylacetamide), $C_6H_5.NH.CO.CH_3$. White, crystalline, odorless powder; soluble in water (1:190); liquefies with chloral or antipyrine. Dose, 0.2 Gm., 3 grains; maximum, 0.5 Gm., 8 grains, in powders or capsules. ***Acetophenetidin,** U.S.P. (Acetophenetidinum; Phenacetin), $C_2H_5O.C_6H_4.NH.CO.CH_3$, 1:4; white, odorless, nearly tasteless powder or scales; slightly soluble in water (1:1310); liquefies with chloral and antipyrine. Dose, 0.3 Gm., 5 grains; maximum dose, 1 Gm., 15 grains, in powders or capsules. *Acetophenetidin Tablets*, U.S.P.; usual sizes, 0.12, 0.2 and 0.3 Gm., 2, 3 and 5 grains.

SALICYLIC COMPOUNDS

Salicylic acid (ortho-oxybenzoic acid, $C_6H_4OH.CO_2H$, 1:2) and its compounds produce marked antipyretic and analgetic effects and striking relief of the phenomena of acute articular rheumatism. The systemic toxicity is relatively low, but large therapeutic doses produce the so-called "toxic" symptoms of "salicylism," resembling cinchonism. The different compounds act qualitatively similar, but present quantitative differences. The salicylates are excreted by the urine, partly free and partly combined. Free salicylic acid is an antiseptic, active irritant and slow corrosive.

Historical.—Salicylic acid was first prepared in 1838 by Piria from salicin, which had been isolated by Leroux. Cahours, in 1844, and Procter, prepared the acid from gaultheria oil. Kolbe and Lautemann produced salicylic acid synthetically from phenol in 1860, and Kolbe devised a commercial practical synthetic process in 1874. He also investigated its antifermentative action. It soon became established as a surgical antiseptic (Thiersch, 1875); antipyretic (Buss, 1875); and antirheumatic (Strickler, 1876).

Relation of Constitution to Antirheumatic Action.—Phenol, $C_6H_5.OH$, is quite inactive. Benzoic acid, $C_6H_5.CO_2H$, has a limited efficiency. The OH and CO_2H groups are both necessary, and must be in the ortho position to obtain the full efficiency. Derivatives, which can be converted into salicylic acid in the organism, are effective, in proportion to the ease of their conversion. Introduction of additional groups into the benzene nucleus, as in the cresotinic acids, does not disturb the action (May, 1909; Stockman, 1913).

Cresotinic acids were at one time blamed for the reputed higher toxicity of synthetic salicylates. In fact, however, they act similarly and have about the same toxicity as salicylic acid (Stockman, 1890, 1912; Waddell, 1911). They have a similar specific effect in rheumatic fever, although they are somewhat inferior. They have even been used therapeutically in doses up to 8 Gm. (Buss, 1876; Gatti, 1879; Demme, 1888).

Isomers of Salicylic Acid.—Meta- and para-hydroxybenzoic acids are practically inactive and nontoxic. These isomers are excreted in combination with sulfuric acid instead of glycocoll (Sherwin, 1918).

Salicyl Esters.—The desire to avoid the disagreeable taste and the gastric symptoms of the ordinary salicylates led to the introduction of esters and similar compounds, more or less insoluble, in which the salicyl radical is bound so as to be liberated only in the intestine or after absorption. These compounds have little or no direct action on the stomach, but they do not avoid the nausea and vomiting (Hanzlik, 1913), since these are chiefly central. In this respect they are not superior to sodium salicylate, which also does not produce direct gastric irritation, if properly guarded by bicarbonate. The taste is materially improved. The alkyl esters (methyl salicylate) are more efficiently absorbed from the skin and are therefore better for external use. The acyl derivatives (acetyl salicylic acid) have higher analgetic and antipyretic action and therefore a special field.

These compounds may be arranged under three types: 1. **Replacement of the H of the Hydroxyl by Acyl Radicals.**—To this type belong: acetylsalicylic acid (aspirin), $C_6H_4.O(COCH_3).COOH$, and the corresponding compounds of salicylic acid with methylene citric acid (*Novaspirin*); with salicylic acid (*Disalicylic Acid*); and with succinic acid (*Diaspirin*). 2. **Replacement of the H of the Carboxyl by Alkyl Radicals.**—Methyl salicylate, $C_6H_4.OH.CO_2(CH_3.)$, and the corresponding salicyl esters of ethyl (*Sal Ethyl*); of methoxymethyl (*mesotan*); and of monoglycol (*spirosal*). 3. **Replacement of the H of the Carboxyl by Phenyl Radicals.**—Phenyl salicylate (*salol*), $C_6H_4.OH.CO_4(C_6H_2)$ and the corresponding salicyl esters of naphthol (*betol*); of guaiacol; and of acetparamidophenol (*salophen*). To these may be added *salicin*, from which salicylic acid is formed in the organism.

"Natural" and Synthetic Salicylates.—It was formerly claimed that synthetic sodium salicylate, owing to the presence of supposed impurities, is more toxic and less efficient than that prepared from oil of wintergreen or birch. The evidence for this view did not stand critical examination. There need be no hesitation in employing the much more economical synthetic product (Report, Council on Pharmacy and Chemistry, 1913, J.A.M.A., *61:* 979).

Various impurities were announced in synthetic salicylates, but Hilpert, 1913, showed that the cheapest commercial samples are quite as pure as the most expensive. Waddell, 1911, proved that the effects of natural and synthetic salicylates on animals are quantitatively alike; and the cooperative clinical tests, instituted by the Council on Pharmacy and Chemistry showed that their effects on patients are indistinguishable (Hewlett, 1913).

Fate.—The salicylates are rapidly absorbed from mucous membranes, and circulate as such. Salicylic acid may be liberated in the stomach, but not in the blood or tissues. The esters are also readily absorbed from the intestines, partly after hydrolysis, partly without decomposition. Some absorption of the esters occurs from the intact skin. Salicylate is excreted in all the secretions (sweat, Tachau; none in the feces, Hanzlik; practically none in the bile, Halpert *et al.*, 1930), but by far the larger part appears in the urine, mainly free, but partly conjugated. A part is oxidized to dioxybenzoic acid and hydroquinone. The excretion begins within fifteen minutes, and is practically completed in six to forty-eight hours. The rapid excretion explains the need of large and frequent doses. Larger doses may color the urine green.

Absorption of salicylates starts promptly, but a part of sodium salicylate may remain a considerable time in the stomach, especially if it has been precipitated as salicylic acid. Sodium salicylate is absorbed from the rectum (Massol and Minet, 1908), though not so readily as by mouth (Fiedler, 1905).

Absorption of the Esters from the Alimentary Canal.—The insoluble esters pass rapidly through the stomach, without material change, and are gradually absorbed from the intestines (Burow, 1911, dogs with duodenal fistula). They are partly hydrolyzed and saponified, but a part is absorbed without decomposition. With full therapeutic ("toxic") doses the median percentage of unchanged esters in the urine of patients averaged about 25 per cent of the total salicylate in the urine, when acetylsalicylic acid was given; 6 per cent with salicylsalicylic acid; and only 0.2 per cent with methyl salicylate. Acetylsalicylic acid was found to be hydrolyzed in acid and in alkaline buffer mixtures within the physiological range (*i. e.*, in the stomach as well as in the intestines), but was fairly stable at neutral reaction. Salicylsalicylic acid and methyl salicylate underwent but little hydrolysis; they must be decomposed in the tissues rather than in the alimentary tract (Hanzlik and Presho, 1925).

Absorption from the Skin.—Free salicylic acid, sodium salicylate, methyl salicylate and some of the other esters, in ointments or alcoholic solutions, are absorbed by the skin, but less rapidly than by mouth (Sauerland, 1912). Salicylate can generally be demonstrated in the urine after clinical application of salicylic acid ointment or washes (Leslie-Roberts, 1928). Sodium salicylate is absorbed from the skin much less than free salicylic acid (Lenertowicz, 1914). Methyl salicylate is absorbed most effectively from aqueous suspensions (E. W. Brown and Scott, 1934), but the quantity would not be significant therapeutically.

Diffusion through colloid membranes is hastened by salicylic acid or sodium salicylate (Oswald, 1910; Hanzlik, 1912). Salicylic acid also enters living cells which are impermeable to most other acids (Harvey, 1914).

Quantity of Total Salicyl Recovered from Urine.—With therapeutically toxic doses of sodium salicylate, Hanzlik recovered about 80 per cent; with acetylsalicylic acid, a median of 9 to 37 per cent; with salicylsalicylic acid, 63 per cent; methyl salicylate, 51 per cent. The higher values reported by older investigators were due to faulty methods.

Normal Time of Excretion.—Blanchier, 1879, found that sodium salicylate, administered by mouth, appeared in the urine in fifteen to eighteen minutes; with doses of 1 to 2 Gm. the excretion was completed in twenty-two hours; with 4 to 5 Gm., in forty-four hours. After continued administration, the excretion persisted from three to eight days. In dogs, the excretion was relatively slow; in herbivora, somewhat quicker than in man. Gaulier, 1913, reported the excretion as completed in eighteen to twenty-six hours. After application of a salicyl ointment to the skin, the excretion lasted two days (Schumacher, 1909). The elimination after intravenous injection was studied by F. Mandel, 1908.

The *excretion in rheumatic fever* averages about 10 per cent less than in normal individuals; the deficit is greatest in the first ten to twenty hours of administration. It is not due to retention, or to differences of diuresis, but partly to excretion in the sweat, and chiefly to increased destruction. The percentage of salicyl in the blood and urine at this time is little more than half of that in normal subjects (Scott, Thoburn and Hanzlik, 1917). The excretion is diminished in chronic alcoholism and morphinism, tuberculosis and diminished renal efficiency (Scott and Thoburn, 1917). Purpus and Chebchowski report delayed excretion in *renal and circulatory diseases.*

Time of Excretion of Salicyl Esters.—Full therapeutic doses of acetylsalicylic acid required a median of nearly five days; salicylsalicylic acid and methyl salicylate, two to three days (Hanzlik and Presho, 1923 and 1925). Phenyl salicylate is excreted more slowly than the other esters (Pinczower, 1910).

Urinary Metabolites of Salicylic Acid.—Kapp and Coburn, 1942, isolated four substances from human urine: salicylic acid, 20 per cent; salicyluric acid, 55 per cent; gentisic acid, 4 to 8 per cent; and Baldoni's uraminsalicylic acid. About 25 per cent was conjugated with glycuronic acid. *Salicyluric acid* (Bertagnini, 1856) is a compound with amino-acetic acid, analogous to hippuric acid. Some observers have failed to find it (Hanzlik, 1916; Angelico, 1921). *Gentisic acid,* C_6H_3.COOH-$(OH)_2$, dioxybenzoic acid, is an oxidation product intermediate to hydroquinone, $C_6H_4(OH)_2$ (C. Neuberg, 1911). It causes the urine to darken on alkalinization (Lutwak-Mann, 1943). *Conjugation with amino-acetic acid* occurs with the OH group in the meta and para, but practically not in the ortho position; similarly with bromo, iodo and nitro groups. Conjugation with gylcuronic acid is affected in the same direction, but to less degree (Quick, 1932).

Distribution in Organs.—Blanchier, 1879, investigated this in dogs and found the salicyl in the saliva, bile, cerebrospinal fluid, articulations, and so forth. Nencki, 1895, found it in the bile, but not in the gastric juice. Olmer and Totiau, 1910, confirmed its presence in cerebrospinal fluid, its quantity being independent of the dose. Stockman, 1906, found none in the saliva, traces in sweat, and considerable in the joint fluid, blisters, bronchial mucus and pleural effusions. Scott, Thoburn and Hanzlik, 1916, found the percentage in joint fluids of rheumatic patients a trifle smaller than in the blood. The concentration in the aqueous humor was reported higher than that of the blood (S. R. Gifford, 1922). The concentration in the serum is perhaps a little higher than in the corpuscles (Fridericksen, 1917). Most of the salicylate in plasma is bound to nondiffusible components, presumably plasma proteins. Very little is found in the corpuscles. After oral administration of acetylsalicylic acid only unesterized salicylate is demonstrable in the plasma (P. K. Smith, Gleason *et al.*, 1946).

Free Salicylic Acid Does Not Exist in the Tissues.—Although salicylic acid may be liberated from sodium salicylate by high concentrations of carbon dioxide (Binz, 1879), the buffer action of the tissues prevents the acidity from rising to the necessary level, even in asphyxia (Hanzlik, 1921). Scott, Thoburn and Hanzlik, 1916, also failed to find free salicylic acid in the joint fluids of rheumatic patients.

Antiseptic Action.—Free salicylic acid is about equivalent to phenol and benzoic acid; its salts are scarcely antiseptic (Kolbe, 1874). The irritant effects disqualify salicylic acid as a surgical antiseptic. It has been used as a food preservative, but it is doubtful whether this should be permitted. Salicylates have a moderate antiseptic effect on the urine (Jordan, 1911), and may be used for this purpose. Saturated solution of salicylic acid has been recommended as a harmless fly poison.

Local Actions on Skin.—Application of salicylic acid in substance or strong solution produces slow and painless destruction of the epithelium. It is used as ointment, 2 to 10 per cent, in itching skin diseases (urticaria) and against pityriasis versicolor; as lotion, 1 to 2 per cent, in alopecia; as powder, 3 per cent in talc, against sweating feet; and in collodion, 10 to 20 per cent, and plasters to *soften corns and warts.* An ointment containing 3 per cent of salicylic acid and 5 per cent of benzoic acid in petrolatum (*"Whitfield's Ointment"*) is used especially against ringworm. Sulfosalicylic acid acts purely as a corrosive acid (Göpfert, 1938).

Hypersensitiveness of Skin to Salicylates.—Sauerland, 1912, found that external applications (not the systemic administration) of salicyl preparations gradually develop persistent sensitiveness, leading to eruptions after an incubation period. This involved all parts of the skin, not only that to which the salicylate had been applied. The skin was not hypersensitive to other irritants.

Local Actions.—Strong solutions of salicylic acid produce considerable irritation and superficial corrosion of *mucous membranes.* The salts are free from this objection, and the free acid is therefore little employed internally. Salicylic and acetylsalicylic acid soften the enamel of the *teeth* and should not be used in mouth washes. Acetylsalicylic acid produces some local irritation of the mouth and throat and possibly also of the stomach.

The **analgetic and antipyretic effects** are discussed in a previous section. They do not differ materially from those of acetanilid. Large doses of salicylates are safer, but have more disagreeable side actions. Acetylsalicylic acid (aspirin) is used extensively against *headache.*

Heat regulation apparently is affected quite differently *in health and in fever.* With normal men at muscular rest, 1 Gm. does not lower the temperature, but increases the heat production (CO_2 excretion about 6 per cent), with the heat dissipation practically unaffected (Barbour and

Devenis, 1919). With febrile patients, even with mild fever or when the temperature is merely unstable, the same dosage lowers the temperature to 0.8° C. below normal; and produces a great increase (38 per cent) of heat dissipation, and a slight decrease of heat production. When the effect passes off, there is compensatory decrease of heat dissipation to half the normal level (Barbour, 1919). Nitrogen excretion is primarily increased (Weber); there is often a later decrease. The oxidation of excised muscle is retarded by small concentrations.

Salicylate on Cold-Fatigue.—Immersion of the forearm in a cold bath for thirty to forty-five minutes causes a dull ache, with rapid fatigability of the muscle. Therapeutic doses of acetylsalicylic acid remove the ache and restore the normal activity, even though the cold immersion is continued. Alcohol, 17 to 33 cc. by mouth, as 33 per cent solution, acts similarly. Caffeine does not (Menschel and de Rochemont, 1926).

Time-Sense of Insects.—Ants and bees can be trained to come for feed at a certain time of the day. This is disturbed by drugs (probably by altering the speed of metabolism): ants come earlier when treated with salicylic acid or yellow phosphorus; arsenic trioxide has complex effects (Grabensberger, 1934). Bees are delayed by carbon dioxide or low temperature, unaffected by thyroid feeding and by ether (Kalmus, 1934).

Therapeutic Effects in Rheumatic Fever.—Adequate administration of salicylates controls the manifestations of this disease in a remarkable manner in nearly all typical cases. The pain and fever disappear; the local inflammation, the immobility, swelling and redness subside; the general condition of the patient is vastly improved; and the disease is under complete control in one to at most five days. These benefits last only so long as the patient is kept salicylated, and relapses occur when this is discontinued. The total duration of the disease is not shortened, as judged by the stay in the hospital (J. L. Miller, 1914), and by the sedimentation rate (Wégria and Smull, 1945). The rheumatic cardiac lesions are not relieved directly (Vulpian, 1880), although the A-V conduction may be restored to normal during salicylation (R. L. Levy and Turner, 1927). Indirectly, salicylate treatment may have an important tendency in this direction by favoring rest and avoiding the extra tax of fever, pain and insomnia.

The urine output is increased. There may be some temporary casts.

Efficiency in Related Conditions.—Salicylates are much less effective in atypical, subacute, chronic and muscular rheumatism, lumbago, and the like, although they usually have some analgetic effect (Hanzlik, 1913). In acute gout they are often quite effective (Vulpian, 1880). They are notably inefficient in scarlatinal and gonorrheal arthritis (G. Sée, 1877; Stockman, 1906). They are used in headache, neuralgias, sciatica, tabes and other similar pains, but with inconstant results. In chorea it is difficult to prove any benefits. Large doses (10 Gm. of sodium salicylate per day) have been administered over long periods in all types of *intra-ocular inflammation*, with the claim that they check or relieve the congestion (H. Gifford, 1922).

The **mechanism of antirheumatic action** is probably connected with the analgetic and antipyretic action. It is improbable that the salicylates have a germicidal effect in the tissues; nor do they improve chemical irritations and edemas (Hanzlik and Tainter, 1923). The analgetic explanation is based on the efficiency of salicylates in other painful conditions (Vulpian, 1880), and on the effect of other analgetics in rheumatic fever. Hanzlik *et al.*, 1918, found that combination of other analgetics (for instance, morphine) and antipyretics (for instance, quinine) also relieve the symptoms of acute rheumatic fever promptly and effectively. Quantitatively, however, salicylates are superior.

Salicylate prevents the *precipitation of antigen* by antibody *in vitro*, apparently by an action on the antibody (Coburn and Kapp, 1943). This is suggestive for the explanation of rheumatic fever as delayed antigen-antibody reaction. It has not been shown, however, that this salicylate effect occurs in the living body. Physiological concentrations have little effect on known *enzyme systems;* but when injected into animals, salicylate produces prompt disappearance of nearly all *liver glycogen*, with full restoration within a day (Lutwak-Mann, 1942).

Administration of salicylate to rabbits antagonizes the spreading action of the hyaluronidase of testicular extract. Sulfadiazine does not have this action (F. Guerra, 1946).

Tissue antisepsis was suggested by the large doses which are required; the lesser efficiency of other antipyretics and analgetics; the relative inefficiency of the salicylates in other forms of arthritis. Against this view speak the prompt recurrence of the symptoms if the salicylate is discontinued and the failure to prevent the cardiac infection. In rabbits, the prophylactic use of salicylate does not prevent or even influence arthritis from intravenous injection of rheumatic hemolytic streptococci (Miller, 1914; Davis, 1915); but this is not conclusive, since the etiology has not been established, and the administration is different.

Administration.—Free salicylic acid is too irritant for internal use. It may be neutralized by sodium bicarbonate, but acetylsalicylic acid is commonly used for headache, and the less toxic and cheaper sodium salicylate for the large doses required in rheumatic fever. Its mawkish taste can be greatly diminished by dilution; flavoring with peppermint or wintergreen water is not very successful.

To be effective in rheumatic fever, the amount of salicylate must be sufficient to make the patient "toxic," with tinnitus, nausea and hebetude, requiring a plasma level of at least 25 mg. per 100 cc. This may be secured by intensive oral administration of sodium salicylate, 1 to 1.5 Gm. (15 to 25 grains) in a half glass of water, every hour until relief is secured. It may then be given every four hours for several weeks, keeping the patient in bed. Sodium bicarbonate is sometimes administered in equal dosage, but it probably serves no useful purpose and tends to lower the salicylate level of the blood. Enteric capsules appear undesirable, for the salicylate is absorbed mainly from the upper intestines (R. W. Huntington, Ryan *et al.*, 1946).

Wégria and Smull, 1945, recommend 1.8 to 3.6 gm. of sodium salicylate, according to body weight, every four hours for three doses, then half this dose every four hours day and night until the sedimentation rate remains below 20 for two weeks. They find that this maintains the salicylate concentration of the plasma better than intravenous administration.

Sodium bicarbonate was originally given to dissolve free salicylic acid when this was prescribed, and was then thought to avoid acidosis, but its benefits are questionable. Alkalinization of the urine lowers the salicylate concentration in the plasma of patients by increasing its excretion. Acidification by ammonium chloride raises the blood level (F. S. Coombs *et al.*, 1944; Smull *et al.*, 1944; P. K. Smith, Gleason *et al.*, 1946). R. W. Huntington, Ryan *et al.*, 1946, found no change in the serum level with bicarbonate in daily doses up to 4 Gm.

Methyl salicylate also gives some relief when applied externally to the affected joints, but this is purely by counterirritation. The amount absorbed is not sufficient for systemic effects; nor can it make a short cut to the joints, because it is carried off by the intervening circulation. Sodium salicylate may be administered by rectum, if it is not retained by the stomach (Heyn, 1914), but the rectal absorption is poor (R. W. Huntington, Ryan *et al.*, 1946). The absorption from oral administration is so prompt that there is no real necessity for parenteral administration. Intravenous drip was advocated by Coburn, 1943, to start the treatment, but it does not materially hasten the response, and serious toxic reactions have occurred (Hench, 1946). Concentrated solutions produce sclerosis. Hypodermic injection may cause local necrosis.

The plasma salicylate level is the determining factor in the therapeutic response. A. F. Coburn, 1943, reported that at least 25 mg. per 100 cc. are necessary to obtain prompt and progressive subsidence of the inflammation. This can be secured and maintained by oral administration of 10 Gm. of sodium salicylate per day (Butt *et al.*, 1945). The oral dosage of Wégria and Smull, 1945, maintains 35 to 50 mg. per 100 cc. A single dose of 3.3 Gm. brings the level to 18 mg. per 100 cc. (R. W. Huntington *et al.*, 1945). *Intravenous drip injection* of 10 Gm. in 1000 cc. of saline or lactate-Ringer solution, during four to six hours, attains the 35 mg. level more rapidly with a minimum of salicylism. R. C. Manchester, 1946, recommends a routine of daily intravenous injections of 10 Gm. for four to ten days, followed by oral. In severe cases, 20 Gm. may be injected in eight hours. Salicylate levels of 10 to 25 mg. relieve the symptoms, but the inflammation progresses.

Salicylism.—When the dosage of salicylate is raised to the full therapeutic effect, there occurs usually a series of side actions resembling cinchonism. They consist in nausea and vomiting, ringing in the ears and deafness, vertigo and headache, mental dulness and confusion, diaphoresis, quickened pulse and increased respiration, respiratory alkalosis; rarely skin eruptions (especially pustular acne), albuminuria, impaired vision (de Schweinitz, 1895; Claiborne, 1906) and maniacal delirium, the latter especially in alcoholic patients. All these effects are usually without danger, disappearing promptly when the drug is discontinued. Abortion has sometimes occurred, but it is doubtful whether this was due to the drug or to the disease.

The *nausea and vomiting* are exceptional if sodium salicylate is used as enteric-coated tablets (Wégria and Smull, 1945); however, they do not appear to be caused by local irritation, except if free salicylic acid is given. The salicylates and esters are not especially irritant; and if fractional doses are used, the gastric phenomena set in only after some hours, about the same time as the ear and other systemic effects. They are therefore probably central. This has been confirmed by the direct method of Eggleston and Hatcher, 1915. The *ear symptoms* are perhaps connected with congestion of the auditory apparatus (Kirchner, 1881; but Haike, 1904, believes these lesions to be asphyxial artefacts). The *brain vessels* are dilated (Berezin, 1916).

The toxic symptoms follow the plasma salicylate concentration. Tinnitus usually begins with 25 mg. per cent. More serious symptoms may set in with 50 mg.; most commonly, hyperpnea with the serum CO_2 as low as 25.8 vol. per cent. A few patients have sinus tachycardia. Apathy and drowsiness are generally present; a few have hallucinations. All symptoms disappear quickly when the plasma level falls below 50 mg. per cent (Wégria and Smull, 1945). Children under intensive salicyl therapy may develop roentgenographic evidence of bronchopneumonia (D. L. Stevens and Kaplan, 1945).

The "*toxic*" *dose* was investigated by Hanzlik, 1913, in over 500 administrations. If the salicylates are administered in repeated doses of about 1 Gm., one or two hours apart, the "toxic" effects appear usually when the total dose of sodium salicylate attains between 7 and 13 Gm., 100 to 200 grains, the mean being about 12 Gm., 180 grains. Women require about four-fifths of this dose. There are no differences between sixteen and seventy-five years of age. Children have a relatively high tolerance, *i. e.*, the toxic dose is much higher than would be calculated from their age (Archambault, 1878). The dose is the same for the white and the colored race. It is not affected by the presence or nature of disease. Occasionally there are unexplained idiosyncrasies or tolerance (toxic doses as low as 20 and as high as 1300 grains). These are usually only temporary. The toxic dose of acetylsalicylic acid and methyl salicylate is about two-thirds, that of salicylsalicylic acid (MacLachlan, 1913) about one-half that of sodium salicylate. The toxic dose and effects of strontium salicylate are the same as for the sodium salt (Blankenhorn, 1916).

Decreased prothrombin level of the blood occurs early with intensive salicylate administration if the vitamin K income is scanty. The action is probably related to that of dicumarol, but salicylate is much less potent, and hemorrhagic manifestations are not likely to occur if the vitamin K income is normal. It may be advisable to protect prolonged administration with menadione.

The prothrombin level runs inversely to the salicylate level of the plasma; the lowering is insignificant until the salicylate reaches 6 mg. per cent (F. W. Clausen and Jager, 1946). The massive Coburn doses lower the level in all patients to 55 to 75 per cent, sometimes even to 20 per cent, but this usually returns to normal after some days, even if the salicylate is continued (G. C. Owen and Bradford, 1946).

Degradation of dicumarol *in vitro* leads to salicylic acid (Huebner). This has not been established *in vivo*, but Link *et al.*, 1943, showed that salicylate prolongs the prothrombin time in rats, and O.O. Meyer and Howard, 1943, reported that this occurs in the therapeutic use of sodium salicylate or acetylsalicylic acid, and can be prevented by administering menadione. This has been confirmed by others, but it has not been shown that it leads to hemorrhagic complications. These would not set in unless the prothrombin is decreased below a fifth of the normal (review, A. J. Quick, 1944; Butt *et al.*, 1945). Rats are more susceptible to the prothrombin decrease than rabbits, and these more than dogs. The effect is greatly augmented by increased metabolism, hyperthermia, thyroid administration and alcohol. It is about equal for equimolecular amounts of sodium salicylate, acetylsalicylic acid and methyl salicylate. The prothrombin level is also lowered by other antipyretic drugs, antipyrine, aminopyrine, acetanilid, acetophenetidin, cinchophen and quinine (B. B. Clark and Spitalny, 1946).

Dangerous poisoning by sodium salicylate is rare, and it is often difficult to judge whether the effects attributed to the salicylate were not really due to the disease.

The *symptoms* are described as vomiting, unconsciousness, delirium, dyspnea and deepened respiration (Quincke, 1888), fall of temperature, arrhythmia, albuminuria, paresis, collapse, asphyxial convulsions (Peterson, 1877; Weckerling, 1877; Allaire, 1879; Vinci, 1905). Sicard and Meara, 1915, attributed a case of sino-auricular block, with standstill of the entire heart, to salicylate. The *fatal dose* is stated as 5 to 12 Gm., but is exceptional; even severe cases generally end in recovery. The *autopsy* in Quincke's case showed hyperemia of the brain and its membranes, of the kidneys and lungs, and pericardial ecchymoses.

Toxic Effects in Animals.—These are similar to those in man. The respiration is deepened and labored, first quickened, then slowed to final asphyxia with convulsions. The blood pressure rises at first, then falls severely; the pulse is inconstant. The intracranial vessels are constricted (Wiechowski, 1902). There are general collapse and sometimes paralyses. The heart stops with the respiration. The autopsy shows the same congestions as in man (Koehler, 1876; Quincke, 1882). The toxicity is low, the fatal dose per vein for dogs being about 1 Gm. per kilogram. Methyl and ethyl salicylates intravenously produce pulmonary edema by injuring the capillary walls.

Acidosis.—Vuipcke called attention to the resemblance of serious salicylate poisoning, especially the hyperpnea, to diabetic coma. Langmead, 1906, and Lees, 1908, emphasized this resemblance in children, and described the occurrence of acetone even after relatively small doses of salicylates. The acetonuria is probably often due to the associated conditions of the disease rather than to the salicylate. It is prevented by administering sodium bicarbonate (H. B. Myers and Ferguson, 1929). However, the matter is not clear. There is reduction of CO_2 capacity (alkali reserve), but generally not nearly enough to account for the hyperpnea (Bowen *et al.*, 1936). The hyperpnea produces alkalosis, with significant fall of serum CO_2 (Wégria and Smull, 1945). When the dosage of sodium salicylate reaches 6 Gm., the blood reaction shifts toward alkaline, and *alkali administration* would be undesirable (K. Gebert, 1931).

Kidneys.—Salicylates may have a diuretic effect (Blanchier, 1879); or they may decrease the output of urine, partly by diaphoresis, partly by water retention. This is accompanied by evidences of renal irritation (slight albumin and casts) and diminished renal permeability (phthalein test and nonprotein nitrogen of blood). With the ordinary doses, these changes disappear rapidly, and apparently without permanent damage, on discontinuing the administration (Scott, Thoburn and Hanzlik, 1916; Ehrmann, 1907).

The albuminuria occurs in normal individuals, and is therefore due to the drug, not to the rheumatic fever (Hanzlik *et al.*). It is also produced in animals, by doses corresponding to the therapeutic. Their kidneys show histologically various grades of nephritis, especially cloudy swelling (Hanzlik and Karsner, 1917). The albuminuria, edema, and so forth, are not modified by the administration of bicarbonate (Hanzlik *et al.*, Ehrmann, 1907), contrary to the earlier claims.

Salicyl Edema.—Full therapeutic doses of salicyl diminish markedly the quantity of urine, with an almost corresponding increase of body weight. This is demonstrable about twenty to eighty hours after the start of the salicyl administration. There is no dilution of the blood hemoglobin, so that the fluid must be mainly in the tissues (Hanzlik, Scott and Reycraft, 1917).

Metabolism.—Salicylates increase the elimination of nitrogen (Laqueur, Bruenecke and Crampe, 1912), especially in the form of *uric acid;* the latter is followed by a compensatory decrease (Kumagawa, 1898; Ulrici, 1901; Schreiber and Zaudy, 1899). The increase of uric acid is probably due chiefly to lowered renal threshold for urate, as with cinchophen. The excretion of *ascorbic acid* is increased by therapeutic doses, as also the *phosphate. Creatinine* excretion is not affected (Daniels and Everson, 1936). The normal *nonprotein nitrogen* of the blood is not lowered; but when abnormally high it may be decreased. The creatine of the blood is not affected (Denis, 1915). Gaulier, 1913, claimed that the chloride excretion is diminished. There are few definite data on the respiratory metabolism (review, S. Weber, 1904). Denis and Means, 1916, found uncertain changes in the basal metabolism in man.

The gastric secretion is somewhat decreased (Klocman, 1912); but the absorption of food is not materially affected. The secretion and flow of *bile* are somewhat increased, as with cinchophen.

Continued consumption of moderate doses (0.2 to 1 Gm. per day) by healthy individuals has no significant effect on metabolism and nutrition (Wiley, 1906).

Uric Acid.—The increased elimination is due (as with cinchophen) to increased permeability of the kidneys to uric acid; for the uric acid content of the blood falls during salicyl administration, to resume its original level when the salicyl is discontinued. In man, 6 Gm. of sodium salicylate may reduce the blood uric acid to one-half or one-third. The efficiency may be greater even than with atophan (Fine and Chace, 1915; Frank and Pietrulla, 1914; Denis, 1915). The increase of urate excretion may reach 30 per cent (Denis and Means). Excised organs destroy uric acid more rapidly in the presence of salicylic acid (Stookey and Morris, 1907). Waucomont, 1911, concluded that salicylates decrease the urate and purine excretion in experimental gout. The para- and meta-isomers do not affect the uric acid excretion (Denis, 1915).

Postmortem autolysis of the liver is increased by small, and decreased by large, concentrations (Laqueur, 1912).

Cholagogue Action.—Salicylates are among the few drugs which increase the secretion of bile (Pfaff and Balch, 1897; Okeda, 1915). Other aromatic products which conjugate with sulfuric acid act similarly (Petrowa, 1912). Salicylates have been used in obstructive jaundice and biliary colic, but it is doubtful whether they are of value.

Diabetes Mellitus.—Salicylates have been credited with decreasing the output of sugar and the consumption of water (Ebstein and Mueller, 1876; von Noorden, 1912), but their efficiency is at best inconstant (Kaufmann, 1903).

Excised Heart.—The Straub frog heart and the excised rabbit heart are depressed by perfusion with sodium salicylate 0.1 to 0.2 per cent in blood; but the concentrations that could be attained in life have no effect (Fridericksen, 1917).

Skeletal muscle and nerve are practically unaffected by moderate concentrations of salicylate.

Action on Leukocytes.—Binz, 1875, found that these are paralyzed and killed, as with quinine and many other aromatic derivatives. Ikeda, 1916, observed no effect on the emigration of white cells from inflamed mesentery. In mammals, the leukocytes of the blood are said to be doubled an hour after the administration, and return to normal in two hours, but Gehrig, 1915, reported that salicylate and other antipyretics do not produce leukocytosis, as was commonly believed.

PREPARATIONS.—***Salicylic Acid,** U.S.P. (Acid. Salicylicum; Orthohydroxybenzoic Acid), occurs as white, light crystalline powder or needles; of sweetish, then acrid taste; slightly sol. in water (1:460), freely sol. in alc. (1:2.7). Dose, 0.3 to 0.6 Gm., 5 to 10 grains. ***Sodium Salicylate,** U.S.P. (Sodii Salicylas), is a white, or faint pink, amorphous or crystalline powder or scales. It is odorless or has a faint characteristic odor and a disagreeably sweet saline taste. It is soluble in water (1:1) and in alc. (1:10). Dose, 1 Gm. (0.6 to 2 Gm.), 15 grains (10 to 30 grains). Watery solutions become discolored on standing, especially if alkaline. This may be disguised by Syrup of Cinnamon, but it is advisable to dispense it as powders, to be dissolved in a tumblerful of water at the time of taking. The solution occurs rapidly. *Sodium Salicylate Tablets,* U.S.P.; usually available as 0.3 and 0.6 Gm., 5 and 10 grains. *Salicin* is sol. in water (1:28) and alc. (1:80). It has a bitter taste. It occurs in willow bark, which was used as an antipyretic in antiquity. It also occurs in poplar bark. It was introduced against rheumatic fever by Maclagan, 1876, on the basis of the fancied resemblance to malaria. It is inferior to the salicylates, because its conversion is often incomplete. Salicin is a glucoside, yielding on hydrolysis *saligenin,* $C_6H_4(OH)$-CH_2OH; this in turn is oxidized to salicylic acid (Nencki, 1870), but a part is excreted unchanged. Salicin yields 45 per cent of salicylic acid, and is therefore at most half as effective. Dose, 0.3 to 1 Gm., 5 to 15 grains, in solution or wafers.

Salicyluric Acid.—The properties of the synthetic compound of salicylic acid and amino acetic acid were studied by Hanzlik and Seidenfeld, 1930. It is stable *in vitro,* but is completely and fairly rapidly hydrolyzed into salicylate in living animals, so that it could not play a part in detoxication. Its effects are chiefly due to the liberated salicylate.

ACETYLSALICYLIC ACID (ASPIRIN)

This was introduced by Dreser, 1899. It was supposed that it would pass unchanged through the stomach, thus avoiding gastric irritation, and that the salicylic acid would be liberated in the intestine. In fact, however, it produces some gastric irritation (Roch)—indeed, large doses result in gastric ulcers; the intestinal decomposition is slow and incomplete, a part being absorbed unchanged. Acetylsalicylic acid is about one and one-fifth times as toxic as sodium salicylate in man (Hanzlik, 1913); about twice as toxic in animals (Chistoni and Lapresa). In man even small doses (0.3 to 0.65 Gm., 5 to 10 grains) occasionally produce *alarming allergic symptoms*, especially acute, local or general edema of the skin and mucous membranes, bronchial spasm, urticaria, erythema, pruritus, and so on (Graham, Morgan, Gilbert, 1911; Krause, 1914). The effects of poisonous doses in animals are similar to other salicylates (Block, 1909). These side effects make this drug inferior to sodium salicylate in rheumatic fever. It has, however, stronger analgetic and antipyretic actions, even in nonrheumatic affections, perhaps because the undecomposed acetyl compound enters the nerve cells more readily. It is used extensively in colds, influenza and other fevers; and in neuralgias, headaches, tabes, and other pains, in tablets or capsules of 0.3 Gm., 5 grains. They should be swallowed, with water, for if they dissolve in the mouth, the acidity causes some irritation and may injure the teeth, especially in gargling (D. B. Dodd, 1940). It cannot be administered dissolved by alkalis, since these decompose it. It is dangerous for persons with allergic tendencies.

The mechanism of the antipyretic action is chiefly by sweating, aided by hydremia and cutaneous vasodilatation. Hypothalamic lesions suppress the sweating, but not the lowering of temperature (F. Guerra *et al.*, 1943, 1944).

Acute Acetylsalicylic Acid Poisoning.—Suicidal attempts with 20 to 30 Gm. of the drug are fairly common in Europe. The mortality rate is about 50 per cent, death occurring sometimes with 10 Gm., but usually with 30 to 40 Gm. A patient recovered under treatment after taking nearly 65 Gm. The most prominent symptoms are intense salicylism, exophthalmos, profuse sweating and intense thirst, delirium, coma, fixed pupils, fast pulse, low blood pressure, deep abdominal breathing, severe acidosis (Oakley and Donnell, 1942). Dogs receiving 2 to 4 Gm. per Kg. by stomach tube vomit in one-fourth to one hour, then develop dyspnea, ataxia, sometimes convulsions, low blood pressure, coma, and death in eight to thirty-eight hours, preceded by brief terminal convulsions. Sodium bicarbonate prolongs life by three to eight hours, but does not prevent death (J. E. Davis, 1945). A case described by Dyke, 1935, developed hyperpnea, moderate fever, profound disturbance of metabolism, with bile, albumen and casts in the urine.

Allergy to acetylsalicylic acid is much more common than is generally supposed. It is limited almost exclusively to persons of general allergic and asthmatic tendency. Sixteen per cent of asthmatic patients reacted to 0.3 Gm. (van Leeuwen, 1928). It develops most frequently between the ages of twenty-one and fifty years. The most common reactions are asthma, urticaria and angioneurotic edema. The asthmatic attacks are likely to be severe, prolonged and resistant to treatment. They may be acutely fatal (death by laryngeal edema in a few minutes after taking 5 grains; Dysart, 1933; other cases are discussed in the J.A.M.A., 1941, *116:* 145). Other types are vasomotor rhinitis, purpura, abdominal cramps, salivation. Epinephrine is relatively ineffective (Prickman and Buchstein, 1937). Before prescribing the drug to allergically inclined patients who have not had recent experience with it, they should be tested with a minute particle on the tongue (W. W. Duke, 1933). Skin tests are not reliable, and are therefore dangerous. Desensitization by graduated doses was recommended by Widal and Vallery-Radot, 1920, but it is much simpler to employ sodium salicylate, for the allergy does not usually extend to this.

Gastric Ulcers.—Large doses of acetylsalicylic acid (150 mg. per Kg. of body weight by mouth; 300 mg. per day hypodermically) produce mucosal ulcers of the stomach in rats. They heal nearly completely in ten days. With oral administration, the corrosion is due largely to the acidity, and administration of sodium bicarbonate diminishes their severity (not calcium carbonate or gluconate, as had been reported by some). Their occurrence after hypodermic injection (which is not mitigated by bicarbonate) shows that another factor is also concerned (Barbour and Dickerson, 1938).

It is not known whether acetylsalicylic acid plays a part in the production of gastric ulcers in man. Administration of therapeutic doses definitely increases gastric acidity, and sometimes causes gastric retention (Schnedorf, Bradley and Ivy, 1936); but swallowing of two or three tablets, whole, does not produce hyperemia, edema or hemorrhage of the normal gastric mucosa (W. D. Paul, 1943).

Calcium Antagonism.—Barbour and Dickerson, 1938, could not confirm that calcium gluconate protects against gastric ulcers, as had been claimed; nor had it any effect on the acute toxic phenomena in dogs (Barbour and Porter, 1937). It could be expected to diminish the local acid action somewhat, as a buffer. Mutch, 1934, reported that calcium acetylsalicylate had less effect than the free acid in producing epiphyseal bone changes in rats. Calcium acetylsalicylate is soluble in water, but hydrolyzes with liberation of salicylic acid (H. E. Thompson and Dragstedt, 1933).

PREPARATIONS.—***Acetylsalicylic Acid,** U.S.P. (Acid. Acetylsalicylicum; Aspirin), $C_6H_4.COOH.OCOCH_3$, 1:2; a white crystalline, odorless powder of a sour taste; slightly sol. in water (1:300), freely sol. in alc. (1:5). Its incompatabilities are so numerous that it should always be prescribed in pure, solid form. It is stable in dry air, but moisture hydrolyzes it gradually to salicylic and acetic acid. It is decomposed by water, weak alkalis and acids; it is incompatible with acetanilid, antipyrine, quinine, methenamine, ammonium chloride, potassium iodide, iron salts and tannates. Dose, 0.3 to 1 Gm., 5 to 15 grains, in powders, tablets or capsules. *Acetylsalicylic Acid Tablets,* U.S.P.; usual sizes, 0.06 and 0.3 Gm. *Salicylsalicylic Acid* (Salysal, Diplosal) is tasteless and yields one-half more salicylic acid than aspirin and one-fourth more than sodium salicylate. Its toxicity in man is twice that of sodium salicylate (MacLachlan 1913). It is resistant to gastric juice, but is rapidly saponified by the duodenal secretion (Tocco 1912).

METHYL SALICYLATE

This acts somewhat more slowly, but otherwise as efficiently as sodium salicylate; the "toxic" dose is about two-thirds that of the sodium salt. The effects may be considerably delayed, suggesting slow and irregular absorption (Hanzlik and Presho, 1925). It is given internally in extemporaneous capsules, or externally as counter irritant, generally diluted with 1 to 2 parts of olive oil and painted over the affected region. *Fatal poisoning* by methyl salicylate is fairly common, especially with young children and from its use as abortifacient. An ounce is usually fatal, with convulsions, coma, gastritis and congestion of the kidneys (Pinkham, 1887).

Rosenbloom and Johnston, 1919, reported severe poisoning after 1 ounce, but with ultimate recovery. There was immediate emesis; later, severe salicylism and albuminuria, both persisting about a week. They cite the bibliography.

Ethyl salicylate is less irritant and half as toxic (Houghton, 1905). **Spirosal** is used externally, being nonirritant and easily absorbed (Impens, 1907; literature, Seifert, Nebenwirk, 1915, p. 32).

Mesotan was introduced by Floret, 1902. It is decomposed by water into salicylic acid, formaldehyde and methyl alcohol. It is used externally, but has caused dermatitis.

Methylben, U.S.P., *Methyl Parahydroxybenzoate,* Nipagen, an isomer of methylsalicylate, and **Propylben,** U.S.P., *Propylparahydroxybenzoate,* Nipasol, are used (0.05 to 0.2 per cent) as preservatives for injection solutions.

Salicylanilide ointment is used for treating ringworm of the scalp (L. Schwartz, Peck *et al.,* 1946).

PREPARATIONS.—*Methyl Salicylate,* U.S.P. (Methylis Salicylas; Oil of Gaultheria, Oil of Wintergreen, Oil of Betula, Oil of Sweet Birch), is produced synthetically or obtained from distillation from Gaultheria procumbens or from Betula lenta. It is a colorless, yellowish or reddish liquid; characteristic odor and taste of gaultheria; sparingly sol. in water, sol. in alc. in all proportions. Dose, 0.3 to 1 cc., 5 to 15 minims.

PHENYL SALICYLATE (SALOL)

This was introduced by Nencki, 1886. Being insoluble, it passes the stomach practically unchanged; but is gradually decomposed into its components, 40 per cent of phenol and 60 per cent of salicylic acid, in the intestine, by the saponifying action of the alkali, pancreatic lipase and putrefactive bacteria. This avoids the taste of the components and the local gastric action; and since the decomposition is gradual, the local intestinal action is less violent and the toxicity is materially lessened. This "Nencki's salol principle" has been extensively applied in the form of other phenolic esters, *f. i.,* guaiacol carbonate, to mitigate the taste, local actions and toxicity of other active phenols or acids.

Phenyl salicylate (and methyl salicylate) are used in "sunburn ointments" to protect the skin against ultraviolet radiation. Absorption, if any, is insignificant (Luckiesh *et al.,* 1946).

Therapeutic Uses.—Salol did not fulfill expectations. The toxicity of the phenol limits the dosage, and its absorption is so slow that it is practically inferior to the other salicyl compounds in rheumatism or as urinary antiseptic (Sollmann, 1908). The phenol component was thought to be valuable as intestinal antiseptic, especially infantile diarrhea; but the decomposition is so slow and the absorption of the phenol so rapid that effective quantities could not come into action. The clinical and experimental evidence is not conclusive (Harris, 1912). As a wound antiseptic it would be valueless because it is not decomposed by wound secretions and only slowly by bacteria. Its use in tooth powders has caused eczema of the lips (Hugenschmidt, 1907). Perhaps its main value is as a coating for "enteric pills," *i. e.,* pill masses which are intended to pass the stomach unchanged (*f. i.,* ipecac in dysentery). It must be remembered that a coating sufficiently heavy to be effective introduces large doses of salol.

Decomposition and Antiseptic Action.—Salol is decomposed to a slight extent in the mouth and stomach by bacteria (Lesnik, 1887). It is split by human milk, so that its administration to nursing infants may cause gastric irritation (Usener, 1912). Its saponification by pancreatic ferments and alkalis is slow and incomplete, insufficient to prevent putrefaction even in test tube experiments; it is inferior to sodium salicylate or bismuth subnitrate (Sollmann, 1908). A part escapes decomposition in the intestines and passes unchanged into the feces—5 to 8 per cent in the experiments of Bondzynski and Humnicki, 1909; but doubtless often much more. If given in capsules, it may be found in the feces as crystals, "*salol calculi*" (Brossard, 1897), formed by the partial fusion and recrystallization of the salol (C. R. Marshall, 1897). It should therefore be administered subdivided as an emulsion or with indifferent powders.

Preparations.—*Phenyl Salicylate* (Phenylis Salicylas; Salol) is a white, crystalline powder melting at about 42° C., of a faint aromatic odor and taste; slightly sol. in water (1:6670); very sol. in alc. and fixed and vol. oils. Dose, 0.3 Gm., 5 grains; maximum dose, 2 Gm., 30 grains; in powders, generally with bismuth. Externally, as 5 per cent ointment.

BENZOIC ACID AND BENZOATES

Benzoic acid, $C_6H_5CO_2H$, occurs in balsams (Benzoin, Tolu, and so forth), in cranberries and in other vegetables; and in the decomposed urine of herbivora. It is now prepared synthetically. It is a fairly strong antiseptic of about the same rank as phenol; the salts are somewhat less efficient. The free acid in concentrations above 0.1 per cent produces moderate local irritation; the salts are not irritant. The systemic toxicity is low, even large doses producing mainly digestive derangement, sometimes with further effects, resembling those of salicylates. There is also a similar, but weaker, therapeutic action in rheumatic fever. Fatalities are unknown. Benzoic acid combines in the kidneys with glycocoll to form the inactive hippuric acid. This is used as a test of liver function. It also conjugates with glycuronic acid (review, L. Young, 1939). The low toxicity and the absence of odor or marked taste have led to the use of benzoates for the *preservation of foods*, especially fruits and vegetable products. Sodium benzoate is generally employed for this purpose in the concentration of 0.1 per cent; in acid foods, especially fruits, most of the benzoic acid would be liberated. This concentration suffices to restrain bacterial growth considerably, but may not prevent it completely. The *local actions* of benzoic acid are analogous to those of salicylic acid, and it is used similarly in dermatology, as a mild antiseptic stimulant and irritant, as an ingredient of Whitfield's ointment, and in the form of benzoin to promote the healing of small wounds, chapped hands, and the like.

Antiseptic Efficiency.—Buchholz, 1875, found the free acid germicidal in 0.4 per cent, and antiseptic in 0.1 per cent. Salkowski, 1899, found that 0.25 per cent kept meat sterile for five months; with 0.1 per cent there were only a few colonies. Sodium benzoate in neutral media inhibits growth in 0.3 to 0.5 per cent (Th. Smith).

Action on Digestive Ferments.—In test tubes, benzoic acid up to 0.1 per cent does not interfere markedly, but higher concentrations are detrimental, especially to pepsin (Leffmann, 1899). Peptic digestion proceeds fairly rapidly, however, even in a saturated solution (Dakin). These actions have no practical importance (Long, 1912)

Hippuric Acid Synthesis.—Benzoic acid and its homologs (cinnamic acid, quinic acid, and so forth), combine in the body with amino-acetic acid (glycocoll) to form hippuric acid. In man, benzoic acid up to 10 Gm. per day is excreted almost quantitatively as hippuric acid (Dakin, 1910) (85 to 90 per cent within five or six hours; H. B. Lewis, 1914). With large doses (25 Gm., Lewinski) a part escapes synthesis. Injected hippuric acid is excreted rapidly, *i. e.*, within nine hours (Raiziss, Raiziss and Ringer, 1914). The normal hippuric acid (averaging 0.7 Gm. per day in man) arises in this matter from the benzoic acid occurring naturally in vegetable foods; and from its homologs which are formed in protein putrefaction in the intestines (Baumann, 1886). Meissner and Shepard, 1866, showed that the synthesis of hippuric acid occurs in the *kidneys*. Bunge and Schmiedeberg, 1877, demonstrated the process in excised kidneys, and believed that this is the only organ concerned in dogs. Considerable hippuric acid is formed, however, in nephrectomized dogs (Kingsbury and Bell, 1915). In herbivorous animals, the synthesis takes place partly in other organs (Salomon, 1877), in the small intestines and liver (Jaarsveld and Stokvis, 1879). The *liver* also participates in dogs, for the hippuric acid is diminished by the injection of hydrazine, which induces fatty degeneration of the liver, but is supposed to leave the kidneys untouched (Lackner *et al.*, 1918). Chickens do not form hippuric acid (Yoshikawa, 1911).

Hippuric Test of Liver Function.—The conversion of benzoic into hippuric acid is incomplete if the supply of amino-acetic acid is inadequate, since this is formed in the liver, its deficiency indicates derangement of liver function. The test consists in the slow intravenous injection of 1.77 Gm. of sodium benzoate in 20 cc. of water (A. J. Quick, 1939). The hippurate output has been reported below normal in acute and epidemic hepatitis, obstructive jaundice, hepatic cirrhosis, hepatic carcinoma (Rennie, 1932); in schizophrenic catatonia (Quastel and Wales, 1940); also after anesthesia, general and spinal (Boyce and McFetridge, 1938). The latter, however, may be due to renal deficiency (Mann). The *conjugation of substituted benzoic acids* was studied by Quick and Cooper, 1932. *Diphenylene oxide* increases hippuric acid excretion, indicating that it is hydrolyzed with the formation of benzoic acid (Christomanos, 1929).

The **actions of sodium hippurate** resemble those of benzoate and salicylate, but are more feeble. The absorption of hippuric acid from the digestive tract is slower than with benzoic acid; its urinary excretion is more rapid. Both acids inhibit the uptake of oxygen by minced or sliced tissue (Griffith, 1938).

Clinical studies of moderate doses of benzoate are important in view of the use of benzoates for the preservation of food. Chittenden, Long and Herter, 1911 (Report 88, U. S. Dept. Agr.), could not demonstrate any effects on healthy individuals if larger quantities than are likely to be used in foods, 0.5 Gm. per day, were continued for weeks. Even 4 Gm. were not generally injurious. Others found no untoward effects with 12

Gms. daily over long periods (A. J. Quick, 1944). Wiley *et al.*, 1908, claimed some digestive disturbance by 1 to 2.5 Gm. in capsules, but the results were not striking, and their significance is doubtful (K. B. Lehmann, 1911). Excessive concentrations (above 0.1 per cent) of the free acid, consumed too liberally (as in cider or fruit juices) probably cause more pronounced gastro-intestinal irritation (Lucas, 1910), but not albuminuria (Herter, 1910). These concentrations have a noticeable taste which serve as a warning. There is no reason to assume that the benzoate has a cumulative action, since it is promptly excreted as hippuric acid; nor is there any evidence that the formation of this acid is in any way detrimental.

Permissibility of Benzoated Foods.—These investigations justify the conclusion that healthy individuals may safely consume reasonable quantities of benzoated foods (0.5 Gm. of benzoate per day, in concentration of 0.1 per cent), if these foods are not otherwise spoiled or unhealthful. Benzoate is probably the least harmful of food preservatives, and where these are needed, its use appears permissible, provided that its presence is stated so that it may be avoided by patients with gastro-intestinal or renal diseases to whom it could be harmful.

Possible Objections.—The evidence in favor of benzoates is really negative, viz., that no deleterious effects have been proved. Such negative evidence is always open to the objection that the methods of investigation may not be sufficiently delicate or comprehensive, or otherwise are not adapted to reveal the possible deleterious effects. More serious probably is the objection that the investigations were confined almost exclusively to healthy individuals. It is conceivable that irritant actions too feeble to influence normal organs might become deleterious to these organs, especially the gastro-intestinal tract or kidneys, if these are already diseased, or when the general resistance is lowered. Herter, 1910, advised against the free use of benzoates in dyspepsias. There is also evidence that the formation of hippuric acid, which is probably in part responsible for the harmlessness of benzoic acid, is interfered with in at least some types of kidney diseases.

Effects of Large Doses.—Sodium benzoate is tolerated without serious symptoms even in much larger doses, at least up to 60 Gm. per day (Jaksch, 1897). Such doses were formerly used in therapeutics. There are generally symptoms resembling those of salicylates (Rost, Franz and Heitzel, 1913). The dose required to elicit these symptoms varies greatly: nausea and vomiting were obtained in some cases with 6 to 8 Gm. (Meissner and Shepard, 1866); in others, 25 Gm. had no effect. The urine sometimes contains reducing substances, presumably glycuronic acid, especially if large doses (25 Gm.) are taken (Lewinski). The *toxic effects on animals* are analogous to those of phenol: gastric irritation, vomiting, dyspnea, decrease of reflexes, narcosis, sometimes convulsions (Kobert and Schulte, 1880). Dogs tolerate 1.7 Gm. per kilogram by vein without danger. This produces short vagus stimulation and prolonged rise of blood pressure (Naumann 1879). No effects *on the growth of rats* were observed with a diet containing 2½ per cent of the salt; but with 3 per cent, a third of the rats died (Griffith 1929).

The **internal therapeutic uses** are not important. The slightly irritant action of free benzoic acid has been used in *bronchitis* to promote expectoration, especially when the secretion is thin and abundant. Slow intravenous injection of sodium benzoate 5 to 10 cc. of 25 per cent solution, once or twice daily for two weeks, has been tried against *tuberculous cough* (Quaranta, 1936) and *pulmonary suppuration* (Goldkorn, 1937). These would be expected to produce acid flocculation, and would therefore act by colloidoclastic reaction rather than as benzoates. It has been claimed that hypodermic as well as intravenous injection of large doses of benzoate (and of iodobenzoates and iodosobenzoates) inhibit *mustard oil chemosis* in rabbits (Bernheim *et al.*, 1932), but this is notoriously difficult to judge. Benzoate could be used in *arthritis* as substitute for salicylates; but it is not so effective, and has no advantage. Benzoate has been used in *cystitis* as diuretic and to render the urine acid and antiseptic. The diuresis is uncertain, and the antiseptic action on the urine is weaker than that of salicylate (Sollmann, 1908). Benzoate was formerly employed to eliminate *uric acid* (Ure, 1841), but it is less effective than salicylate. Large doses (8 Gm. per day, in man) increase the elimination of urates in the urine, and decrease the urate content of the blood. The creatinine of the blood is not lowered (Denis, 1915). H. B. Lewis and Karr, 1916, observed a marked decrease in uric acid excretion during the period of maximal hippurate excretion, after 7 to 8 Gm. of benzoate. This effect is not produced by administering hippuric acid directly. Creatinine excretion was not affected by the benzoate.

PREPARATIONS.—*Benzoic Acid,* U.S.P. (Acid. Benzoicum), C_6H_5COOH; white crystalline scales or needles; slightly sol. in water (1:275), freely sol. in alc. *Sodium Benzoate,* U.S.P., is freely sol. in water (1:2). Dose, 1 Gm., 15 grains.

CINNAMIC ACID

Not much is known about the pharmacologic actions of cinnamic acid, $C_6H_5.CH:CH.COOH$, which occurs in Balsam of Peru. Erdmann and Marschand, 1842, showed that it is largely converted into benzoic and hippuric acids. After administration of 6 Gm. to man, 4 Gm. of hippuric acid are excreted in the urine within four hours, the same as with equivalent doses of benzoic acid (I. Snapper, Yu and Chiang, 1940). It has no effect on urate metabolism (Denis, 1915). Intravenous injection into rabbits first decreases, then increases, the blood platelets. This is followed by mild leukocytosis, especially of the lymphocytes (Claeson, 1929). Sodium cinnamate (*hetol*) was used intravenously by Landerer against tuberculosis, to cicatrize the foci by localized inflammatory reaction, but the results were disappointing. Cinnamic acid was proposed as a food preservative, but the German commission decided that while its toxicity is low, its harmlessness had not yet been sufficiently demonstrated to make its use permissible (Heffter and Rubner, 1914).

QUINIC ACID

This is hexahydro-tetraoxy-benzoic acid, $C_6H_7(OH)_4$·COOH.H_2O. It occurs in cinchona bark, coffee and many other plants. In man (also in rabbits, not in dogs; Stadelmann, 1879) it is largely transformed into benzoic acid and excreted as hippuric acid (Lautemann, 1863). Weiss, 1899, claimed that it lessened the formation of uric acid and had a beneficial effect upon gout. Decreased urate elimination was also claimed by Forester, 1900. Several observers reported clinical benefits, and various compounds were placed on the market (*urosin, sidonal, chinotropin*, and so on). Further observations showed the effects to be negative. Denis, 1915, found neither increase of urate elimination nor decrease of the urate content of the blood.

CINCHOPHEN (PHENYLCINCHONINIC ACID)

This substance, *phenyl-quinoline-carboxylic acid*, was introduced under the name of *atophan*. Its actions resemble those of the salicylates. It is about equally effective as antipyretic; it is often more effective as analgetic, particularly in chronic arthritis, and it provokes a greater excretion of uric acid, by a direct action on the kidneys. The minor side actions are usually smaller than with the salicylates. It was introduced by Nicolaier and Dohrn, 1908, to eliminate uric acid in gout, but the relief seems to be due almost entirely to its general analgetic effect. Occasionally, severe and fatal hepatitis develops, sometimes after a few therapeutic doses. The drug should therefore be avoided, or used only under close supervision, and stopped with the first indication of gastro-intestinal disturbance, itching, skin rashes or jaundice. Cinchophen and neocinchophen are not suitable for self-medication, and should be used by physicians only if the risks appear fully justified by the expected benefits. Most physicians do not consider them indispensable. They should not be used on persons with allergic tendencies (Report, Council on Pharmacy and Chemistry, 1941). The precipitation of uric acid from the urine furnishes a special contraindication in urate calculism. Cinchophen is but slightly soluble in water; but its acidity produces some irritation in the throat and stomach. *Neocinchophen* (tolysin), in which the carboxyl hydrogen is replaced by an ethyl group, and a hydrogen in the quinoline by a methyl group, lacks this acid action, and is nonirritant. Its limited solubility hinders the absorption of acutely toxic doses, but is sufficient for the therapeutic effects. Other *related compounds* were investigated by Impens, 1912, and the relation of their chemical configuration to the diuretic action by Kaku and Yamaguchi, 1929.

Fate of Neocinchophen.—In *man*, oral doses of 6.6 Gm. are absorbed practically completely and without saponification. The greater part is destroyed in the organism. In *rabbits*, a small part is excreted as dioxymethyl cinchophen (O. Fuerth and Kuh, 1930). *Cinchophen* is oxidized in the benzene nucleus (Dohrn, 1912).

Administration as Analgetic and Antipyretic.—The usual dosage of cinchophen is 0.5 to 1 Gm. suspended in water, four times per day. With larger doses, it is advisable to render the urine alkaline for one or two days by the administration of 15 Gm. of sodium bicarbonate, acetate or citrate, to prevent precipitation of urates. Neocinchophen may be given as tablets in the same dosage. The cinchophens are fairly efficient against neuralgic and rheumatic pain, and sometimes even against sciatica (McLester, 1913); but like most analgetics, they tend to become less effective with continued use. Its chief use is in gouty arthritis (Hench, 1936).

The antipyretic action was studied on animals by Barbour and Lozinsky, 1923.

Acute Rheumatic Fever.—Neocinchophen is generally as efficient as the salicylates. Partial relief has occurred with 7 to 8 Gm.; complete relief of fever, pain and swelling generally requires 10 to 16 Gm. The patients do not show the nausea and other symptoms of salicylism, nor does there appear to be any renal irritation with therapeutic doses (Hanzlik *et al.*, 1921; Barbour, Lozinsky and Clements, 1923).

Anticonvulsant Action.—In rabbits, cinchophen diminishes or prevents convulsions by minimal effective doses of metrazol (L. J. Pollock *et al.*, 1942).

Antiphlogistic Action.—It has been claimed that the administration of cinchophen diminishes experimental inflammatory edema in croton oil dermatitis and mustard oil chemosis (Starkenstein, 1919), but this holds true only of doses that produce collapse (Fuerst, 1925). Doses corresponding to the therapeutic toxicity do not improve chemosis or phosgene pulmonary edema (Laqueur and Magnus, 1921), or paraphenylene-diamine anasarca (Hanzlik and Tainter, 1923). Cinchophen inhibits completely the emigration of *leukocytes* in the inflamed frog's mesentery, and exhibits in this respect a potentiated synergism with quinine (Ikeda, 1916).

Use in Gout.—The mobilization of uric acid was supposed to be useful in gout by removing it from the blood and by dissolving the tophi. The uric acid and the nonprotein nitrogen of the blood are in fact lowered by it, the urate especially in gout, since the increase of renal permeability by cinchophen would offset the impermeability characteristic of gout (Folin *et al.*, 1924). Feulgen, 1912, claimed that the tophi are actually decreased in some cases. Clinically, however, cinchophen is much less efficient in chronic gout than in the acute attacks and in nonuratic joint affections. This makes it probable that cinchophen acts as an analgetic similarly to salicyl. In agreement with this, Klemperer, 1913, found derivatives which lack the uratic action equally efficient clinically.

Effect on Uric Acid Elimination.—The excretion of uric acid is greatly increased, sometimes more than doubled, by therapeutic doses, even on a purine-free diet. The increased excretion begins within an hour (maximum in three hours) and lasts only as long as the drug is continued; and it is then followed by a compensatory decrease (Haskins, 1913). The effect is attributed to increased permeability of the kidneys to urates. Several other explanations were proposed and abandoned (see Sixth edition of this Manual, page 636).

With continued administration, the uric acid returns to normal after one or two days, unless the diet contains purines. In that case, the decrease may be postponed till the fifth day (Grabfield and Pratt, 1922). The uric acid of the blood is diminished by the increased excretion (Folin and Lyman, 1913), but soon reaches an irreducible minimum; there is no further lowering even if the administration is continued forty-five days. When the administration is stopped, the initial concentration is restored within two to four days (Fine and Chace, 1914; Frank and Pietrulla, 1914). The response varies rather widely. When the renal cells have been severely injured, in the late stages of interstitial nephritis, cinchophen has little effect on the uric acid excretion (Fine and Chace, 1915). The concentration of urates in the urine may become so great that they are precipitated before the urine is voided; cinchophen apparently also decreases the solubility of urates in urine (Haskins, 1916). The urine is of a dark color, due to urochrome (Skorczewski, 1912). In other respects, its composition and quantity are not notably changed. The leukocytes of the blood are also unaltered.

Other Changes in Urine.—Cinchophen and neocinchophen act similarly to salicylate. They tend in general to increase the renal excretion of solids, most markedly that of uric acid, but also urea and chlorides, if the level of these in the blood is even slightly higher than normal (V. C. Myers and Killian, 1921; A. F. Chace, Myers and Killian, 1921). Cinchophen is much less reliable than salicylate to produce proteinuria and casts (Fine and Chace, 1915). McLester, 1913, reported an increase in the quantity of urine and of total nitrogen. Eisner, 1915, found the excretion of chloride and total nitrogen as often diminished. Renal function tests gave inconstant results.

The creatine content of the blood is not decreased (Denis, 1915).

Bile Secretion.—Cinchophen is one of the most effective choleretic agents. In dogs with ligated cystic duct, it increased the bile flow to five times in the first hour, and even after five hours it was still three times the normal. The output of bile pigments is also increased, but the bile acids and cholesterol are decreased (Chabrol and Maximin, 1929). A considerable part of the injected cinchophen was recovered from the bile (20 per cent in five hours, 55 per cent in a day; W. B. Bradley and Ivy, 1940). The biliary excretion of cinchophen is hastened by bile salts (Annegers *et al.*, 1943).

Biliary Eosin Excretion.—Brugsch and Horsters showed that some acid dyes, notably eosin, are excreted exclusively by the bile. K. Franke, 1930, found that small doses of cinchophen increase this eosin excretion by two or three times, without increasing the volume of the bile; large doses, which increase the bile volume, decreased the eosin excretion. Decholin increased both the volume and the eosin output. Neocinchophen hastens the excretion of sodium tetraiod-phenolphthalein by the bile (R. G. Spurling and Hartman, 1926).

Minor side actions are frequent. They depend in part on the acidity of the cinchophen, resulting in digestive irritation, epigastric distress, acid eructation, complete anorexia and diarrhea. If due solely to the acidity, these may be avoided by administering sodium bicarbonate with the cinchophen; however, digestive disturbances may be the initial symptoms of toxicosis. Large doses may produce symptoms analogous to those of salicylism, including emesis by central action. More specific effects are witnessed occasionally, especially skin rashes, puerperal, scarlatinal, urticarial or vesicular (C. L. Short and Bauer, 1933; Sutton, 1936). Cardiac distress and dizziness may occur as with other antipyretics (Loening, 1913). In cystitis it may produce vesical pain and hematuria.

Clinical Cinchophen Toxicosis.—For fifteen years after the introduction of cinchophen in 1908, only the minor side effects had been reported, and the drug was considered practically nontoxic. In 1923, Worster-Drought described the occurrence of jaundice after its use, and this was brought to general attention especially by Klinkert, 1926, and sporadic cases have continued to accumulate. From the literature of 1922 to 1931, von Oettingen has collected thirty fatal cases of hepatitis, and forty-five serious intoxications from cinchophen or its compounds. Their occurrence is capricious. Most patients do not show any bad effects, although they may have taken large doses day after day, for years (Hench, 1936). Others, with the same history, may suddenly develop the hepatitis; in others it occurs after a few clinical doses, such as 3 Gm. for two days. Most cases have a history of 0.5 Gm., three or four times a day, for varying periods, usually a week or longer. It seems to be especially common when the administration is resumed after an interval (Sugg, 1938).

The *symptoms* start with gastro-intestinal disturbance, nausea and vomiting, marked hepatic tenderness or pain, icterus; they progress to terminal stupor and death in coma, usually within one or two weeks after the beginning of the icterus. About half of the jaundiced cases end in death, notwithstanding prompt withdrawal (Palmer and Woodall, 1936). The *autopsy* generally reveals fatty yellow atrophy of the liver, often with some degeneration of the myocardium and kidneys. In nonfatal cases, *recovery* is slow.

That toxicosis occurs in a relatively small proportion of patients exposed to cinchophen signifies that there must be a *hypersusceptibility*, and it was suggested that this may consist in an incipient hepatitis; however, this has not yet been confirmed, and it is highly toxic to many persons who do not have a history of hepatic impairment. It is probable that large or repeated doses always cause some hepatic damage, but moderate degrees of this are so well repaired that they escape clinical recognition (MacBryde, 1940). It is apparently not an ordinary allergy; nor is acidosis an essential factor. The insoluble esters, because of their limited solubility and absorption, may be less toxic. Biliary and hepatic diseases should be definite *contraindications* to the use of cinchophen.

Precautions.—Cinchophen (and neocinchophen) administration always entails risk of hepatitis; even tried-out tolerance does not assure safety. If it is used, intermissions of six to eight days should be alternated with three or four days of administration. The liver should be palpated daily, and the urobilinogen elimination should be watched.

After the symptoms have developed, *treatment* is not promising. It has been advocated to increase the glycogen store, by a carbohydrate diet and by the injection of glucose and insulin. Calcium therapy has also been suggested, but its justification is doubtful.

Chronic Toxicosis in Animals.—Oral administration of cinchophen to dogs, rats and guinea pigs, when continued over several weeks with doses considerably larger than would correspond to the therapeutic dose, but which do not produce acute effects, results constantly in hepatitis, progressing to fatal yellow atrophy. Degenerative changes occur also in the kidneys and myocardium (Rici, 1932; Van Wagoner and Churchill, 1932; Barbour and Fisk, 1933; K. K. Chen, 1936). Somewhat smaller doses lower the resistance to other hepatic poisons. The toxicity is greater with diets low in carbohydrates, and if the animals are in poor condition (Radavin and Lederer, 1933). Doses of about double the human therapeutic level produce varying degrees of effects in different dogs (Annegers *et al.*, 1943).

Gastric and duodenal ulcers can be produced in dogs by large doses of cinchophen, and several clinical cases have been reported (Bloch and Rosenberg, 1932). The canine ulcers are similar to spontaneous peptic ulcers in man. They start with acute gastritis, beginning within a day after the administration starts, with diffuse cell infiltration or small focal abscesses (Simonds, 1938).

Acute Toxic Actions on Animals.—Large doses produce convulsions, paralysis and coma. Intravenous injection, in rabbits, is followed by stimulation of the vagus and vasomotor centers; these, as also the respiratory center, are finally depressed. The pupils are constricted, even after atropine. Cinchophen is said to prevent asphyxial and puncture glycosuria (Starkenstein and Wiechowski, 1914). The fatal dose of cinchophen with oral administration to dogs is about 1.25 Gm. per Kg., about twice as high as that of acetylsalicylic acid. Neocinchophen is not toxic in any dose, as only a limited quantity is absorbed (Barbour and Lo insky, 1923).

Barbour and Winter, 1929, claimed that the *magnesium salt of cinchophen* is less toxic than the sodium salt, and at the same time more effectively antipyretic.

PREPARATIONS.—*Cinchophen* (Phenylcinchoninic Acid; Atophan) and *Neocinchophen*, U.S.P. (Novatophan, Tolysin), are nearly insol. in water, sol. in alkalis. Dose, 0.3 to 1 Gm., 5 to 15 grains. *Neocinchophen Tablets*, U.S.P.; usual sizes, 0.3 and 0.5 Gm.

◆

SULFONAMIDE COMPOUNDS

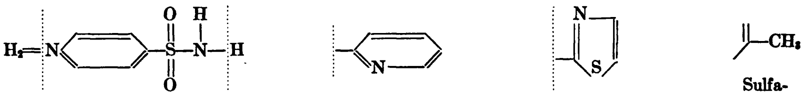
Sulfanilamide, the amide of sulfanilic acid, and its derivatives, colloquially called "sulfa drugs," check the growth of certain bacteria and other micro-organisms in the blood and tissues, producing bacteriostasis and thus giving better opportunity to the natural defense organisms to combat infections, local and systemic. The mechanism of this antibacterial chemotherapy is not directly bactericidal, but apparently involves interference with processes that are important for the metabolism and multiplication of the bacteria. This opened up a new concept of chemotherapy, that of the "*antibiotic*" action, differing rather fundamentally from that of Ehrlich, which aimed at direct death of the invading organisms. The term "*chemotherapy*" is still used somewhat artificially to designate the treatment of infections by chemical means in the living body.

Sulfanilamide was originally reported as acting specifically on infections caused by beta hemolytic streptococci, but it affects several genera of bacteria, especially the gram-negative meningococci, gonococci, pneumococci, certain viruses and, rather feebly, a few protozoa. The effect develops gradually during some forty-eight hours, and must be maintained for a week or two, by continuing the administration, to prevent recurrence. Various toxic effects may complicate the administration and may prove alarming, but are rarely fatal. The administration requires daily supervision by the physician, and it is desirable that the blood concentration of the agent should be frequently checked (by the method of Bratton and Marshall, 1939, J. Biol. Chem., *128*:537), to maintain a level adequate for therapeutic effects without incurring unnecessary danger. Derivatives show quantitative predilections for specific infections, and differ in toxic effects.

Chemical Structure.—Sulfanilamide, para-aminobenzene sulfonamide, was shown by Fourneau to be the active part of the original "prontosil." It permits innumerable substitutions in either of two situations: (1) the amino group, as illustrated by prontosil and neoprontosil, which probably act by conversion into sulfanilamide; and (2) in the sulfonamide group, such as sulfapyridine and sulfathiazole, which are not decomposed in the body and therefore act as such.

Nearly all the active derivatives contain a nitro or amino group in para position to the sulfur. The action is retained if the sulfur is replaced by As, C, P, Se, or Te, and by paranitrobenzoic acid (S. M. Rosenthal, 1939).

SULFONAMIDE SUBSTITUTIONS



Sulfanilamide

Sulfapyridine

Sulfathiazole

Sulfa-methyl-thiazole

The application of the name "prontosil" to a number of substances has caused serious confusion in the literature of the subject. "Prontylin" is sulfanilamide.

Historical.—Sulfonamide chemotherapy started with the discovery of Domagk, 1935, that azocompounds of the sulfanilamide group protect mice against infection with virulent hemolytic streptococci, and "*prontosil*" was introduced as having an especially favorable therapeutic index. The results were confirmed by Colebrook and Kenny, 1936, and applied clinically, especially to puerperal fever. Trefouel *et al.*, 1935, in France, found that other azo dyes derived from para-amidobenzene combat streptococcal infections and suggested that this is due to reduction to sulfanilamide in the organism. Buttle *et al.*, 1936, in England, showed on mice that the therapeutic potency of *sulfanilamide* (which was first prepared by Gelmo, 1908) equals that of prontosil and is less toxic. Various investigators have experimented with many derivatives, but most of these did not appear to have any real advantage, and many had a less favorable ratio of therapeutic and toxic potency, so that only a few were introduced clinically.

Fate.—Most sulfonamide drugs are absorbed more or less readily, from the gastrointestinal tract, the speed varying with the compound. They are distributed readily through all tissues and excreted chiefly by the urine, partly free, partly acetylated, the degree of conjugation varying with the compound and differing with animal species. A part is destroyed, and a small amount is temporarily fixed in the liver and kidneys. The concentration in blood, which determines the therapeutic and toxic actions, must be kept fairly constant day and night (E. K. Marshall *et al.*, 1937). Because of the variables it cannot be predicted with sufficient accuracy from the dosage, but must be checked by chemical tests. The acetylated compounds are generally less soluble and tend to form urinary concretions which may block the urinary tubules and produce mechanical irritation.

The absorption of *sulfapyridine* is slower and more variable than that of sulfanilamide; the proportion of the conjugated form is higher; and the excretion is more sustained (Marshall and Litchfield, 1939; Long, 1939). *Sulfathiazole* resembles sulfanilamide (Long *et al.*, 1940), but is absorbed more rapidly. The absorption of the sodium salts of sulfapyridine and sulfathiazole from the alimentary tract in man and monkeys is faster than that of the free substance, and is further hastened by simultaneous administration of alkalis, sodium bicarbonate or magnesium oxide (Ratish, Davidson and Bullowa, 1940; Barlow and Climenko, 1941). Sulfaguanidine and succinylsulfathiazole are absorbed slowly (E. K. Marshall *et al.*, 1941).

Absorption after Oral Administration.—Sulfanilamide is completely absorbed, usually within four hours. The absorption of sulfapyridine is less complete, averaging about 50 per cent, but it ranges from nothing to nearly complete. The difference is largely explained by the greater solubility of sulfanilamide (Long, 1939). Sulfathiazole and sulfamerazine average about 85 per cent absorption, sulfadiazine about 70 per cent.

Acetylation is a disadvantage, as it decreases the therapeutic efficiency, increases the toxicity and tends to force urinary concretions. The percentage of acetylation of the important compounds during their clinical administration averages about as follows (Chemotherapy Exhibit, A.M.A., 1944): in the *blood*, sulfapyridine, 65; succinylsulfathiazole, 50; sulfapyrazine, 30; sulfaguanidine, 25; sulfathiazole, 20; sulfanilamide, sulfadiazine, sulfamerazine, 15. In the *urine*, sulfapyrazine and sulfapyridine, 70; succinylsulfathiazole, 55; sulfamerazine, 45; sulfanilamide, 40; sulfadiazine, 30; sulfaguanidine, 25; sulfathiazole, 20 (Reinhold *et al.*, 1940; Sadusk *et al.*, 1942). Sulfanilamide is acetylated almost completely in rabbits, almost none in dogs (E. K. Marshall *et al.* 1937).

The *site of acetylation* of sulfanilamide is exclusively in the liver for rabbits and rats (J. S. Harris and Klein, 1938); but acetylation is not a valid test of liver function (Carryer and Swanson, 1942). In cats, the spleen also participates (Van Winkle and Cutting, 1940). Sulfanilamide acetylation in the rat is increased by pyruvate and to a less degree by acetoin. It is diminished materially by acetate, and also by deficiency of thiamine and riboflavin (G. J. Martin and Rennebaum, 1943). Homogenized *liver pulp* acetylates considerable sulfanilamide, sulfathiazole and paraminobenzoic acid, if aerated; very little if air is excluded. Addition of acetate doubles the amount; acetoacetate and pyruvate increase to a less degree (F. Lipmann, 1945). Quinine lowers the ratio of free to conjugated sulfapyridine in the urine by nearly half, quinacrine by less than an eleventh (Harned and Cole, 1942).

Sulfanilamide is used for determining the acetylating capacity of the organism. This is increased by administration of acetate, pyruvate, lactate, glucose, alcohol. It is also increased by giving thiouracil, decreased by thyroid and in hyperthyroidism (review, J. Fraenkel-Conrad and Greenberg, 1946).

The *blood concentration* varies widely for different patients with the same dosage per Kg. of body weight, even with sulfanilamide and sulfathiazole, and more so with sulfapyridine; the latter, however, runs a more even course, since it falls more slowly between administrations (Long and Feinstone, 1938). The therapeutic dosage is aimed at maintaining the blood concentration of sulfanilamide at 10 mg. per 100 cc., with sulfapyridine at 4 to 6 mg. per 100 cc. of the nonconjugated, as determined by the method of Marshall and Litchfield, 1938. With a single oral dose of 5 Gm. of *sulfapyridine*, the peak concentration of 2 to 4 mg. per 100 cc. is attained in six to twelve hours; with the same dose of sodium sulfapyridine, orally, 4 to 6 mg. is attained in four to six hours (Ratish *et al.*, 1940). *Sulfathiazole* gives practically the same concentration of unconjugated substance as equal doses of sulfapyridine, but the latter gives a higher concentration of conjugated (Barlow and Climenko, 1941). The peak is attained in three to six hours, after a single dose. Continuous administration of therapeutic doses maintains the concentration at 4 to 6 mg. per 100 cc. (Sadusk *et al.*, 1940).

B. D. Davis, 1943, reports that dialysis experiments indicate that some of the sulfonamide drugs are *bound by the protein of the plasma.* This increases the solubility, but only the unbound drug is bacteriostatic. The fixation resembles absorption by activated charcoal. PABA is similarly absorbed (A. H. Andersen, 1945).

The concentration in *ascitic fluid* is generally 60 to 90 per cent of the blood level (A.M.A. Exhibit, 1944), and this holds presumably for extracellular tissue fluid.

The *cerebrospinal fluid*, after oral administration of sulfanilamide, contains almost as high a concentration as the blood (Marshall *et al.*, 1937). This holds also for sulfapyridine, but not for sulfathiazole, of which only traces are found (Sadusk *et al.*, 1940). Sulfaguanidine also gives only a fourth of the blood level. Four hours after a single *intrathecal injection* of 80 mg. of sulfanilamide, the cerebrospinal fluid contains 10 to 16 mg. per 100 cc., while the blood contains 1 mg. or less. It is eliminated from the cerebrospinal fluid in eighteen to twenty-four hours.

The *fluids of the eyes* show sulfanilamide within fifteen minutes after oral administration, in dogs. After a single massive dose of 0.2 Gm. per Kg., the maximal concentration is reached in about six hours, when the blood contained 19 mg. per cent, the aqueous humor 12 mg., lens 9.5 mg., vitreous 8.6 mg. After therapeutic doses of 0.075 Gm. per Kg. for six days, the fluids of the eye contained 2.2 to 3.9 mg. per cent, about the same as the blood. Local application of heat, atropine, physostigmine or dionine had no effect on the concentration in the aqueous humor; methylcholine caused a slight increase (Bellows and Chinn, 1939). *Sulfadiazine* also penetrates readily into agneous humor, *sulfathiazole* very little (Scheie and Souders, 1941, cats). In *human eyes* (blind) the concentration in the ocular humors was 1.5 to 3.2 mg. per cent after oral administration in clinical doses, and less than 0.1 mg. after local application to the conjunctival sac (Mengel, 1939).

Gastro-Intestinal Tract.—In dogs, appreciable concentrations of sulfanilamide are attained in the bile; pancreatic, gastric and intestinal juice, and saliva. The *bile* may attain bacteriostatic levels (Carryer and Ivy, 1939; H. Shay *et al.*, 1944). The concentration of sulfanilamide and sulfapyridine in *gastric juice* (dog, isolated pouch) is about three times that of the whole blood; it is less than the blood with sulfathiazole, sulfadiazine and acetylsulfanilamide (M. Cooke *et al.*, 1941). *Bronchial secretion*, with sulfadiazine, contains about 60 per cent of the blood level (C. M. Norris, 1943).

The *breast milk* of normally lactating women contains considerably higher concentrations than the blood, after administration of 2 to 5 Gm. of sulfanilamide. The ratio of conjugated, 35 to 84 per cent, is about the same as in the blood and urine. The total amount of sulfanilamide excreted by the milk did not exceed 0.23 Gm., or 1.6 per cent of the amount ingested, too small to be dangerous to the nursling (Hac *et al.*, 1939).

Prostatic fluid of dogs on 0.18 Gm. of sulfanilamide per Kg. daily contained concentrations that kill B. coli in twenty-four hours (Farrel *et al.*, 1938).

Human placenta transmits sulfanilamide freely, so that the maternal and fetal blood contain practically equal concentrations. It also passes promptly into the amniotic fluid (Speert, 1938).

The *liver* retains demonstrable traces of sulfapyridine up to forty days after the administration (W. H. Brown *et al.*, 1940).

The **urinary excretion** of sulfanilamide and sulfapyridine, free and acetylated, occurs by glomerular filtration with tubular reabsorption up to 80 per cent, similarly to urea (Marshall, 1940). In dogs, the average clearance of sulfanilamide is 36 per cent of the average urea, and 20 per cent of the average creatinine clearance (D. F. Green and Allison, 1938). With full sulfanilamide treatment the urinary excretion equals the intake almost quantitatively when equilibrium has been established, which requires two or three days (Marshall *et al.*, 1937). *Sulfapyridine* is excreted more slowly and may be demonstrated four to five days after withdrawal (Long and Feinstone, 1938). After a single dose of 2 Gm., 60 per cent is excreted in twenty-four hours, three-fourths conjugated; while in the blood only 10 to 20 per cent is conjugated (L. H. Schmidt and Hughes, 1939). *Sulfathiazole* is rapidly excreted by the urine, rendering it more difficult to maintain uniform blood concentration. The excretion is nearly 100 per cent, in twenty-four hours (Sadusk *et al.*, 1940). The percentage of acetylation for the different compounds was given above. The solubility of the acetylated sulfonamide is at least ten times greater than that of the other acetylated compounds. The sulfanilamide excretion is hastened by water diuresis and decreased in *renal insufficiency*. Smaller doses should be used in this condition (Marshall *et al.*, 1937; J. S. Stewart *et al.*, 1938).

Urinary concretions occur from the poorly soluble acetylated compounds, especially from sulfapyridine acetate, and the needle-shaped crystals may cause renal injury, especially if the water output is low. Uroliths have been found in rats, rabbits and monkeys after feeding them the drug for several days (Antopol and Robinson, 1939). Sulfanilamide may also precipitate, chiefly as acetate, if the urine is fairly concentrated. The concentration can be decreased by liberal water consumption, or more rapidly by intravenous injection of 5 to 10 per cent dextrose. Administration of *sodium bicarbonate* increases the renal clearance, by interfering with tubular reabsorption, and at the same time increases the solubility of the conjugated compound so that crystallization becomes minimal (O. L. Peterson *et al.*, 1943, K. H. Beyer *et al.*, 1944; the relations of *p*H to the solubility of sulfonamides are reported by H. A. Krebs and Speakman, 1946).

The mechanism of the antibacterial action is believed to be through interference with the metabolism of the bacteria, since the arrest of bacterial growth is so much more potent than the bactericidal action. The bacteriostasis diminishes the production of toxic substances and checks the spread of the invasion, so that the phagocytes and other antibacterial mechanisms of the body may bring about recovery from the infection. These defensive reactions of the host are generally necessary to complete the suppression of the bacteria (E. A. Bliss and Long, 1937; C. Lyons, 1928).

The bacteriostatic effect is presumably due to inhibition, perhaps analogous to narcosis, of one or more enzyme systems, most probably the respiratory oxidation-reduction system concerned in cell division, rather than of the more general anabolic-catabolic systems (R. J. Henry, 1944). This would be in harmony with their para-structure. The respiratory enzymes differ more or less for the varieties of bacteria, which would explain in part their different susceptibility to antibiotic substances (M. G. Sevag, 1944). An earlier explanation by Woods and Fildes, 1940, involved the concept of *competitive inhibition by biological analogues* (review, A. D. Welch, 1945), the competition of the sulfonamide with the chemically similar para-aminobenzoic acid which plays an essential part in the metabolism of certain bacteria. It is not required, however, by most pathogenic bacteria (review, J. S. Henry, 1944).

In vitro, the blood of patients containing therapeutically effective concentrations of sulfanilamide (10 mg. per 100 cc.) is bacteriostatic, but not generally bactericidal. This holds true also if such concentrations are added directly to cultures (Bliss and Long, 1937; Lockwood, 1938); but higher concentrations are bactericidal for susceptible bacteria, such as pneumococci (Rosenthal, 1937). Elevation of temperature within the febrile range has a marked effect; the antibacterial potency is sometimes 200 to 300 times greater at 39° than at 37° C. (H. J. White, 1939).

Phagocytosis is secondary to the humoral effect of the sulfonamides, for the bacteriostatic potency *in vitro* is about as great in serum as in whole blood (Lockwood, 1938); but sulfanilamide acts as opsonin in cultures (Finkelstein and Birkeland, 1938); and *in vivo* it is not effective if the polymorphonuclear leukocytes have been depressed by the injection of benzene (Bliss and Long, 1937; Macgraith and Collum, 1938). It has no chemotropic action on leukocytes (Coman, 1938). *Antibody* formation is not inhibited, but is additive to the sulfonamide bacteriostasis. This also summates with *bacteriophage*.

Respiratory Enzymes.—Sulfanilamide inhibits aerobic and anaerobic respiration in susceptible bacteria and other cells. The inhibition extends to the utilization of dextrose, dismutation of pyruvic acid, synthesis and utilization of tryptophane (M. G. Sevag, 1944). In fertilized *ova of sea urchin* (Arbacia), sulfanilamide (and azide) inhibits oxygen consumption and cell division, in concentrations that have no effect on unfertilized ova (K. C. Fisher *et al.*, 1944). On *plants*, sulfanilamide acts similarly to colchicine, arresting *mitosis* in midcareer, resulting in large cells with two or four times the normal number of chromosomes and so producing new plant varieties (J. M. Beal, 1941). Sulfanilamide inhibits the *germination of seeds*, as does also penicillin (F. Ribeiro, 1944, 1946). The enzyme system has not been definitely identified, but sulfonamide does inhibit certain dehydrogenases and carboxylase (review, R. J. Henry, 1944). However, inhibition of bacterial respiration *in vitro* is not a reliable criterion of chemotherapeutic bacteriostasis (O. Wyssa *et al.*, 1942).

Antagonistic Substances.—It was early recognized that the addition of peptone checks the antibacterial action of sulfanilamide on bacterial cultures; the maximal potency is therefore obtained only in the absence of protein cleavage products. Serum free from these does not interfere with the bacteriostasis (J. S. Lockwood, 1938; McIntosh and Whitby, 1938). A variety of other substances also antagonize sulfonamide bacteriostasis (C. M. MacLeod, 1940).

They belong to several categories (Henry, 1944): (1) Formation of inactive complexes: peptone and other proteins. (2) Independent stimulation of growth if conditions were suboptimal (dextrose, certain amino acids)

(3) Specific interference with sulfonamide action (para-aminobenzoic acid, procaine, probably methionine [J. S. Harris and Kohn, 1941] and mercuric chloride). A substance may belong to several of these categories, and others may exist.

Synergists.—*Carbamates* (especially butyl carbamate and ethyl carbamate; less effectively *urea*) antagonize the para-aminobenzoic and methionine inhibition of sulfonamide action (Tsuchiya *et al.*, 1942). They also increase the solubility of sulfonamides, and are of value in the treatment of gram-negative infections in man (L. Weinstein and McDonald, 1944). *Azochloramid* in low concentration also increases sulfonamide potency (Schmelkes and Wyss, 1942).

Inhibition of Nicotinic Acid.—Sulfapyridine interferes with the curative action of nicotinic acid in deficient dogs (R. West, 1941). Sulfapyridine and sulfathiazole inhibit the stimulating effect of nicotinic acid amide on the respiration of dysentery bacilli. Sulfanilamide does not have this action (Dorfman, Rice and Koser, 1941).

Para-Aminobenzoic Acid ("PABA") *Antagonism.*—In bacterial cultures, 1 mg. of this substance may inhibit the bacteriostatic effect of 5700 mg. of sulfonamide (D. D. Woods and Fildes, 1940; F. R. Selbie, 1940; Keltch *et al.*, 1941). "PABA" occurs as a metabolite in cultures of certain bacteria and appears necessary to their growth, as part of a metabolic enzyme system. Woods and Fildes suggested that the structural similarity of sulfonamides enabled them to substitute themselves for the "PABA," and so block the system. Addition of excess PABA would displace the sulfonamide and restore normal bacterial growth; the mutual displacement is somewhat analogous to that of oxygen and carbon monoxide hemoglobin. Similarly, bacteria that require pantothenic acid can be inhibited by its sulfonic acid analogue, and this can be neutralized by adding excess of pantothenic acid (Snell). However, Sevag, 1944, pointed out that only a few varieties of bacteria require para-aminobenzoic acid, and these are mostly saprophytes; diphtheria is the only pathogenic organism for which it is important. The explanation would therefore not apply to the therapeutic effects. R. J. Henry, 1944, concludes that the antagonism of peptone, necrotic tissue, and pus to sulfonamides is not due to their PABA content. He adduces examples where PABA inhibits sulfonamides in systems in which it could not be a metabolite. He suggests that the antagonism is "by some type of adsorptive phenomenon." Meta and para monoaminobenzoic acids are also effective antagonists of sulfonamides (Henry).

Procaine. para-aminobenzoyl-diethylaminoethanol and related local anesthetics derived from para-aminobenzoic acid, also inhibit the bacteriostatic action of sulfonamides. There is some evidence that antagonism is due to conversion into PABA (Henry). Much larger proportions are required (1 mg. of procaine to 20 mg. of sulfonamide; Ketch *et al.*, 1941); but the clinical use of these local anesthetics definitely lowers the effectiveness of action of sulfonamide bacteriostasis. Metycaine, which is not a PABA derivative, avoids this interference (C. C. Pfeiffer and Grant, 1944; O. L. Peterson and Finland, 1944).

Spontaneous Resistance to Sulfonamides.—The susceptibility to sulfonamide bacteriostasis varies greatly in different bacterial species and strains, in cultures and in disease, depending presumably on the enzyme systems, and on the presence of inhibitors such as PABA. Restriction of vitamin income during sulfonamide administration has been suggested (Sevag, 1944).

Acquired resistance (*fastness*) *to sulfonamide* develops gradually in some degree (never completely) on continued exposure in cultures, or by unsuccessful therapy. It usually extends to all the sulfonamides, but not to penicillin, and vice versa. It is transmitted to subcultures almost indefinitely and is probably due chiefly to selective survival of the more resistant strains. In some cases the surviving strains synthesize much more PABA, but others acquire fastness without this (Landy and Dicken, 1942). The fastness may sometimes be overcome by adding urea (Tsuchiya *et al.*, 1942).

Therapeutic Scope of Sulfonamides and Penicillin.—The introduction of sulfonamides initiated a change in the whole outlook of the treatment of bacterial infectious diseases, that of chemotherapy by interference with the nutrition of bacteria. As an illustration, the use of specific antitoxins in the United States decreased about 40 per cent between 1937 and 1939, although the two approaches do not exclude each other and may be used together if necessary. The discovery of penicillin has furnished another means of nonspecific chemotherapy, with a somewhat different but overlapping scope. These fields may be defined as follows (F. G. Blake, 1945):

(1) *Infections against which both sulfonamides and penicillin are more or less effective:* Certain gram-positive and negative cocci, hemolytic streptococci, pneumococci, staphylococci, streptococcus viridans, meningococcus and gonococcus. The potency varies for different sulfonamide derivatives and with the strain as well as the kind of bacteria.

(2) *Infections susceptible to sulfonamides but not to penicillin:* Gram-negative bacteria, colon, dysentery, Hemophilus influenzae, Friedländer's bacillus, Ducrey's bacillus. Good results are reported from sulfonamides in plague (Meyer, 1943). They appear fairly successful in trachoma, follicular conjunctivitis, lymphogranuloma venereum, molluscum granulosum, pemphigus vulgaris, dermatitis herpetiformis, lupus erythematosus disseminatus and actinomycosis. They are somewhat effective against experimental, but not against clinical, malaria.

(3) *Susceptible to penicillin but not to sulfonamides:* Syphilis, yaws, possibly other spirochetal infections, Clostridial gas gangrene.

Other infections and organisms resistant to sulfonamides include most animal and protozoan parasites, Rickettsias (typhus) and virus; anaerobic and hemolytic B. streptococci, Brucella melitensis, common cold, diphtheria, influenza, rabies, rheumatic arthritis and rheumatic fever, tuberculosis, tularemia, typhoid and paratyphoid.

Choice of Sulfonamide Compounds.—*Sulfadiazine* is at present the preferred compound for infections with streptococcus hemolyticus, pneumococcus, meningococcus, Friedländer's bacillus and influenza bacillus, also for local application to infected wounds (sterilized crystals) and for intravenous injection (sodium salt). *Sulfamerazine* has even rank for pneumococcal and meningococcal infections. *Sulfathiazole* ranks next for all these. It is preferred against staphylococcus, gonococcus and colon bacillus. *Succinylsulfathiazole* has a special field in bacillary dysentery; *sulfaguanidine* holds second place. *Sulfapyridine* has gone out of favor because of its nauseant action, and *sulfanilamide* similarly because of relatively frequent toxic reactions. It is still preferred for chancroid (N.N.R.).

With ordinary doses of sulfonamides, some forty-eight hours are required to attain the full therapeutic effect; relapse is likely to occur unless the administration is continued for a week or two after the clinical symptoms disappear and the blood cultures are negative. Success requires the cooperation of the natural defense mechanism, and the administration must be continued until this has been sufficiently developed. There is no evidence that sulfonamide therapy interferes in any way with this development (Curnen and MacLeod, 1942). Specific sera and other measures of accepted value should not be withheld from patients receiving sulfonamides; they appear rather to potentiate each other (Marshall, 1940; Lockwood *et al.*, 1938; Long and Bliss, 1937).

Animal experiments on mice led to the discovery of sulfonamide chemotherapy and are indispensable for its development. Their results differ only in degree from those of the clinic, but judgment is necessary in the transfer. The effective dosage differs widely, but this is due chiefly to differences in the absorption, conjugation and excretion: the effective blood concentration is similar in all animals. Acute experiments give little information about the toxicity of continued administration: Concentrations that are innocuous in a few hours may become toxic if they are maintained (Marshall, 1940). Data on the potentiation of chemotherapy and specific antisera are reported by Branham and Rosenthal, 1937.

Pneumococcus Infections.—Sulfonamide therapy is successful in lobar and lobular pneumonia, especially in children, for all types of pneumococci, although there are individual resistant cases that require penicillin. Ordinarily, the temperature drops critically within twenty-four to forty-eight hours after the sulfonamide is started, the other clinical symptoms improve promptly, and the blood becomes sterile. The mortality rate is greatly lowered. Sulfonamides may be used with the specific sera; indeed, with considerable potentiation. They do not interfere with typing. Sulfadiazine is preferred for oral administration. Sulfapyridine and sulfathiazole are equally effective, but are more likely to nauseate. Serious toxic reactions are unusual. Intravenous injection of the sodium salts of sulfadiazine or sulfathiazole is sometimes advisable and may be necessary in starting treatment, especially if absorption is prevented by vomiting, but they should not be used oftener than necessary, as the strongly alkaline solutions sclerose the veins. Oral administration must be continued until convalescence is established, to avoid relapses. The dosage is discussed under the individual drugs. Good results have been reported in pneumococcal meningitis (Neal *et al.*, 1940).

In mice pneumonia, sulfathiazole and sulfapyridine seem to be about equally effective. Pneumococci appear to become *"drug-fast"* by cultivation with increasing concentrations of sulfapyridine, so that they multiply with a hundred times the usual sterilizing concentration. Mice inoculated with such "fast" bacteria resist the doses of various sulfonamides which are ordinarily effective (L. H. Schmidt *et al.*, 1940; E. Netter, 1940). *Intermittent clinical administration* (for endocarditis) also renders the circulating pneumococci more resistant to sulfapyrazine in cultures (M. Hamburger *et al.*, 1942).

Meningococcus infections respond well to sulfonamides. Sulfadiazine is preferred, as in pneumococcal infections. A single dose of 2 Gm. is effective in eliminating carriers (P. H. Long, 1946).

Gonococcus Infections.—All sulfonamides are effective, but sulfadiazine or sulfathiazole is preferred. The dosage need not be so intensive as in pneumonia, although the action is chiefly through the blood. The effectiveness has greatly decreased, however, since the earlier reports, the failures rising from 15 to 35 and even 80 per cent, presumably by development of more resistant strains. It has been almost completely displaced by penicillin (Hench, 1946).

About 70 per cent of gonorrheal patients are cleared in five to seven days; another 10 to 15 per cent by a second course, and the remainder can be cured with penicillin. Hospitalized patients may receive an initial dose of 4 Gm., followed by 1 Gm. every four hours day and night for five days; ambulant patients, 1 Gm. four times daily for five days. Untoward results are not common with this dosage, and it is not necessary to check the concentration except in renal impairment. Fluid should be pushed. No local treatment should be applied (T. B. Turner and Sternberg, 1944). The benefits are independent of the disease and the extent of the involvement of the urinary tract. Practically all patients who are influenced at all by sulfanilamide are symptom-free by the end of the fifth day;. if improvement is not marked by then this drug should be discontinued. The patient should be seen by the physician at least every forty-eight hours, for *side reactions* are frequent and diverse, especially with ambulatory patients. Lassitude, dizziness, profound weakness and fatigue are indications for discontinuing the drugs, and then disappear in a day or two (Dees and Colston, 1937; B. Silver and Elliot, 1939; Pelouze, Barnes *et al.*, 1940).

The efficiency of sulfonamide in gonorrhea is increased by heat; in chick embryos also it is more effective above 37° C. than below (Bang, 1942).

Resistance of gonococci to sulfonamides appears inherent in the patient and not in the bacterial strain: In eighty-five mutually infected couples, both partners were resistant in only one instance, one partner in fifteen instances (A. H. Harkness, 1943).

Gonococcal ophthalmia neonatorum is also greatly benefited by oral sulfathiazole, 0.15 Gm. per Kg. of body weight, so that local therapy is not necessary (M. L. Blumberg and Gleich, 1943).

Urinary Infections Other than Gonococcal.—The efficiency of sulfonamides varies with the bacterial agent. They are less effective than mandelic acid against streptococcus faecalis, and less effective than methenamine against Escherichia coli. Sulfadiazine and sulfathiazole are preferred. This action is not affected by the reaction of the urine. Urinary volume should be at least 2000 cc. to prevent precipitation.

Streptococcus haemolyticus infections are more resistant to sulfonamide than are the meningo-, gono- and penumococci, but the therapy is quite effective against the bacteremia, lymphangitis, erysipelas and cellulitis; especially against early, diffuse lesions with maximal tissue invasion and minimal tissue destruction. It is ineffective against established abscesses, except to prevent their spread. It has no effect on toxemia. The presence of debris decreases the effectiveness. The invasive power is definitely decreased within eighteen hours (Lockwood, Coburn and Stockinger, 1937). The benefit in pharyngitis, tonsillitis and scarlet fever is limited chiefly to prevention of complications (N. Plummer *et al.*, 1945). In *erysipelas*, the inflammation is markedly improved within twelve hours, the lesions become dusky red or purplish within twelve to twenty-four hours and disappear completely in four to ten days, and the temperature falls within a few days by lysis (J. A. Toomey, 1938). Sulfathiazole is the preferred compound. Quinine potentiates sulfathiazole against hemolytic streptococcus infections of mice (B. K. Harned, Miller *et al.*, 1944).

Prophylaxis against Streptococcus Respiratory Infections.—The large scale controlled experience of the U. S. Army (Holbrook, 1944) and Navy (A. F. Coburn, 1944) indicates that the continuous daily administration of 0.5 Gm. of sulfadiazine strikingly decreases the incidence of these infections (by 50 to 75 per cent in the Army, by 90 per cent in the Navy reports). The rheumatic fever morbidity is also decreased. It is conceivable that resistant strains may be developed by unsuccessful cases (P. H. Long, 1946).

Untoward reactions are less than a half per cent with this dosage (as contrasted with 5 to 10 per cent for therapeutic doses). The more common are dermal, in the second or third week of administration. This may generally be resumed after a week's intermission. Serious cases were few, with a fatality rate of 1:46,000.

B. W. Billow and Albin, 1946, also report promising results in mass prophylaxis with 1 Gm. of sulfadiazine daily for five weeks. Only 0.3 per cent showed reactions, chiefly of the skin, none serious.

Rheumatic Fever.—Sulfonamides have little if any effect on the severity and duration of the acute attacks, and are considered useless or worse at this stage (H. F. Swift *et al.*, 1938). Penicillin also fails to influence the course. Prolonged daily administration of sulfonamides during the quiescent intervals appears to reduce the incidence of subsequent rheumatic attacks (review, Hench, 1946).

Wounds and Burns.—The systemic use of sulfonamides probably reduces the incidence of invasive complications of contaminated wounds, but it is difficult to maintain adequate concentrations in the blood under warfare conditions (P. H. Long, 1946). Local application of sulfonamides to wounds is of questionable value. Extensive experience in the war failed to show that it reduces the incidence or degree of infection (J. S. Lockwood, 1944). Dry sulfonamides produce irritation, sometimes even to abscess. Their use in *clean wounds* (including appendectomy stump) is inadvisable. They delay healing at least 50 per cent and promote excessive scarring. They may be justifiable in ulcerations and contaminated wounds (E. M. Bick, 1942; F. W. Taylor, 1942). The U. S. War

Department discontinued the local use, even on infected wounds (J.A.M.A., 1945, *128,* 597). Systemic toxic effects from local wound applications are rare (J. A. Key, 1943), but may be feared from extensive burned surfaces.

The wound is sprinkled with a light to heavy frosting of sterile sulfanilamide or sulfadiazine in 40 to 60 mesh powder, not more than 10 Gm. to a wound or 20 Gm. altogether. (Sulfathiazole is not suitable. It cakes and is more irritating.) A single packing with sulfanilamide may secure a local concentration of 800 mg. per 100 cc. for thirty-six hours. *Sulfapyridine* powder is an effective hemostatic for oozing wounds; sulfanilamide and sulfathiazole lack this effect (B. P. Cunningham, 1942).

Oral administration may start with an initial dose of 2 to 4 Gm. of sulfadiazine (or sulfathiazole), followed by 1 Gm. every six hours for eight days (P. H. Long, 1943).

Intraperitoneal application of sulfanilamide has been advocated for prevention and treatment of *peritonitis,* by spreading 4 to 10 Gm. of crystallized drugs in the area of greatest infection, and sprinkling 2 or 3 Gm. on the wound layers and dressings before closure. This gives a relatively high and persistent local concentration without irritation or toxic effects (H. C. Jackson and Coller, 1942).

Retardation of wound healing by local application of sulfonamides has been studied on denuded *cornea,* where it slows the restoration of epithelium and the growth of fibroblasts; the young cells appear to be more susceptible to the injury (J. G. Bellows, 1943). *Intraperitoneal application* to rats of powdered sulfanilamide produced practically no injury. Sulfathiazole caused only slight irritation; sulfapyridine proved excessively irritant, resulting in adhesions (T. D. Throckmorton, 1941). In *tissue cultures,* sulfathiazole is more toxic than the others, but under *clinical wound conditions* this is modified by solubility, so that the local toxicity decreases in the order of sulfanilamide > sulfathiazole > sulfapyridine > sulfadiazine. In all these, however, the concentration for toxic action is much higher than for bacteriostasis, and the recovery from any injury occurs readily when the drug is removed (F. Jacoby *et al.,* 1941); except with *intracranial application of sulfathiazole,* for this is likely to cause jacksonian epilepsy, in man and in animals. Sulfanilamide, sulfadiazine, sulfapryidine and sulfacetamide do not produce this effect (C. Pilcher *et al.,* 1942; A. C. Watt and Alexander, 1942). Electroencephalography on cats indicates that sulfanilamide is safer than sulfapyridine, sulfadiazine and sulfathiazole (C. Brenner and Cohen, 1943).

Preference for Local Application.—Sulfanilamide powder is generally preferred, not only because it is less likely to delay healing, but also because it is more soluble and less caking than the other sulfonamide powders (F. Hawkins and Hunt, 1942). *Sulfadiazine* ranks second. *Burns* may be sprayed with a 2½ per cent solution of *sulfathiazole in triethanolamine* solution, 8 per cent, which forms a thin eschar; other sulfonamides do not form an eschar. *Sulfathiazole* is indicated only in developed staphylococcus infections. It may be applied as a few drops of a 20 per cent suspension in water and covered with gauze (L. A. Chambers *et al.,* 1942). A 20 per cent sulfathiazole ointment has been recommended for burns (J. G. Allen *et al.,* 1942). *Succinylsulfathiazole* as 20 per cent ointment in hydrous wool fat liberates sulfathiazole gradually (Pulvertaft and MacKenzie, 1943). *Propylene glycol* was suggested as a menstruum for local application of sulfonamides to *mucous membranes,* 3 per cent sodium sulfathiazole or 10 per cent sulfanilamide, applied as such in the mouth and ear, but diluted with ten volumes of saline for the *nasal mucosa* (Yonkman, Craven *et al.,* 1942). However, the use of sulfonamide "nose drops" is questionable, as they sometimes lead to serious sensitization. Severe destruction has followed instillation of 5 per cent sodium sulfathiazole solution (Futch *et al.,* 1942).

Addition of sulfanilamide to *stored blood,* 20 mg. per 100 cc., was advised by N. Novak, 1939, to prevent bacterial contamination.

Skin Infections.—Cutaneous applications of sulfonamide should be limited to chancroidal and superficial primary pyogenic infections of the skin, such as impetigo. They should not be continued longer than five days; and, except for chancroid, they should not be used until other measures have failed, because the skin, conjunctiva and also the nasal mucosa present a special hazard of sensitization, so that future internal or external use may produce serious local or generalized, sometimes fatal, exfoliative dermatitis. "Over-the-counter" sales of sulfonamide ointments are too dangerous (H. N. Cole, 1943).

Chancroidal infections respond strikingly to locally applied sulfonamides. Sulfanilamide is preferred, as powder, diluted with 20 per cent of starch (Combes and Canizares).

Sensitization by Cutaneous Application.—Sulfonamides rarely produce direct local irritation, but continued local use on the skin, or eye or nasal mucosa, often sensitizes to both local and oral administration.This was noted in about 5.5 per cent of the patients (R. A. Darke, 1944). The dermatitis generally begins with an eruption at the site of application. There is also photosensitization to sunlight and ultraviolet rays (C. S. Livingood and Pillsbury, 1943; H. N. Cole, 1943; E. W. Abramowitz, 1944; Report of Council on Pharmacy and Chemistry, 1945, J.A.M.A., *128:*1024).

Experimental Sensitization.—Repeated injection of sulfonamides into guinea pigs does not produce an acute anaphylactic response; but if the sulfonamides are first conjugated with various proteins by the Landsteiner technic, they become antigenic, with cross sensitization to other sulfonamides (A. G. Wedum, 1942).

Intestinal infections indicate sulfonamides that are relatively insoluble, so that their action in the intestinal tract may be prolonged, with relatively low blood concentration. They affect the normal intestinal bacteria sufficiently to interfere with their manufacture of vitamins. *Sulfaguanidine* was introduced for this purpose by E. K. Marshall,

1941. Some toxic reactions have occurred in its clinical use (J. J. Bunting and Levan, 1944), and it has been largely displaced by the less toxic *succinylsulfathiazole* (*sulfasuxidine*) and *phthalylsulfathiazole* (*sulfathalidine*). This is chemically and therapeutically similar to succinylsulfathiazole, and is claimed to be less toxic and more bacteriostatic, effective also in colon infections, with a dosage of 3 Gm. daily. It is sparingly absorbed, and rapidly excreted in the urine, giving low concentration in the blood (M. H. Streicher, 1945). They are used especially for the treatment of bacillary dysentery, 1 to 3 Gm. every four to six hours, and the elimination of carriers (Painton and Hantman, 1945), to protect against infection in surgical operations on the stomach and intestines. Chronic colitis is not markedly benefited. Good results have been reported for epidemic neonatal diarrhea (Twyman and Horton, 1943) and Asiatic cholera (J. S. Huang, 1944). Altogether, however, the results have not equalled the early expectations; sulfadiazine and sulfathiazole appear to be quite as satisfactory in bacillary dysentery (2 Gm. followed by 1 Gm. every six hours).

Tuberculosis.—Several sulfonamide derivatives—notably *promin, diazone, promizole,* the more toxic *diamino diphenyl sulfone,* and some related compounds—restrain the development of experimental tuberculosis in guinea pigs (Hinshaw *et al.*, 1945). Clinical trials have given only equivocal or "mildly encouraging," or perhaps rather discouraging, results.

Experimental tuberculosis in guinea pigs differs materially from the clinical disease. Cooper and Cohn, 1945, believe that the action in guinea pigs involves anoxia which does not occur in man. The clinical dosage of promin is 1.3 to 3.2 Gm. per day, orally. It is very soluble and may be injected intravenously or parenterally.

Virus Diseases.—Only four of these—trachoma, lymphogranuloma venereum (A. A. Knight and David, 1939), inclusion blennorrhea and mouse pneumonitis—have been shown definitely to respond to sulfonamide therapy. It is doubtful whether these are true viruses; and the response might be due to interference with co-invaders (G. Rake *et al.*, 1942).

In *trachoma*, a single three week course of sulfanilamide in most cases results in rapid disappearance of the characteristic epithelial cell inclusions, the corneal lesion responding more promptly than the conjunctival, capillary hypertrophy than follicular. About half the cases are healed, another third improved, about an eighth show little or no change (W. G. Forster, 1940; P. Thygeson, 1940).

The virus of the common cold is not materially affected by sulfadiazine, and the course is not materially influenced. The development of secondary invaders is checked, but its routine use is not advised (R. L. Cecil *et al.*, 1944). *Canine distemper* was reported cured by sulfonamides (Marcus and Necheles, 1938; Dochez and Slanetz, 1938). *Rabies* was reported as prevented by sulfanilyl sulfanilate in about a third of the rabbits inoculated with fixed virus (F. D. Crea, 1939); but after the symptoms have started, treatment is unsuccessful (B. F. Hall and Evans, 1939). In *smallpox*, mitigation of the skin suppuration, fever and scarring was reported by McCammon as the result of sulfanilamide treatment.

Malaria is checked by sulfonamides, especially in monkeys (L. T. Coggeshall, 1938), and chicks (Coggeshall *et al.*, 1941), but it is not sufficient against human malaria (Coggeshall, 1943).

Other Animal Parasites.—Sulfonamides are not effective in rats and mice infected with trypanosomes, Endameba, Trichomonas, Giardia and Hexamita (Zurett and Culbertson, 1940) or Trichina (O. R. McCoy, 1938).

Actinomycosis.—Apparent clinical cure was reported by E. M. Miller and Fell, 1939.

Toxic phenomena in sulfonamide therapy vary greatly in kind and degree, depending on the compound used, on the susceptibility of the patient and on sensitization. Their occurrence has no relation to the therapeutic effects, nor is there a constant relation to the dosage or even to the blood concentration. The duration of the administration is important, and severe toxic phenomena may develop suddenly when a constant dosage has been maintained for several weeks without any symptoms. Most of the symptoms are mild, some are alarming, relatively few are severe enough to enjoin discontinuance of the medication; very few, indeed, have been fatal. As the serious intoxications are unpredictable, close daily supervision of the patients is imperative.

Minor toxic effects comprise nervous and gastro-intestinal symptoms, cyanosis, fever, rashes, acidosis, precordial and abdominal pain, urinary concretions and their consequences. *Dangerous toxic symptoms* are extensive rashes, jaundice, anemia, hemoglobinuria, uremia and granulocytopenia. These sometimes occur with low doses. *Fatal reactions* amount to less than 0.4 per cent, chiefly by uremia, sometimes by agranulocytosis, dermatitis and convulsions (Vilter and Blankenhorn, 1944; Sutliffe *et al.*, 1943).

Precautions against toxicity comprise frequent red and white blood cell counts and estimations of hemoglobin and icteric index. If the abnormalities are recognized early and the drug is withdrawn, they may increase for a few days, but then improve rapidly, especially if a transfusion is given. Patients who have had toxic reactions may develop more severe reactions on a second course (W. T. Tillett, 1940; C. F. Garvin, 1939; Lockwood *et al.*, 1938; Marshall, 1938; Long and Bliss, 1938). As far as is known, all other drugs may be prescribed during sulfonamide medication. Quinine and atabrine do not dispose to untoward reactions, except perhaps to emesis (Harned and Etteldorf, 1944).

Patients who had toxic reactions in the first course are likely to develop toxic effects in a subsequent course, even if considerable time has elapsed. A different sulfonamide should be administered, as the reactions are less frequent (17 per cent) than when the same drug is administered (69 per cent; H. F. Dowling *et al.*, 1946).

Relative Toxicity.—*Sulfonamide* gives the greatest frequency of toxic reactions: about half of the adult patients, a fifth of the children. Cyanosis, acidosis, anemia and fever are especially frequent, nausea is relatively infrequent and urinary injury is insignificant. *Sulfadiazine* gives the fewest reactions (Vilter and Blankenhorn, 1944). With a single dose of 2 Gm., used in respiratory prophylaxis, only 0.5 per cent had any toxic manifestations, and these were serious in only 0.035 per cent. as high fever and mental disturbance (R. V. Lee, 1944). *Sulfathiazole* produced reactions in about a fourth of the patients receiving a single course; about half of these were allergic (Kent and Diefendorf, 1945). It causes vomiting in about 10 per cent of the patients, but not sufficient to prevent its administration. Fever, rashes and conjunctival congestion are more frequent than with sulfapyridine. Renal and hematopoietic effects are relatively slight and transient. The incidence of other toxic reactions is low. Its ready absorption and excretion facilitate even concentrations (Reinhold *et al.*, 1940). *Sulfamethylthiazole* is more toxic than sulfapyridine (Van Dyke *et al.*, 1939). Polyneuritis has been reported from its use; and especially from *sulfanilyl sulfanilamide* (Wighton and Johnson, 1938); it may also occur from sulfanilamide, clinically and in animals (Ornsteen and Furst, 1938), but is rare. *Sulfapyridine* is definitely more toxic than sulfanilamide on the basis of their concentration in the blood; but on oral administration sulfapyridine appears less toxic (Wien, 1938), because it is completely absorbed. However, it often produces severe nausea and vomiting; cyanosis and acidosis are less; severe leukopenia is apparently more common, especially with children; renal concretions and injury are more marked and call for greater water intake. The other toxic phenomena are closely similar to those from sulfanilamide (W. H Brown *et al.*, 1940). *Acetyl sulfapyridine* is more toxic to animals than is the free form and may cause marked lowering of the kidney function (creatinine clearance) clinically (Marshall and Litchfield, 1939; W. H. Brown *et al.*, 1940).

Sensitization by Oral Administration.—About a third of the patients treated with sulfonamide drugs develop a hypersensitivity sufficient to interfere with their subsequent use (R. H. Lyons and Balberor, 1941). This allergy is manifested chiefly by fever, skin eruptions and conjunctivitis. It sets in usually about nine days after starting the administration, and may persist for at least two years (J. R. Gallagher, 1939). It may show up in a later course even when the initial course was without symptoms (J. Nelson, 1942). Any one sulfanilamide sensitizes to all the others.

The allergic hypersusceptibility (but not the other toxicities, such as liver injury or hemolytic anemia) may be recognized by a wheal *reaction to intracutaneous injection* of 0.5 cc. of blood serum of patients receiving sulfonamide therapy, even though these are without symptoms. It is probably provoked by a combination of the sulfonamide group with plasma protein (W. B. Leftwich, 1944).

Untoward reactions may be grouped as (1) *allergic sensitization*, especially fever, skin eruptions and conjunctivitis; (2) *direct toxic;* (3) *mechanical*, from the precipitation of the drugs or their acetyl conjugates in the urinary passages (G. T. Kent and Diefendorf, 1945).

Fever, often with dermatitis, and with or without conjunctivitis, occurs in about a fourth of the patients, less often with sulfadiazine and sulfapyridine than with sulfanilamide and sulfathiazole. It is a sensitization phenomenon, developing usually between the seventh and tenth day of administration, sometimes on the second or third, with a peak on the ninth day. It is twice as frequent in patients who had a previous course of the same sulfonamide, although most of these did not have fever in the first course; but the fever is less frequent if a different sulfonamide was used in the first course (Dowling and Lepper, 1944). It may set in after a dosage has been decreased, so that it does not depend on concentration of the drug. It may occur without other toxic symptoms. Most commonly the temperature rises slowly and returns to normal in two days after the drug is stopped. Treatment may then be cautiously resumed, preferably with another sulfonamide. A few patients develop high fever twenty-four hours after starting the treatment. Fever also usually precedes the more serious effects of acidosis, acute hemolytic anemia, agranulocytic angina, dermatitis, toxic neuritis and hepatic jaundice (Lockwood *et al.*, 1938; Hageman and Blake, 1937).

Skin eruptions and conjunctivitis are common with systemic as well as local administration of all sulfonamides. They often accompany the fever and are also due to allergic sensitization. Sulfathiazole is perhaps especially subject to this (B. Shaffer *et al.*, 1943). The rashes are of various types and degrees, often resembling confluent measles, but sometimes take other forms, such as purpura. They may be evoked by sunlight or ultraviolet radiation (H. B. Blum, 1940; R. G. Park and Platts, 1942). They generally disappear in two or three days after withdrawal, and the administration may then be cautiously resumed, preferably with another sulfonamide (W. H. Brown *et al.*, 1940). If they extend over the whole body, however, and if the itching is severe, it should be a warning to discontinue altogether, as they may turn into acutely fatal exfoliative dermatitis. Such has been reported for ordinary doses of sulfathiazole (Weinstein and Domm, 1941) and sulfadiazine (R. D. Johnson, 1944). Severe pemphigus has occurred with sulfamerazine (L. A. Kasselberg, 1943). Bronchial asthma as a manifestation of sulfonamide therapy has been observed (Randolph and Rawling, 1944), but is rare.

Nausea and vomiting are especially common with sulfapyridine, and may be so severe as to preclude its oral administration. They appear to involve both local and systemic actions. A 1 Gm. dose of sulfapyridine delays the emptying time of the human stomach by an average of nearly a third (Northrup and Van Liere, 1940). A few patients have severe diarrhea and abdominal pain. Gastric disturbance is much less frequent with sulfathiazole, still less with sulfadiazine and exceptional with sulfanilamide.

Nervous disturbances as direct actions of the sulfonamides are frequent but usually mild: confusion, restlessness, dizziness, headache, nausea, vomiting; irritable, depressed or elated moods, lassitude and fatigue. They disappear completely after discontinuing the drug. Controlled tests on normal men showed no significant effect on reaction time, coordination and mental efficiency during the ordinary course of sulfadiazine or sulfathiazole (Reynolds and Shaffer, 1943; A. H. Price and Pedulla, 1944). Not infrequently, however, *serious nervous changes* develop in patients under sulfonamide treatment, especially if there was preexistent disease of the nervous system. They include severe melancholia (Lockwood *et al.*, 1938), aphasia, agraphia, stammering, toxic psychosis, peripheral neuritis, encephalomyelitis, optic neuritis, transitory myopia, blindness, convulsions (S. C. Little, 1942).

Animal experiments indicate that all sulfonamide drugs have toxic effects on the nervous system. Large doses abolish weak conditioned reflexes in dogs (Gantt and Marshall, 1945). Chickens develop peripheral neuritis, involving also the spinal cord and to a less extent the brain, the toxicity increasing from sulfanilamide (least) to sulfapyridine, sulfathiazole, and sulfamethylthiazole (most) (R. N. Bieter *et al.*, 1941). In *dogs*, different phenomena were evoked by sulfapyridine and sulfanilamide with doses above therapeutic levels (C. F. Morgan *et al.*, 1944). Sulfanilamide administration to *rats* does not alter their susceptibility to volatile and gaseous *anesthetics*, but materially increases their susceptibility to poisoning by the briefly acting barbiturates, especially the thiobarbiturates (Adriani, 1939); narcosis and fatality by papaverine is also increased (Glaubach, 1939). Sulfapyridine is reported to increase the intensity, duration and toxicity of the effects of morphine and codeine (Glaubach, 1941).

Cyanosis occurs in most patients with sulfanilamide, infrequently with sulfapyridine, rarely with sulfathiazole and sulfadiazine (R. R. Kracke, 1944). It develops generally about the third day of sulfanilamide administration, but sometimes within twelve hours, as a slate gray to deep blue color, first seen in the lips and finger nails, and spreading over the entire body. Its intensity does not parallel the drug concentration of the blood (Wendel, 1939). It clears rapidly on withdrawal. It is not a serious complication and does not call for decrease of dosage.

The mechanism of the cyanosis was at first in dispute, but it is now agreed that it is due to methemoglobin, although there may still be a few discordant voices (Chesley, 1938; F. H. King and Leslie, 1938). This pigment would be expected from the analogy of the clinical structure of sulfanilamide to aniline, while the sulfamido group could give rise to sulfhemoglobin. The latter, however, is present only in traces, regardless of the administration of sulfates (which were said to form this pigment; J. P. J. Paton and Eaton, 1937; Discomb, 1937). A. P. Richardson, 1940, reports that the sulfhemoglobin formation in mice depends on the sulfur content of the diet, and that it is increased by giving thiosulfate, sulfur, or potassium sulfonate, not by magnesium sulfate or thiourea.

The degree of cyanosis is parallel to the oxygen-carrying power (Hartmann *et al.*, 1938), and depends on the methemoglobin content, being detectable with 5 per cent and striking with 15 per cent of the hemoglobin in this form; 25 per cent has been reported. These levels are not high enough to cause symptoms of oxygen deficiency, except perhaps in pneumonia and in cardiac insufficiency. The cyanosis can be prevented or promptly removed by the administration of methylene blue, 0.065 to 0.130 Gm. every hour by mouth, or 1 to 2 mg. per Kg. intravenously (Wendel, 1939; Hartmann *et al.*, 1938; Campbell and Morgan, sulfapyridine, 1939; Vigness *et al.*, 1940; Richardson, 1939).

Marshall and Walzl suggested that the cyanosis is due to aniline black; Fox, Cline and Ottenberg, 1939, produced a purple dye by irradiation of sulfanilamide, but the spectrum is quite different from that of the sulfanilamide cyanosis, which is that of methemoglobin (Wendel, and Wendel, 1939). Oxidation of sulfanilamide and sulfapyridine by hydrogen peroxide also results in colored oxidation products which are absorbable by the fat of the envelope of the red corpuscles, without affecting the oxygen capacity. Oxidation products of sulfanilamide have been isolated from the urine (G. V. James, 1940) and may be responsible for cyanosis in the absence of met- and sulfhemoglobin.

Clinical acidosis occurs in about 3 per cent of the patients receiving sulfanilamide (Long and Bliss, 1938) and probably less frequently with sulfapyridine. It is not of important degree, but has prompted the routine administration of 0.5 Gm. of sodium bicarbonate for each gram of sulfanilamide. A. F. Hartmann, 1939, considers the decrease of plasma bicarbonate secondary to hyperpnea, and therefore primarily as a CO_2 deficit alkalosis, so that routine administration of alkali would not be indicated. The changes in dogs with large doses of sulfanilamide are also of the type of compensated CO_2 deficiency (McChesney *et al.*, 1939). Dogs receiving sulfanilamide for twelve days in doses equivalent to the clinical, showed slight decrease (5 per cent) of serum CO_2, without significant changes of *p*H. Administration of citrate prevents the CO_2 decrease (A. H. Free *et al.*, 1943). Sulfanilamide lowers the CO_2 combining power of the blood in man

(H. Southworth, 1937), perhaps by specific inhibition of carbonic anhydrase, which has been demonstrated for sulfanilamide, but does not occur with sulfapyridine (T. Mann and Keilin, 1940).

Ability to tolerate high altitudes (20,000 feet) is not significantly altered in normal persons by full therapeutic doses of sulfathiazole (E. W. Peterson *et al.*, 1945), although it was reported as improved in rabbits and dogs (F. L. Lawson, 1942).

Acute hemolytic anemia, destroying a third to over half of the red blood corpuscles within one or two days, may occur with any of the sulfonamides, in about 4.3 per cent of the clinical courses (C. B. Hendricks, 1942), irrespective of dosage or concentration in the blood. It begins usually on the first to third day of administration and reaches its acme between the third and seventh day, usually about the fifth day, but it may be delayed till the tenth day or longer, and it may increase for a day or two after the drug is withdrawn. No definite predisposing factors have been discovered, except that it tends to recur if a second course is given (W. B. Wood, 1938). It is perhaps more common with sulfanilamide, but occurs with sulfapyridine (Ravid and Chesner, 1940), sulfathiazole (Quick and Lord, 1941) and sulfadiazine (N. H. Boyer, 1943). The cause of the hemolysis is not known. There is marked hematogenous jaundice and hemoglobinuria, often with some hematoporphyrin. It is usually accompanied by high leukocytosis, fever, weakness and other symptoms which may be secondary to the hemolysis. Liver and renal injury are present in some cases. The erythrocytes do not show increased fragility (Spring and Bernstein, 1940). Erf and MacLeod, 1940, found increased urobilinogen excretion in about a third of pneumonia patients treated with sulfapyridine. Jaundice is usually due to hemolysis, and is a definite warning to discontinue the medication.

Secondary anemia is common with all sulfonamides, regardless of dosage, averaging nearly 40 per cent (Hendricks, 1942). The red corpuscles decrease gradually, sometimes to half of the normal, and return to normal when the drug is stopped. *Aplastic anemia* has been reported with sulfathiazole (L. M. Meyer and Perlmutter, 1942).

Sulfonamide Anemia in Animals.—In *white rats*, daily administration of large doses (1 Gm.) of sulfanilamide develops marked decrease of the red blood cells and other changes of macrocytic anemia. The bone marrow shows initail myeloid stimulation, then depression (Higgins and Machella, 1939). The anemia is accompanied by congestion of the spleen with extensive deposits of brown, granular pigment, the histologic picture returning to normal in four weeks after discontinuing the drug (Rimington, 1938). In *mice*, small Heinz bodies appear in most mature erythrocytes within a day after beginning the administration of sulfanilamide. They consist of cholesterol and protein with very little iron (A. P. Richardson, 1942). Sulfadiazine and sulfamerazine produce hemolytic anemia in 50 per cent of mice when their blood concentration reaches about 33 mg. per 100 cc.; sulfapyridine does so with 2.8 mg. per cent (Latven and Welch, 1944). Sulfanilamide is about twice as potent as sulfapyridine (A. P. Richardson, 1939).

Decrease of blood platelets, leading to severe thrombopenia purpura, is occasionally produced by sulfonamides (Kracke and Townsend, 1943).

Decrease of the prothrombin level may occur by inhibition of the intestinal bacteria which produce vitamin K (Daft *et al.*, 1942).

The leukocyte count tends to fall during the first week of the clinical administration and generally remains low for the next two weeks (C. J. C. Britton and Howkins, 1938). The acute leukopenia is more frequent with sulfapyridine, and may occur with small doses and brief administration (W. H. Brown *et al.*, 1940). It does not ordinarily involve the granulocytes (Bigler *et al.*, 1938).

Agranulocytosis occurs in about 0.9 per cent of sulfonamide therapy (C. B. Hendricks, 1942); fatal cases have been reported for sulfapyridine (W. H. Brown *et al.*, 1940) and sulfathiazole (P. C. Kennedy and Finland, 1941). It has been produced in weanling rats and corrected by administering liver (S. S. Spicer *et al.*, 1942; A. Kornberg *et al.*, 1943). On the other hand, sulfadiazine is useful to prevent bacteremia in agranulocytosis from other agents (H. Tarnower, 1945). *Interstitial myocarditis* with eosinophilic cellular infiltration is reported by A. J. French and Weller, 1942, as a common occurrence in autopsies of patients who had been recently treated with sulfonamides.

Hepatitis, with diffuse necrosis, occurs exceptionally (P. A. Herbet and Scaricacottoli, 1945), especially with exfoliative dermatitis (C. F. Garvin, 1938). Histologic liver injury has been described in children by Menten and Andersch, 1943. Jaundice, however, is generally due to hemolytic anemia. Indeed, sulfonamides do not aggravate the dysfunction of chronic liver damage, and they improve acute hepatitis associated with bacterial infection. With severe portal cirrhosis, serious toxic effects, other than on the liver, are exceptionally frequent (O. L. Peterson *et al.*, 1943).

Renal damage by sulfonamides may be of two types: (1) obstruction of the urinary tubules by crystals of the sparingly soluble acetylated derivatives (sulfanilamide is not subject to this); and (2) direct toxic renal lesions, tubular or sometimes interstitial, not dependent on obstruction. This is the most frequently fatal sulfonamide complication (Vilter and Blankenhorn, 1944). The renal injury is largely independent of the dose; fatalities have occurred in a range of 0.6 to 41 Gm. (F. D. Murphy *et al.*, 1944).

Urolithiasis, with renal and ureteral obstruction, is a fairly common complication of all sulfonamide therapy, except sulfanilamide, unless precautions are taken, especially in hot climates. It may become serious if not treated promptly. It is due to the crystallization of the acetylated compounds. This is influenced chiefly by the concentration of the drug, urinary stasis, *p*H and temperature of the urine (R. W. Barnes and Kawaicki, 1943). It is prevented by liberal water income, maintaining the daily urine volume above 2000 cc., and keeping it alkaline. Penna and Christopher, 1946, recommend daily intravenous injection of 15 Gm. of sodium bicarbonate for intensive sulfadiazine therapy.

The renal obstruction symptoms may develop on the second day or later, with abdominal or renal pain, hematuria, oliguria and nitrogen retention. Sulfapyridine urolithiasis occurs fairly constantly in rabbits, rats and monkeys, but not in dogs and mice, probably because these do not acetylate readily (Molitor and Robinson, 1939; Antopol and Robinson, 1940). Sulfadiazine lesions have been studied in dogs. The crystals formed high in the descending loop of Henle, with inflammatory reaction extending to and involving the glomeruli (B. Maisel *et al.*, 1942).

Direct toxicity to the kidneys is perhaps still somewhat in dispute. Prolonged administration of sulfanilamide to rats with nephrotoxic nephritis did not aggravate the course (Smadel and Swift, 1939). Nephrotoxic action has been observed clinically, however, in the absence of tubular obstruction (Priest, 1945). Sulfadiazine is reported to be more toxic than sulfamerazine and sulfamethazine (L. H. Schmidt *et al.*, 1944).

The **general toxicity** of sulfanilamide, as determined on animals, is low both for acute experiments and for continued administration, but the two are not necessarily parallel for different compounds. The acetyl derivatives are somewhat more toxic. The *acute fatality* of rats with oral administration of a single dose of *sulfanilamide* suspended in acacia is none at 3 Gm. per Kg., 20 per cent at 4 Gm., and 50 per cent at 10 Gm. (Murayama and Leake, 1938). With intraperitoneal injection into rabbits, 0.4 Gm. per Kg. had no effect, 1.0 Gm. caused mild symptoms, 1.5 marked symptoms (weakness of the legs, dyspnea and spasticity), and 2 Gm. were fatal to some of the rabbits and also to some of the cats. These showed chromatolysis of the central nervous system, especially in the spinal cord. Those which survived and were killed a week later showed no changes in the liver or kidneys (Hawking, 1937). Kohn-Richards, 1940, reports that the toxic effects resemble those of picrotoxin and that urethane, barbiturates and bromide are somewhat antagonistic, especially to the convulsions. Intravenous injection of 0.17 Gm. of sulfanilamide per Kg. in dogs and cats does not alter the blood pressure. *Sulfapyridine* injected by vein into dogs had little if any toxic effects with 0.1 Gm. per Kg.; 0.2 Gm. caused slight ataxia and muscular twitching; 0.3 Gm. caused vomiting, tremors and convulsions; 0.5 Gm. was fatal in two of five dogs (Marshall and Long, 1939). *Sulfathiazole* was studied on animals by H. A. Walker and van Dyke, 1941; *sulfadiazine* by W. H. Feinstone *et al.*, 1940; *sulfamerazine* by A. D. Welch *et al.*, 1943.

Continued oral administration of sulfanilamide to dogs, rabbits or rats at the rate of 0.2 Gm. per Kg. three times daily was not fatal after eight or more doses, but several of the animals had convulsions; none had anuria or renal or liver changes (Geiling, Coon and Schoeffel, 1937). Adult rats receiving 2 Gm. per Kg. of body weight daily, in acacia suspension, for five days, then 1 Gm. for five weeks, gradually lost weight and developed greatly enlarged spleens (Murayama and Leake, 1938). Parenteral injection for fourteen days into white mice produced marked hemosiderosis in the spleen, suggesting increased blood destruction. No pathologic lesions were found in the liver and kidneys (Hageman, 1937).

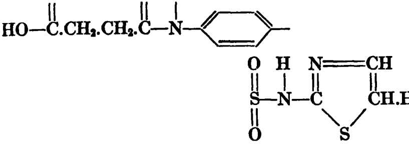
The *influence of diet* on sulfanilamide toxicity is reported by Kapnick *et al.*, 1942. *Thiamine deficiency* increases the toxicity of sulfapyridine (V. V. Cole and Harned, 1942). The addition of sulfapyridine (H. D. West *et al.*, 1943) or succinylsulfathiazole (E. Nielsen and Black, 1944) to the food of rats produces alopecia and other symptoms of *pantothenic acid* deficiency, alleviated by adding this substance or inositol, increased by biotin and folic acid. Sulfonamides also produce *vitamin K deficiency* in rats, parallel to their bacteriostatic effects on coliform bacteria. Ordinary absorbable sulfonamides are more effective than sulfaguanidine and succinylsulfathiazole (A. Kornberg *et al.*, 1944). The latter produced accumulation of calcium in the liver, and hepatic enlargement (Pilgrim and Elvehjem, 1945).

Various sulfonamides have different effects on the *blood sugar level and on liver glycogen* formation and storage (Greisheimer *et al.*, 1941). The *basal metabolic rate* of rats drops sharply when sulfonamides are fed. This is accompanied by thyroid hyperemia and hyperplasia, the phenomena of thyroid deficiency, including changes in the cells of the anterior pituitary (J. B. Mackenzie and Mackenzie, 1944). The effects resemble those of thiourea. The hyperplasia is not influenced by administering iodides, but it is inhibited by giving thyroid or by hypophysectomy. The hyperplasia is attributed to failure of thyroxin synthesis (Astwood *et al.*, 1943). Sulfonamides impede the *in vitro* conversion of iodide by slices of thyroid into diiodotyrosine and thyroxin (A. L. Franklin and Chaikoff, 1944). If sulfonamides are administered to rats during the latter part of gestation, the fetus shows almost complete absence of calcification. This is attributed to inhibition of phosphatase (R. Benesch *et al.*, 1945).

The *autonomic system* is but little affected by sulfonamides. Sulfanilamide, 1:1000, has no effect on *excised intestine* of rabbit and *uterus* of guinea pig (Hawking, 1937). Sulfonamides do not affect the response of the isolated intestines of rabbits and guinea pigs to epinephrine, acetylcholine, neostigmine, histamine and barium chloride, but they do inhibit the effects of *nicotine*. This is not antagonized by para-aminobenzoic acid. The response of striated muscle and the general toxicity of nicotine for frogs is not inhibited by sulfonamides (E. P Pick *et al.*, 1944). The excised *frog heart* is stimulated, then depressed; the maximal stimulation occurs with 0.25 per cent; 0.5 per cent slows to half or stops (Mendenhall and Shreeve, 1939). Sulfanilamide is directly toxic to the *skeletal muscle* of frogs (Litchfield, 1939). Administration of sulfanilamide or sulfapyridine inhibits the *calcification of egg shell*, so that this is soft, thin and pitted. This action is much weaker with other sulfonamides. It occurs without other symptoms and has been attributed to inhibition of carbonic anhydrase (Keilin and Mann), which is presumably necessary to shell formation (Benesch *et al.*, 1945). The evidence is not conclusive (R. Bernard and Genest, 1945). The *luminescence reaction* of luciferase on purified luciferin of cypridina is retarded (but not diminished) by sulfonamides, also by para-aminobenzoic acid and by urethane (F. H. Johnson and Chase, 1942). Sulfanilamide is reported to stimulate the formation of roots on *plant cuttings*.

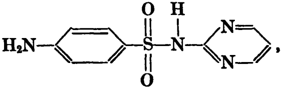
PREPARATIONS.—Sulfonamides generally are but sparingly soluble in water, but dissolve freely in dilute mineral acids and in alkali hydroxides. The sodium compounds are soluble and are used parenterally in sterile water for injection. The following sulfonamides are arranged in alphabetic order:

Succinylsulfathiazole, U.S.P., "*sulfasuxidine*,"



resembles sulfathiazole, but is little absorbed (not more than 4 per cent) after oral administration, so that the toxicity is low (A. D. Welch *et al.*, 1942). It is used for its bacteriostatic effect on the gastro-intestinal tract, and is safer than sulfaguanidine. It is employed for prophylaxis in intestinal operations, and for the treatment of acute bacillary dysentery, and on carriers of these bacteria. It is not effective against typhoid. The *preoperative dosage* is 0.25 Gm. per Kg., followed by the maintenance dose of 0.04 Gm. per Kg. every four hours, day and night, continued for one or two weeks after the operation. This maintenance dosage for seven days is also effective in eliminating carriers of Sonne dysentery (J. F. Painter and Hantman, 1945). Succinylsulfathiazole occurs as a white, crystalline, almost tasteless powder, slightly soluble in water (1:4800), soluble in dilute alkali. *Succinylsulfathiazole Tablets*, U.S.P., are usually available as 0.3 and 0.5 Gm.

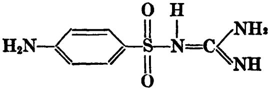
***Sulfadiazine**, U.S.P.,



is at present the preferred preparation for all internal administration. It has the advantage of more uniform absorption, sustained blood concentration and relatively low acetylation. It is as effective as any of the others, less nauseant than sulfapyridine and sulfathiazole; other toxic reactions are probably also less frequent. Sulfadiazine is administered in powder or tablets. The dosage is aimed to maintain the blood level about 10 to 15 mg. per cent in severe infections, 5 to 10 mg. in mild. In *severe infections*, the administration should start with 0.1 Gm. per Kg. of body weight, followed by 1 Gm. every four hours with 2 Gm. of sodium bicarbonate, day and night, until the temperature has been normal for seventy-two hours, when it may be discontinued. The daily urine output should be kept above 1000 cc. Oliguria or hematuria indicates that the drug should be discontinued and fluids forced. The alkali increases the solubility of the acetylation products in the urine (D. R. Gilligan *et al.*, 1943). Its absorption is slower and less complete than with sulfathiazole or sulfanilamide, but its excretion is also slower, so that relatively high concentrations are attained in the blood with smaller doses. Acetylation is also less. *Toxic reactions* are relatively infrequent, occurring in about 8 per cent of patients; the most frequent are renal. Nausea, vomiting, drug fever and cyanosis are rare, hemolytic anemia and agranulocytemia are still rarer. Acidosis is absent. In *mild infections*, the initial dosage may be half of the above. Sulfadiazine is a white powder, stable in air, darkening slowly in light. It is slightly soluble in water (8 mg. to 100 cc. at room temperature, 12.3 mg. per cent at 37° C.) Human serum dissolves 160 mg. per cent at 37° C. Average dose, 2 Gm., 30 grains. *Sulfadiazine tablets*, U.S.P., are usually available as 0.3 and 0.5 Gm.

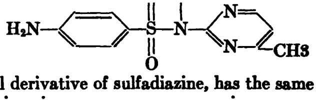
Sulfadiazine Sodium, U.S.P., is freely soluble in water (1:2). The 5 per cent solution of *Sterile Sulfadiazine Sodium*, U.S.P., is suitable for intravenous injection when prompt action is imperative or when vomiting prevents oral administration. The dosage is the same as by mouth. The solution is strongly alkaline (*p*H 9 to 10), and tends to produce thrombosis, so that it should be used only once or twice; never intramuscularly, as sloughing or gangrene results. The total dosage should usually not exceed 5 Gm.

Sulfaguanidine, U.S.P.,



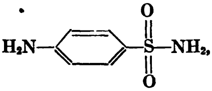
sulfanilylguanidine monohydrate, is fairly soluble in the intestinal contents, but is not readily absorbed, so that its blood level rarely exceeds 5 mg. per 100 cc., if it is properly administered. It is intended for local action in the intestinal tract, to secure bacteriostasis. It is used as *prophylaxis in colonic surgery*, 0.05 Gm. per Kg. of body weight, every eight hours, day and night, for five days before and seven days after the operation. Its usefulness in the treatment of *bacillary dysentery* is limited. The dosage is 0.05 Gm. per Kg. every four hours day and night till the stools are definitely decreased, then every eight hours for at least three days. If improvement does not occur in seven days, further administration is not likely to be successful. It is also used in treating carriers of bacillary dysentery (J. J. Bunting and Levan, 1944). Toxic reactions are relatively infrequent, but nearly a tenth of patients develop fever (Bunting and Levan); severe intoxication with rash and hematuria has been reported (S. L. Cole, 1942). Sulfaguanidine occurs as a white crystalline powder, sparingly soluble in water, freely soluble in dilute acids, insoluble in dilute alkali. Average dose, 2 Gm., 30 grains. *Sulfaguanidine Tablets*, U.S.P., are usually available as 0.3 and 0.5 Gm.

Sulfamerazine, sulfamethyldiazine,



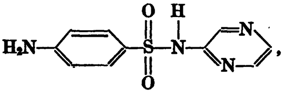
a methyl derivative of sulfadiazine, has the same field as sulfadiazine in pneumococcus, meningococcus, gonococcus and streptococcus infections (Macartney *et al.*, 1942). It is absorbed more rapidly and excreted more slowly than sulfadiazine, so that effective blood concentration is attained and sustained with about half the dosage, and the interval between doses may be doubled (Hageman *et al.*, 1943). It is well tolerated; nausea and other untoward effects are about as with sulfadiazine (H. F. Dowling *et al.*, 1944). Peripheral neuritis has been reported, but is exceptional. Urinary precipitation should be less (R. A. Goodwin *et al.*, 1942). A larger proportion is acetylated, but the acetylated as well as the unconjugated substance is more soluble than with sulfadiazine. Dowling *et al.*, however, found renal calculi rather more frequent, although not serious. Sulfamerazine was first described by R. A. Robbins *et al.*, 1940; its pharmacology and toxicology were studied by A. D. Welch *et al.*, 1943. The *clinical dosage* to keep the blood level at 10 to 15 mg. per 100 cc. starts with an initial dose of 3 or 4 Gm., followed by 1 Gm. every eight hours, continued for seventy-two hours after the temperature has returned to normal, unless there are toxic complications. Sulfamerazine occurs as a white, tasteless crystalline powder, which may darken on exposure to air. It is soluble in dilute acids and alkalis; slightly soluble in water, 22 mg. in 100 cc. at 25° C. Average dose, 2 Gm. *Sulfamerazine Tablets*, U.S.P., usually contain 0.5 Gm. *Sulfamerazine Sodium*, U.S.P., and *Sterile Sulfamerazine Sodium*, U.S.P., are freely soluble in water (1:3). The dosage for severely ill patients is 0.05 Gm. per Kg. of body weight, as 5 per cent solution, followed to 0.025 Gm. per Kg. at twelve hour intervals. The blood concentration should not exceed 15 mg. per 100 cc.

Sulfanilamide, U.S.P., p-amino benzene sulfonamide, "Prontylin,"



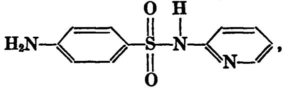
the structural basis of all the sulfonamides, is now but little used, since its derivatives surpass it in therapeutic effectiveness, and are less subject to toxic side effects, except as regards urinary crystallization. The *therapeutic dosage* of sulfanilamide should be such as to maintain fairly constantly an effective concentration in the blood, about 10 mg. per 100 cc., for serious infections. This should be checked at frequent intervals (by the method of Bratton and Marshall, 1939; J. Biol. Chem., *128:*537). The administration is generally started with 1 Gm. (15 grains) every four hours (for adults), totalling 6 Gm. per day; after forty-eight hours this is reduced to 0.5 to 0.66 Gm. every four hours, totalling 3 to 4 Gm. per day. This should be continued for some days after clinical recovery; in gonorrhea for at least two weeks. In milder infections, the daily dosage may be 3 to 4 Gm. from the start. Infants tolerate ⅓ to ½, children ½ to ¾ of the adult dose. Fluids should be restricted to 3590 cc. per day. It is customary to administer sodium bicarbonate in about half the quantity of the sulfanilamide. The absorption of the sulfanilamide is so prompt that it need not be administered parenterally except when it is not retained by the stomach. It may then be given by hypodermoclysis of a 1 per cent solution in sterilized physiologic saline solution or M/8 sodium lactate, in the same daily dose, divided into six- or eight-hour intervals. Sulfanilamide occurs as a white crystalline powder, of slightly bitter taste, sparingly soluble in water, 1 Gm. in 125 cc. Average dose, 2 Gm. *Sulfanilamide Tablets*, U.S.P., are usually available as 0.3 and 0.5 Gm.

Sulfapyrazine, 2-sulfanilaminopyrazine,



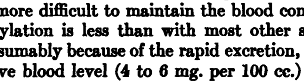
is absorbed and excreted rather slowly; the blood level rises gradually, but is easily maintained. Conjugation is relatively small. Its efficiency is similar to that of sulfadiazine; it is reported more effective against Shigella paradysenteriae. Side actions are as with other sulfonamides. Vomiting and renal injury are reported as less common. The *dosage* aims to establish its blood concentration as 5 to 12 mg. per 100 cc. The initial dose is 2 to 4 Gm., followed by 1 Gm. every four to six hours. In severe infections, *sulfapyrazine sodium* may be injected intravenously, as 5 per cent solution, starting with 0.05 Gm. per Kg. of body weight, with subsequent doses of 0.025 Gm. per Kg. in eight to twelve hour intervals. The blood concentration should not exceed 15 mg. per 100 cc.

Sulfapyridine, N.F., 2-sulfanilaminopyridine,



is already obsolescent, as its side actions are more frequent and severe and its effectiveness is rather less than with sulfadiazine or sulfathiazole. Its absorption is irregular, generally rather poor; acetylation is high, the excretion relatively slow. The blood level therefore requires close attention, preferably by chemical control, aiming at 4 to 6 mg. of free sulfapyridine per cent. Nausea and vomiting are frequent and severe; other side actions, including urinary obstruction, are about as with the other sulfonamides; dangerous complications are perhaps more frequent: acute hemolytic anemia, agranulocytosis, hepatitis. The *dosage* in pneumonia and other severe infections may start with 4 Gm., followed by 1 Gm. every four hours until the temperature has remained normal for seventy-two hours. In gonococcic infections, 3 Gm. may be given on the first day, and 2 Gm. per day, in divided doses, for the succeeding nine days. Sulfapyridine occurs as a white, crystalline, practically tasteless powder, sparingly soluble in water (1 Gm. in 3500 cc.), freely soluble in dilute mineral acids and in alkalis. *Sulfapyridine Tablets*, N.F., are usually available as 0.3 and 0.5 Gm. *Sterile Sulfapyridine Sodium* is freely soluble in water (1 Gm. in about 1.5 cc.), with strongly alkaline reaction (*p*H 10.4 to 11). It must not be used hypodermically or intramuscularly. A 5 per cent solution was employed intravenously.

***Sulfathiazole**, U.S.P., 2-sulfanilaminothiazole,



practically equals sulfadiazine in efficiency, but is more liable to toxic reactions, although distinctly less so than sulfapyridine. Its only advantage over sulfadiazine is in its lower cost. It is slightly more potent than sulfadiazine *in vitro*, but this could be adjusted by the dosage. It is rapidly absorbed, but it is also more rapidly excreted, so that it is more difficult to maintain the blood concentration. Acetylation is less than with most other sulfonamides, presumably because of the rapid excretion, so that the effective blood level (4 to 6 mg. per 100 cc.) can be attained more promptly. Nausea, emesis and dizziness are less frequent than with sulfapyridine, and mental disturbances are uncommon. Drug fever, rashes and especially scleral conjunctivitis ("pink-eye") are more frequent; blood changes and hepatitis are rare. Urinary obstruction may occur. The *dosage* for pneumococcal infections starts with 4 Gm., followed by 1 Gm. every four hours, day and night, until the temperature has been normal for seventy-two hours. For gonococcal infections, 3 Gm. may be given on the first day, then 0.5 Gm. four to six times daily for six to nine days. For *local use* in wounds, the powder may be mixed with an equal weight of sulfanilamide, to prevent clumping. Sulfathiazole occurs as a white, crystalline, practically tasteless powder, slightly soluble in water (1:1700). *Sulfathiazole Tablets,* U.S.P., are usually available as 0.3 and 0.5 Gm. *Sterile Sulfathiazole Sodium,* U.S.P., is freely soluble in water (1:2.5). It may be injected intravenously, as 5 per cent solution, starting with 0.1 Gm. per Kg. of body weight, with subsequent doses of 0.05 Gm. per Kg. in six hour intervals. The blood concentration should not exceed 12 mg. per 100 cc. Intramuscular or hypodermic injections would result in sloughing.

◆

PARA-AMINOBENZOIC ACID

"PABA," $C_6N_4.NH_2.COOH$, 1:4, a fairly nontoxic substance, is essential to the *growth of certain bacteria* (P. Fildes, 1940). It has been isolated from yeast, and is credited as the constituent of yeast extract which inhibits the bacteriostatic effect of sulfonamides, as discussed under that heading. *The bacteriostatic antagonism of PABA to sulfonamides* is shared quantitatively by its derivative, procaine, but not by ortho- and meta-benzoic acid (B. S. Walker and Derow, 1945). It occurs in life as well as *in vitro,* but does not extend to the toxic sulfonamide effects on animals, the fever and rash (E. Strauss *et al.,* 1941). PABA influences several metabolic oxidation-reduction systems, *catalytic reactions* which may furnish an explanation of its actions.

Para-aminobenzoic acid antagonizes the sulfanilamide inhibition of *carboxylase,* and the sulfanilamide inhibition of the *adsorption of methylene blue* on charcoal. It inhibits the destruction of *epinephrine* by *tyrosinase,* and the enzymatic oxidation of *stilbestrol.* It retards the aerobic oxidation of *tyrosine* and *dopa.* (Aniline has a similar but weaker effect; meta- and ortho-aminobenzoic acids are intermediate; Wisansky *et al.,* 1941.) It retards the action of the *luciferase* of Cypridina (F. H. Johnson and Chase, 1942).

Para-aminobenzoic acid acts as a *growth factor* for chicks, and has been included in the B complex (G. J. Martin and Ansbacher, 1941; review, S. Ansbacher, 1944), but its action is probably indirect by stimulating the intestinal bacteria to increased production of vitamins, presumably biotin and folic acid (L. D. Wright and Welch, 1943). It does not influence the growth of young rats (Ahlström *et al.,* 1943), but it sometimes cures the *gray hair* which rats develop on certain synthetic diets. This is probably also an indirect action, ascribed to better utilization of pantothenic acid. Excess of PABA also results in slight graying, attributed to increased growth of bacteria that destroy pantothenic acid (G. J. Martin, 1942). PABA prevents the syndrome of excessive inositol income (G. J. Martin, 1942).

P-aminobenzoic acid is an effective *antidote to carbarsone and certain other phenylarsonates,* as are also both its isomers, benzoic acid, phenylacetic acid and many other aromatic compounds (J. H. Sandground, 1944). The mechanism is not clear. It does not destroy the trypanocidal action of the arsonates. It is independent of the route of administration of the arsenical, but is more effective if the PABA is injected three hours in advance of the arsenic. It also protects against stibosan. It has no effect on the MLD of trivalent arsenicals, but is reported to inhibit clinical toxic reactions to these, as well as to pentavalent arsenicals in the treatment of neurosyphilis. It does not prevent nitritoid crises, gastro-intestinal reactions or optic injury (A. S. Rose *et al.,* 1944).

Louse-borne typhus fever is materially improved by intensive p-aminobenzoic acid treatment (Yeomans *et al.,* 1944), and has shown promising results in various rickettsian infections (Anigstein and Bader, 1945; tsutsugamushi disease, N.A. Tierney, 1946). The *dosage* starts with 4 to 8 Gm., then 2 Gm. every two hours, aiming to keep the blood concentration at 10 to 20 mg. per 100 cc. for at least three days, until normal temperature is maintained for twenty-four hours. Higher levels produce slight delirium (Tierney). As the free acid is irritant, it is administered as powder suspended in 25 cc. of 5 per cent sodium bicarbonate solution, followed by water. It causes no untoward effect except that the leukocyte count tends to fall, and if this drops below 3000 it should be discontinued. The mechanism of the effect on typhus is not clear, but it probably acts on the metabolism of the Rickettsias to prevent their multiplication. High concentrations check their growth in the yolk sac membrane of chick embryos (C. H. Andrews *et al.,* 1943; Greiff *et al.,* 1944).

The *prophylactic dosage* against rickettsian infections is 0.5 to 1 Gm. daily, conveniently as tablets of 0.25 Gm., with 0.65 Gm. of sodium bicarbonate per gram of PABA.

Fate.—On oral administration of 4 Gm. the plasma level rises sharply, reaching the peak in about an hour, and then falls rapidly. From 20 to 100 per cent is unconjugated in the plasma. The urine contains chiefly free p-aminobenzoate and conjugated p-aminohippurate, with smaller amounts of conjugated p-aminobenzoate and free p-aminohippurate (P. K. Smith, Bayliss *et al.,* 1946). The conjugate is chiefly acetylate, perhaps also glycuronate. Rabbits also acetylate it; dogs do not (E. K. Marshall *et al.,* 1937). *Myasthenia gravis* does not interfere with the acetylation (C. Torda and Wolff, 1944). It is *secreted by the renal tubules* so effectively that 88 per cent of its arterial concentration is removed in a single passage through the human kidneys (J. V. Warren *et al.,* 1944). Mice excrete 82 per cent within twenty-four hours; only traces remain in the organs (Lustig *et al.,* 1944). Normally, the blood, liver and kidneys contain at most a few gamma per 100 Gm. (Ahlström *et al.,* 1943).

The toxicity of p-aminobenzoic acid is low, with chronic as well as acute administration (R. K. Richards, 1942). The acute LD ($_{50}$) for various animals is 1 to 3 Gm. per Kg., orally; 2.8 to 4.6 Gm. per Kg. of the sodium salt by vein. In dogs, large doses (1 Gm. per Kg. by mouth) may produce intestinal hemorrhage; 2 Gm. per Kg. may result in acute hepatic necrosis (C. C. Scott and Robbins, 1942). S. Rothman and Rubin, 1942, claim that *in vitro* ultraviolet irradiated p-aminobenzoic acid produces a substance that sets up an inflammatory reaction when injected into the human skin.

G. R. Goetchius and Lawrence, 1947, report on the bacteriostatic and bactericidal action of a series of *N-alkyl p-aminobenzoic acid* derivatives.

Para-aminohippuric Acid, "PAHA," is excreted partly by the renal tubules and is used to estimate tubular excreting function (see Index).

PROPAMIDINE

This is an aromatic diamidine derivative, 4:4 diamidino diphenoxypropane dihydrochloride, prepared by Ewins, which arrests the multiplication of bacteria and protozoa (Lourie and Yorke, 1939), and is not inhibited by peptones and para-aminobenzoic acid (Thrower and Valentine, 1943). Local application of the 0.1 per cent solution is useful clinically in treating chronic wound infections (McIndoe and Tilley, 1943) and in burns (G. H. Morley and Bentley, 1943).

◆

"ANTIBIOTIC SUBSTANCES"

This name is applied to numerous chemical substances produced by living organisms, generally bacteria, fungi and actinomyces, which exert an "antimicrobic" action by interfering selectively but not specifically with the multiplication of certain micro-organisms. They occur especially in the saprophytic flora of the soil. Only a few are as yet of practical importance, notably penicillin and streptomycin.

Waksman and his associates, who introduced the term "antibiotic," found that 10 to 50 per cent of all actinomyces cultures show antibiotic activity, often very great, but differing widely in scope. Some are effective against only a few varieties, others have a wide field. The therapeutically useful antibiotic agents are highly specific. Gram-positive organisms are more susceptible than are gram-negative ones. The production of the antibiotic agent depends on the strain rather than on the genus or even species.

A species often produces several such substances; for instance, *Penicillium notatum* also furnishes *penatin*, reported to be a more potent bacteriostatic than penicillin. Aspergillus fumigatus of stable manure yields four antibiotic agents. On the other hand, the same substance, for instance *clavacin*, may be produced by different organisms (review, S. A. Waksman, 1944).

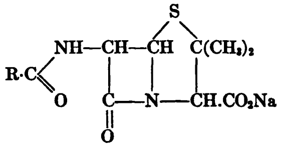
Penicillin and streptomycin are rapidly excreted, and have a low toxicity for animals. They act primarily on bacteria, but little on virus, and practically not on fungi. Penicillin is effective especially against cocci, gram-positive aerobes and anaerobes and against spirochetes. It has little effect on gram-negative and acid-fast bacteria. *Streptomycin* is effective against both gram-positive and gram-negative and acid-fast bacteria, relatively less against cocci, spirochetes and anaerobes.

These two agents also differ in facility of developing resistance, and resistance acquired to the one does not extend to the other (review, Waksman, 1947).

PENICILLIN

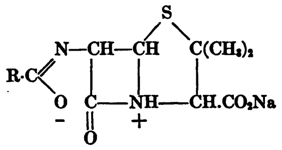
Penicillin is an outstanding "antimicrobial agent," producing successively, with increasing concentrations, arrest of growth, death and disintegration of susceptible bacteria, fungi, protozoa and other micro-organisms. It is used to overcome infections on the principle of arresting multiplication of the parasites, presumably by interfering with their metabolism, rather than by killing them outright. This is fundamentally analogous to the action of sulfonamides. The bacteriostatic action of penicillin was discovered by A. Fleming in 1929; its therapeutic application originated with Chain, Florey *et al.*, 1940 (history, L. A. Falk, 1944). It was originally prepared as progressively purified extracts from cultures of a special strain of the mold *Penicillium notatum.* Its synthesis has been accomplished by du Vigneaud, Carpenter *et al.*, 1946, but not in commercial quantities. Four varieties of penicillin, designated as F, G, K and X, have been isolated from the same mold, their quantities differing with cultural conditions. They are esters of a substance which probably has one of the following formulas (Med. Res. Com., 1945, Science, *102:*627):

(I)



or:

(II)



In G penicillin, R stands for benzyl, in X for p-hydroxybenzyl, in F for Δ^2-pentenyl, in K for n-heptyl. They are strong monobasic acids and are marketed as somewhat impure calcium or sodium salts which are readily soluble in water.

Dilutions of 1:50,000,000 completely inhibit the growth of susceptible bacteria, while other varieties, for instance the tubercle bacillus, are quite resistant. In general, gram-positive bacilli and gram-negative cocci are susceptible, and gram-negative bacilli are insusceptible, but the strains may differ more than the species. The action is not significantly impaired by blood or pus or by the number of bacteria. Penicillin is not hemolytic, and is remarkably nontoxic to body tissues, including tissue cultures. Its clinical use against susceptible forms is spectacularly effective, supplementing and overlapping the sulfoniamides and supplanting them to a considerable degree because of its nontoxicity as well as its potency. Oral administration can be made effective, but is wasteful, since it is rather poorly and capriciously absorbed from the gastro-intestinal tract and is rapidly excreted. It is best administered by intramuscular or intravenous drip instillation, to maintain effective concentrations. It is not toxic to animals in concentrations hundreds of times greater than are needed for bacteriostasis.

Preparation.—Penicillin is obtained by growing special strains of the Penicillium mold on suitable media for an optimal time. The culture fluid contains more than the felt of mold, and is extracted with differential solvents and dried. It must be preserved in a vacuum, as it is *readily destroyed,* especially when it contains moisture. The decomposition of crystalline sodium penicillin in solution is autocatalytic, and if once started it is difficult to control. Its rapidity increases with temperature (B. Berk *at al.,* 1947). Solutions of crystalline penicillin G lose their potency more rapidly than the purified. The decomposition is retarded by small amounts of phosphate, 0.005 M (R. Pratt, 1947). Commercial penicillins before 1944 contained chiefly G or mixtures of G and F. Then changes in manufacture decreased the G considerably, with increase of F and especially K. There is little of X in most. Purification has increased the potency from 200 units to the current level of 900 to 1400 units per milligram (Com. Med. Res. 1946, J.A.M.A., *131:271*). The varieties differ somewhat in potency *in vitro,* and much more so *in vivo.* The X is considerably more potent against most bacteria, including gonococcus. It also maintains its blood concentration better with intramuscular injection, so that smaller doses suffice (Libby and Holmberg, 1945; Ory *et al.,* 1945). K is so rapidly destroyed in the body that its therapeutic efficiency is much weaker; for instances, in experimental syphilis (Eagle and Musselman, 1946; Heller, Moore *et al.,* 1946).

Esterification of the carboxyl group of penicillin greatly increases the stability (K. Mayer *et al.,* 1943). *Benzyl penicillin* is at least three times as potent as sodium penicillin (C. J. Cavallito *et al.,* 1945).

“*Penicillin B*” is an entirely different substance, a flavoprotein which oxydizes glucose to gluconic acid and hydrogen peroxide. Through the latter, it is a highly effective bacteriostatic, but it is toxic (E. C. Roberts *et al.,* 1943; van Bruggen *et al.,* 1943).

The *penicillin unit* is used to assay the penicillin preparations and to express the dosage. The present international unit is 0.6 micrograms of pure crystalline sodium penicillin G (A. C. Hunter, 1944; P. Hartley, 1945); 100,000 units would correspond to 60 mg. of the pure penicillin salt, and 1 mg. would contain 1667 units. This unit is close to the older *Oxford* (Florey) *unit,* “that amount of penicillin which, when dissolved in 50 cc. of meat extract broth, just inhibits completely the growth of the test strain of staphylococcus aureus.” *In vitro,* 0.03 unit per 100 cc. suffices to sterilize all susceptible bacteria except some strains of meningococcus and staphylococcus, which require 0.06 to 0.24 units; some staphylococci require more (Finland *et al.,* 1945).

Fate.—Penicillin is distributed freely through all fluids and tissues except the nervous system. The major portion is excreted in the urine (about 60 per cent with intravenous, 14 per cent with oral, administration; A. H. Free *et al.,* 1945); minor fractions by the bile and saliva. The fate of the remainder is not known. It is not rapidly destroyed in the blood *in vitro* at body temperature (Cutting, Ludueña *et al.,* 1945).

Absorption of orally administered penicillin varies with the individual and with conditions, but is always incomplete. Effective doses can be given, but with considerable waste. It requires generally five times as much as with intramuscular injection to maintain an equal blood concentration. The absorption occurs chiefly from the duodenum and takes place promptly, reaching the maximum blood level in half an hour to one hour after ingestion, but about two-thirds are not absorbed, presumably because they pass beyond the absorbing area. The unabsorbed penicillin is destroyed by the intestinal bacteria or escapes in the feces. A small amount is inactivated by the gastric acidity. The effect is therefore somewhat greater if it is administered when the stomach is not acid, fasting, or still better in patients with achlorhydria; but not more than a third is absorbed even in the entire absence of acid (W. McDermott *et al.,* 1946). Buffering with alkali is but little better than simple saline; aluminum hydroxide protects somewhat better, but not much (M. Finland *et al.,* 1945; J. Charney *et al.,* 1945). Enteric-coated capsules give absorption similar to that in achlorhydria, but are far inferior to intramuscular injection (L. D. Seager, 1946). Even when penicillin is placed directly in the intestines, its absorption is poor and variable. In the rectum it is destroyed by some of the fecal bacteria. *Vaginal absorption* of penicillin is quite good, except near the end of gestation (J. Rock *et al.,* 1947).

Distribution.—The concentration of penicillin in the blood reaches its peak within thirty minutes after *intramuscular or hypodermic injection,* remains moderately high for an hour and falls rapidly in the second hour, persisting at lower levels for three or four hours (J. V. Cooke and Goldring, 1945). The concentration falls to almost nothing within an hour after *intravenous injection.* It passes promptly into the urine and extracellular fluids; the concentration in the pleural and peritoneal fluid, and in the joint fluid in rheumatoid arthritis, approximates that in the blood. The concentration in the *red blood cells* is less than a tenth of that in the plasma (Rammelkamp and Keefer, 1943). It passes through the human *placenta* so as to raise the titer of the fetal blood considerably above the bacteriostatic level (H. J. Greene and Hobby, 1944). It is not excreted into bovine *milk* (Seeley *et al.*, 1945). It passes into the fluids of the *eye* promptly, but in small amount. Subconjunctival injection or constant corneal bath attains high concentrations in the ciliary body, moderate in the humors (Struble and Bellows, 1944). The concentration in the *cerebrospinal fluid* is materially less than in the blood, but reaches therapeutic levels (to 0.55 units per cubic centimeter) with intravenous injection of 10 to 25 million units, but is capricious. There is practically none with intramuscular injection of 500,000 units (Schwemlein *et al.*, 1946). Intrathecal injection of a large therapeutic dose keeps the concentration high for twenty-four hours, and passes readily into the cerebral meninges. It produces various degrees of meningeal irritation, but not sufficient to preclude its use (Rammelkamp and Keefer, 1943; Cooke and Goldring, 1945).

The level in the plasma is lower for K than for G. Both are partly bound in by plasma protein, K much more than G. With continuous infusion, G and K accumulate in the liver, kidneys and lungs in higher concentration than that of the plasma. K differs from G by relatively greater accumulation in the liver and less in the lungs (A. P. Richardson, 1947). Serum albumin antagonizes the potency of the four penicillins in different degree, proportional to the degree of binding (R. Trumpsett *et al.*, 1947).

The *excretion of penicillin* occurs rapidly by the urine. On intravenous injection, half to two-thirds are excreted within an hour; most of the remainder is destroyed in the body, possibly in the liver. With oral administration the urinary excretion is considerably less, 8 to 33 per cent of the dosage, because of the gastro-intestinal destruction (A. H. Free *et al.*, 1944). In renal insufficiency, the concentration in the blood and cerebrospinal fluid stays considerably higher (J. V. Cooke and Goldring, 1945). The *renal clearance* of K, G and X penicillin in man normally approximates the total renal plasma flow, being about equal to the clearance of parahippuric acid, and four or five times that of inulin or thiosulfate. It is independent of the blood level and of the rate of urine flow, and could be used to test renal plasma flow and function. The clearance of K penicillin is only a fourth to a half that of G, F or X, perhaps by inactivation in the kidneys (H. Eagle and Newman, 1947).

Glomerular filtration and tubular excretion both participate in the urinary elimination of penicillin. In man, about 20 per cent of the output is glomerular, 80 per cent tubular. Blockage of the tubular secreting mechanism by intravenous injection of 30 cc. of diodrast solution decreases the urinary excretion route by half and the blood level falls correspondingly slowly (Rammelkamp *et al.*, 1943). A similar blockage is produced by the less toxic *p-aminohippuric acid*, "PAHA." The "PAHA" is excreted so rapidly that 88 per cent is removed from the blood by a single passage through the human kidney circulation. With continuous intravenous injection in dogs, 78 to 92 per cent is excreted in the urine; with oral administration, 55 per cent in the urine and feces (K. H. Beyer, Mattis *et al.*, 1946). These agents are excreted by the same tubular mechanism, and higher concentrations block the tubular excretion of penicillin by "main action," probably by substrate competition; but the necessary doses are too high for clinical use (K. H. Beyer, 1947). With moderate doses, the only untoward reactions consist in contraction of the large intestine and bladder, without discomfort (K. H. Beyer *et al.*, 1944; Finkelstein *et al.*, 1941; J. V. Warren *et al.*, 1944). Very large intravenous injections of the sodium salt into dogs, at plasma concentration of 0.6 Gm. per cent, produce widespread passive congestions and edemas, focal necrosis of the liver, and toxic nephrosis (P. A. Mattis, Beyer *et al.*, 1945). *Benzoic acid* has a similar effect (four capsules of 0.6 Gm., or in orange syrup, with restriction of water and sodium chloride intake; Bronfenbrenner and Favour, 1945).

Caronamide, 4'-carboxyphenylmethane sulfonalide, also blocks the tubular excretion of the penicillins, presumably also by competing for the substrate, although it is not itself excreted by the tubules. Much smaller doses therefore suffice to increase the plasma level of the penicillins materially. The action is reversible, apparently without ill effects. It is effective by mouth and parenterally (K. H. Beyer, 1947). Its clinical use is in the experimental stage.

The mechanism of the penicillin action and of the different susceptibility of various bacteria is not known (review, C. N. Frazier and Frieden, 1946). In general, the bacteriostatic action is parallel to the concentraton, *in vivo* and *in vitro;* but the minimal effective concentration, 1:50,000,000 for gonococcus, is of the order of magnitude of enzymatic reactions. Presumably it interferes with enzymatic processes essential to the multiplication of bacteria, acting on the fission rather than on the growth (E. Chain and Duthie, 1945). Antibiotic substances in concentrations that do not effect complete inhibition tend to produce extreme elongation of the cells by preventing division (A. D. Gardner, 1940). Electromicrographs indicate that it inhibits and kills the vulnerable bacteria without preceding cellular changes, resembling sulfonamides and gramicidin (L. J. Weiss, 1943). Penicillin does not cause lysis of the bacteria, as does bacteriophage (review, Schmitt, 1944). It appears to protect mice to a considerable degree against the lethal action of *endotoxins* of certain gram-negative bacteria, for instance meningococcal and gonococcal. The mechanism is not understood (A. K. Boor and Miller, 1945; G. Ramon *et al.*, 1946; C. P. Miller, Boor and Hawk, 1947).

Penicillin is inactivated by various *sulfhydryl compounds*, including thioglycolic acid and cysteine, suggesting that it interferes with the function of sulfhydryl groups in the normal bacterial metabolism (Cavallito and Bailey, 1944). *Amino acids* generally antagonize the penicillin action against gram-negative bacilli, and this may explain the natural resistance of this group. Methionine, threonine and methionine sulfoxide greatly increase their susceptibility (G. Shwartzman, 1946). The bacteriostatic action is destroyed by *diastatic ferments*, taka-diastase, 1:200, or "*clarase*," 1:4000 (C. A. Lawrence, 1943).

Ordinary penicillin inhibits the *germination of seeds*. This is due to contamination with indole-3-acetic and phenylacetic acid. Pure penicillin has no effect on germination (W. J. Smith, 1946).

Resistance to penicillin develops in bacterial subcultures subjected to gradually increasing concentrations, and may reach 6000 times the normal, with corresponding decrease of virulence (C. M. McKee and Houck, 1943), but a considerable degree of virulence may be retained (C. P. Miller and Bohnhoff, 1945). The resistance is due to selection by survival of the more resistant individuals (M. Demerec, 1945), which perhaps avail themselves of substitute metabolic mechanisms that are not inhibited by the antibiotic agent (Waksman, 1947). The resistance also develops in the bacteria if patients are subjected to insufficient penicillin treatment, and becomes a fairly stable hereditary quality (L. H. Schmidt and Sesler, 1943). It does not alter the susceptibility to sulfonamides, and vice versa (H. M. Powell and Jamieson, 1942). Certain bacteria and molds develop an enzyme, *penicillinase*, which destroys penicillin (E. P. Abraham and Chain, 1940), but this is not the mechanism of tolerance (A. Bondi and Dietz. 1944).

Untoward reactions are rather infrequent and mild. No fatalities or very serious toxic effects have been reported clinically, and its toxicity for animals or excised tissues is low (W. Cutting *et al.*, 1945). Many of the milder reactions were attributable to impurities and are decreasing as the commercial product is becoming purer. They may, however, occur with the crystalline product, which may sometimes produce sensitization (review, C. J. Lyons, 1943; Schmitt, 1944)

Local irritation varies with the purity, but even the purer commercial penicillins may cause transient burning *pain* at the site of intramuscular injection (R. P. Herwick *et al.*, 1945). *Thrombophlebitis* may occur if the same vein is used too long for intravenous injections. Mild *nitritoid reactions* are sometimes seen during intravenous administration. *Early reactions,* generally rashes and edemas, may occur in 16 per cent of the patients, especially in dermatologic patients. Delayed reactions, especially *urticaria* and *pruritus*, develop one or two weeks after starting penicillin therapy, in about 7 per cent of the patients, not materially more in dermatologic cases (Kolodny and Denhoff, 1946). They do not prohibit further administration, since they tend to subside within five days, even if the injections are continued. A few patients develop symptoms of serum sickness, with effusion into the joints and exfoliative dermatitis, but they recover spontaneously in seven to ten days (E. J. Gordon, 1946). Some cases of peripheral neuritis are reported after intramuscular injection of penicillin, the majority with complete recovery (L. C. Kolb and Gray, 1946).

The *coagulation time* is markedly shortened after clinical use of penicillin (L. F. Moldavsky *et al.*, 1945).

It is not known whether the reactions are due to penicillin proper, or to impurities. The pain and dermatitis vary with the samples. They are generally much less in the purer drug, and are not parallel to the therapeutic efficiency (review, H. Molitor, 1946). The urticaria and angioneurotic edema suggest allergy, especially as they respond to epinephrine and ephedrine. Commercial penicillin produces anaphylactic sensitization in guinea pigs (McClosky and Smith, 1944), but the clinical reactions show no significant relation to previous penicillin therapy or to past allergic history (Kolodny and Denhoff, 1946). W. C. Chu and Cutting, 1946, demonstrated mild local sensitization of the Arthus type in man and in animals, with pure as well as with commercial penicillin. Old healed mycotic lesions may react to penicillin (J. H. Lamb, 1943), and the higher frequency in dermatologic patients may be due to residual fungi.

Muscular cramps, tingling of the testes and *eosinophilia* may occur. *Chills* and *fever* may accompany the urticaria, but are infrequent since the preparations are tested for absence of pyrogens.

Direct application of 500 units of crystalline penicillin to the *cerebral cortex* of dogs and monkeys produces convulsive movements, probably due to the penicillin itself, since it parallels the antibiotic potency (A. E. Walker and Johnson, 1945). The threshold in man appears to be considerably higher, much above the therapeutic level (H. C. Johnson, Walker *et al.*, 1946). Streptothricin, streptomycin, clavacin and actinomycin also produce these effects (A. E. Walker *et al.*, 1946). The acute and chronic *toxicity for rodents* is reported by Hamre *et al.*, 1943, and by H. J. Robinson, 1943. It varies for different samples and has no relation to the therapeutic potency (review, H. Molitor, 1946). It is much more toxic for guinea pigs than for man and many other animals (Heilman and Herrell, 1944).

Therapeutic Uses.—Penicillin is employed especially in pneumococcus pneumonia, staphylococcus septicemia, gonococcus infections, meningitis, thoracic empyema, bacterial endocarditis, osteomyelitis and other serious infections of organisms susceptible to it, and in agranulocytosis.

In *gonococcal urethritis,* penicillin appears to be the most successful treatment, and its nontoxicity is an added advantage. The chief objection is that it masks the usual development of acute syphilis and so interferes with diagnosis; secondary syphilis following penicillin therapy is reported by D. W. Atcheson, 1945. Penicillin is also ineffective against chancroid and lymphogranuloma venereum.

The gonococcus is the most sensitive of all organisms to penicillin; 85 to 98 per cent of urethral infections are curable by penicillin alone. Successful results in gonorrheal arthritis are reported as somewhat less, 58 per cent, ascribable largely to errors of diagnosis. Resistant strains have not been encountered (review, Hench, 1946).

Acute and chronic gonococcus infections respond with remarkable rapidity to penicillin treatment. Definite improvement, both as to symptoms and bacterial count, is noticeable in two to five hours after an intramuscular injection, and these usually completely clear within forty-eight hours. With the penicillins now on the market, satisfactory results may be expected with a total dosage of 200,000 units (four hourly intramuscular injections of 50,000 units), even with ambulatory patients (J. R. Heller, 1946), and those resistant to sulfonamides (G. J. Thompson, 1944); indeed, a single intramuscular injection of penicillin X may suffice (H. Welch *et al.*, 1944).

Syphilis in its early stages yields well to intensive penicillin treatment. This effects the clinical and serological cure as satisfactorily as intensive arsenic therapy, with much greater safety. Relapses are rare and in inverse relation to the total dose. The dosage used for gonorrhea is quite inadequate and merely obscures the early symptoms (B. Shafer and Zakon, 1944).

Dosage Schedule for Early Syphilis.—Aqueous injections of penicillin sodium should be administered intramuscularly every two or three hours day and night for at least seven and a half days. For serum-negative cases the total should be not less than 3,600,000 units, *i. e.*, 90 injections of 40,000 units every two hours, or 60 injections of 60,000 units every three hours. For serum-positive cases, the total should be not less than 5,400,000 units, *i. e.*, 90 injections of 60,000 units every two hours or 60 injections of 90,000 units every three hours. In case of relapse of early syphilis, the course must be repeated, and, in addition, with 60 mg. of oxophenarsine hydrochloride intravenously two or three times weekly, to a total of six injections (360 mg), together with intramuscular injections of 0.2 Gm. of bismuth subsalicylate twice a week for six doses (totalling 1.2 Gm.). In case of a second relapse, the treatment should be changed from penicillin to the arsenic and bismuth routine. In *later or latent syphilis* of adults, the dosage of penicillin should total not less than 3,600,000 units; in *paralytic dementia* not less than 10 million units, divided over twelve to fifteen days. It may be joined with fever therapy. Oral administration of penicillin against syphilis is not justified. The suitability of beeswax oil suspension is not decided (Com. Med. Res., 1946, J.A.M.A., *131:265*).

Experience with experimental syphilis in rabbits illustrates that relatively small doses of penicillin suffice to abort the infection, and that the dosage must be much increased, progressively, as the infection becomes established (H. Eagle, Magnuson and Fleischman, 1947).

The response in early syphilis is immediate and profound, with disappearance of the organisms from open sores, healing of the lesions and a trend toward serologic reversal. Herxheimer reactions (hyperpyrexia) are frequent, but not sufficiently serious to interrupt the treatment (J. E. Moore *et al.*, 1944). Very early infections respond most favorably; infections that have lasted two months or longer give twice as many failures as those treated in the first week (Com. Med. Res., 1946, J.A.M.A., *131:265*); some cases appear relatively resistant, and some are practically failures (J. F. Mahoney *et al.*, 1944). The immediate results are as good from the minimal effective dosage as from much larger doses, but the relapses occur in inverse ratio to the dosage and to the length of administration (W. McDermott *et al.*, 1945). Failures within eleven months after treatment are four times as frequent with 600,000 than with 2,400,000 units (62 per cent against 15 per cent). The addition of oxophenarsine or bismuth reduces the failures by half (Com. Med. Res., 1946, J.A.M.A., *131:265*). With the above dosage, nearly all patients are seronegative twelve to twenty months after the treatment (W. Leifer, 1945). The proportion of failures appears to have increased with the purification of the penicillin, suggesting that the antisyphilitic action is due in large part to some impurity (W. B. Dunham and Rake, 1945), but this may not be the explanation; it may be the preponderance of penicillin K. H. Welch, Randall and Price, 1947, report a "factor" in many commercial penicillins which enhances the effectiveness of pure penicillin, without having any effect by itself.

The antispirochetal potency of penicillin can be rapidly appraised by experimental infection with Borrelia novyi (Buck, Farr and Schnitzer, 1946).

In *late syphilis* the results are also good. The abnormal spinal fluid is improved in most. Benign gummas, skin, bone and vascular lesions heal in twelve to sixty-four days with the dosage of 300,000 units. Oxophenarsine and bismuth may be given concurrently.

Syphilitic pregnant women should be treated with penicillin in the same dosage as for early syphilis, in preference to metals. Children born under this treatment are free from syphilis (Stokes *et al.*, 1944; Ingraham *et al.*, 1946; Goodwin and Moore, 1946). *Infantile syphilis* gives about 70 per cent success with 64,000 units per pound, spread over seven to fifteen days; larger doses might give better results (Ingraham *et al.*, 1946; Platou *et al.*, 1945).

Neurosyphilis is more or less improved in early and late cases; two courses of larger doses are recommended (G. H. Gammon *et al.*, 1945). The most striking effect is on the spinal fluid formula, which shows definite improvement in about 71 per cent and becomes nearly or quite normal in 36 per cent, with corresponding clinical improvement. The spinal fluid cell count, protein and gold curve return to normal. The serum reaction turns toward normal; severity of leg pains is decreased; dementia is at least improved. Meningeal neurosyphilis responds much better than does parenchymatous. The greatest improvement is in the first 120 days, and this is not materially increased by repeating the course. Relapse may occur, but rarely to the original severity (Stokes, Steiger *et al.*, 1946). Penicillin does not increase the response to fever therapy (P. A. O'Leary *et al.*, 1946).

In *agranulocytosis*, penicillin is used to prevent infection, in preference to sulfathiazole, which is also effective, but may itself produce decrease of granulocytes; penicilllin does not affect them. The dosage should be 1,000,000 units or more daily (E. W. Boland *et al.*, 1946).

Indications for penicillin depend chiefly on the susceptibility of the infecting organisms. They may be placed in four groups (following essentially Keefer *et al.*, 1945).

Group I: Effective.—All infections by staphylococci, clostridia, hemolytic streptococci, anaerobic streptococci, pneumococci, gonococci, anthrax (F. D. Murphy *et al.*, 1944); chronic pulmonary suppurations in which surgery is contemplated; meningococcal infections that fail to respond to sulfonamides; bacterial endocarditis due to susceptible organisms; erysipeloid infections; Vincent's infections; prophylaxis against secondary infections as tonsillectomy; or tooth extraction on patients with history of rheumatic fever. Penicillin is also used in treating certain diseases of plants (J. G. Brown and Boyle, 1944). In scarlet fever, penicillin is about as effective a convalescent serum, and more so than sulfonamides. It produces prompt fall of temperature, decreases the toxicity and secures a smaller incidence of pyogenic infections (H. L. Hirsh *et al.*, 1947; A. L. Hoyne and Brown, 1947).l

It is now considered as specific against the tropica spirochetal diseases, yaws, pinta, relapsing fever and leptospirosis (review, E. C. Faust, 1946).

Group II: Effective, but Requiring Additional Experimental Work.—Syphilis, actinomycosis, diphtheria in conjunction with antitoxin, psittacosis in mice, Weil's disease in guinea pigs (Heilman and Herrell, 1944).

Group III: Questionable Value.—Mixed infections with predominant gram-negative flora.

Group IV: Ineffective.—All gram-negative bacteria, such as H. influenzae, typhoid, dysentery, colon, pyocyaneus, Friedländer's bacillus, undulant fever, tularemia, Klebsiella pneumonia, tuberculosis, toxoplasmosis, histoplasmosis, acute rheumatic fever (R. F. Watson *et al.*, 1944; F. P. Foster *et al.*, 1944); lupus erythematosus, infectious mononucleosis, pemphigus, Hodgkin's disease, leukemia, ulcerative colitis, coccidioid mycosis, malaria, poliomyelitis, blastomycosis, monilia, virus infections, cancer.

Synergism of penicillin and sulfonamides is marked *in vitro*, but clinical data are inadequate (Rammelkamp and Keefer, 1943). The effectiveness of penicillin is greatly increased by *hyperthermia* (on spirochetes *in vitro*, Eagle and Musselman, 1944; on bacteria, S. W. Lee and Foley, 1944).

The *dosage* should aim to bring the infection under control as rapidly as possible; this also diminishes the hazard of inducing fastness. The daily dose is usually between 40,000 and 100,000 units, and up to 240,000 units. The rapid elimination requires a continuous supply, day and night, to maintain adequate blood concentration, generally about 0.5 to 0.3 units per cubic centimeter. This may be accomplished (1) by intravenous injection of 15,000 to 20,000 units, followed by intravenous drip instillation of 2000 to 5000 units per hour; or (2) it may be approximated by intramuscular injection of 10,000 to 20,000 units every two to three hours (Florey and Florey, 1943); or effectively but rather wastefully by oral administration of about four times the intramuscular dose every three to five hours. Hypodermic injection is painful and should not be employed. The penicillin may be discontinued when the temperature is normal.

The range in which organisms in cultures succumb to penicillin is quite narrow, about a decimal. The therapeutic efficiency depends on keeping within this range continuously for a considerable time. Lower concentrations would be ineffective, higher would be superfluous. Larger doses would not increase the action; they would only prolong it (H. Eagle, 1947).

Preparation of Solutions.—Penicillin is marketed as the partly purified dry calcium or sodium salt, in vacuum-packed vials or ampuls of 25,000 and 100,000 units. It is quickly soluble, and its solutions deteriorate rapidly. It is dissolved at the time of injection in sterile pyrogen-free distilled water or isotonic salt solution, or 5 per cent dextrose solution, in the following ratios: for intravenous injection with syringe, 1000 to 5000 units per cubic centimeter; for continuous intravenous injection, 25 to 50 units per cubic centimeter; for intramuscular injection, 5000 units per cubic centimeter; for intrathecal injection, 1000 units per cubic centimeter; for local application, 250 to 500 units per cubic centimeter. Solution not used immediately should be kept in a refrigerator, preferably not longer than twenty-four hours and never longer than forty-eight hours. It loses in potency, but does not become toxic.

Irritation from intramuscular injection is materially greater with some lots than with others. Intragluteal injections produce least pain (R. P. Herwick *et al.*, 1945).

Prolongation of the action to about double the ordinary duration of injected penicillin may be secured (1) *by blocking the excretion through the renal tubules* with diodrast or p-aminohippuric acid or benzoic acid (see under Excretion); and (2) *by slowing absorption from intramuscular injections* by applying an icebag to the site (Trumper and Hutter, 1944); or by injecting epinephrine (R. T. Fisk *et al.*, 1945); or by adding 6 to 20 per cent of gelatin (W. M. Parkins *et al.*, 1945); or by suspending the penicillin in peanut oil containing 1 to 6 per cent of beeswax. A single intramuscular injection with this medium often suffices to cure gonorrhea (Romansky and Rittman, 1944).

Oral administration of penicillin was at first discouraged as wasteful of the limited supply. This no longer holds, especially as the same degree of purification is not necessary. The blood level is perhaps somewhat less predictable than with parenteral injection, but therapeutically effective concentrations can be obtained and maintained in pneumonia as well as in gonorrhea (Finland *et al.*, 1945; P. A. Bunn *et al.*, 1945) by the oral administration of 100,000 units five times per day, taken fasting, in watery solution, or in tablets or capsules of 20,000 units. The blood concentration rises somewhat higher, but not significantly so, if an alkali buffer is taken at the same time: sodium citrate, 1 to 5 Gm. for each dose, or disodium phosphate, 2.5 Gm., in a tumbler of water (P. György *et al.*, 1945; Charney *et al.*, 1945); or somewhat better with a tablespoonful of aluminum hydroxide cream (A. L. Barach *et al.*, 1945). Suspension in oil (R. L. Libby, 1944) does not appear of material advantage (W. McDermott *et al.*, 1945). *Theobroma suppositories* with sodium penicillin are reported by L. Loewe *et al.*, 1945, to produce effective levels, but absorption from rectal instillation is poor.

Intrathecal spinal injections of 10,000 units in 10 cc. of saline solution, once or twice daily, are used in meningitis to supplement systemic administration, since the latter alone attains only low concentrations in the cerebrospinal fluid. They are harmless, although there may be some headache (Rammelkamp and Keefer, 1943).

Local injection of 20,000 to 40,000 units, diluted to 5000 units per cubic centimeter of saline, may be made into pus cavities, empyema and joints, after aspirating the pus. In brain abscess, the dilution should be 1000 units per cubic centimeter. There is considerable absorption of penicillin from these situations, so that a single injection of 120,000 units renders the blood bacteriostatic for twenty-four hours, or for forty-eight hours with 240,000 units (M. E. Florey and Heatley, 1945).

Aerosol of calcium penicillin, 0.5 to 1 cc. containing 25,000 to 50,000 units, inhaled as a mist, is useful in patients with bronchial asthma, chronic bronchitis, bronchiectasis and lung abscess (A. L. Barach, 1945). Penicillin mist is rapidly absorbed through the respiratory mucosa, giving blood concentrations intermediate between intramuscular and intravenous injection (Mutch and Rewell, 1945).

Topical application may be made by compresses saturated with 250 to 500 units in saline; or by *ointment* of calcium penicillin containing not less than 250 units per gram, never by penicillin in substance. *Troches*, with not less than 500 units, may be used in Vincent's angina. Penicillin *dental cones* are inserted into the socket after tooth extraction.

PREPARATIONS.—***Penicillins** are marketed as the partly purified sodium or calcium salt. They must comply with the requirements of the Federal Food and Drug Administration, and all specimens are checked for sterility, toxicity and pyrogen (Keefer, Herwick *et al.*, 1945). They occur as a yellow or brown powder, put up in airtight vials or ampuls. They are fairly stable, but deteriorate slowly, especially if the temperature s warm; they should be stored in a refrigerator. They are very soluble in water, and the solution loses rapidly in potency. The calcium salt is the more stable, and is equally satisfactory in every other respect. Dry crystalline penicillin is stable.

Commercial penicillin contains chiefly F, G and K; crystalline, chiefly G as sodium or potassium salt. When labeled as G, it must contain at least 90 per cent of G and have a potency of at least 1500 units per milligram. Penicillin for parenteral or oral use must not contain more than 30 per cent of the K variety.

***Penicillin Cal ium,** U.S.P., "the calcium salt of an antibiotic substance produced by the growth of Penicillium notatum or chrysogenum, or produced by other means."—*Penicillin Calcium for Injection,* U.S.P. Its potency must be not less than 500 units per milligram, except when it contains not less than 90 per cent of the salt of penicillin X, when its potency must be not less than 350 units per milligram. Average intramuscular dose, 300,000 units. *Penicillin Calcium for Oral Use,* U.S.P., contains not less than 300 units per milligram. Average dose, 300,000 units, fasting.

Penicillin Sodium, U.S.P. Potency requirement as for the Penicillin Calcium.

Penicillin Injection in Oil and Wax, U.S.P., is a suspension of penicillin calcium in a menstruum of vegetable oil in which white wax has been dispersed. Usual sizes, 100,000 and 200,000 and 300,000 in 1 cc. *Penicillin Tablets,* U.S.P., penicillin calcium or sodium, buffered with calcium carbonate, sodium citrate, aluminum hydroxide or other buffers. Usual sizes, 20,000 and 25,000 units. *Penicillin Troches,* U.S.P., contain penicillin calcium or sodium; usual sizes 500, 1000 and 20,000 units. *Penicillin Dental Cones,* and *Penicillin Ointment,* U.S.P., contain penicillin calcium.

STREPTOMYCIN AND STREPTOTHRICIN

These are soluble, thermostable nitrogenous bases found by Waksman *et al.*, 1943, in species of streptomyces (streptothricin in S. lavendulae; streptomycin in S. griseus), soil micro-organisms (actinomycetes) related to bacteria and fungi. They are bacteriostatic to both gram-positive and negative bacteria. Streptomycin, which has been isolated as crystals, contains guanidine as one of its functional groups (H. E. Carter *et al.*, 1946). Streptothricin has a delayed toxic action on animals, but streptomycin is practically nontoxic on hypodermic injection. Its clinical scope is under trial, especially in nonspecific urinary infections (H. F. Helmholz, 1945). Its antisyphilitic potency is only 1/3000 that of penicillin (W. B. Dunham and Rake, 1946). Even high doses are only moderately effective and do not prevent relapses (Herrell and Nichols, 1945). It suppresses but does not eradicate experimental tuberculosis in guinea pigs (W. H. Feldman *et al.*, 1945). It is more effective than promin, and the best results are obtained by using them together (M. I. Smith and McClosky, 1945). In human tuberculosis it appears to be somewhat bacteriostatic, but the results are not so good as in animals. It promises to be a useful adjuvant to other methods of treatment, however. Large doses continued for several months appear to arrest the progress, and this gives opportunity for therapeutic intervention. These doses, however, generally develop some toxic manifestations (H. C. Hinshaw and Feldman, 1947). Untoward reactions are not infrequent (10 per cent) with ordinary doses, but are generally mild and clear promptly on discontinuing the medication, but this is rarely necessary (L. L. Terry, 1947).

Therapeutic Scope.—Keefer, Blake *et al.*, 1946, conclude that streptomycin has proved *most effective* against tularemia, Hemophilus influenzae, urinary infections by gram-negative bacteria, and gram-negative bacteremias and meningitis. It has proved *disappointing* against typhoid, brucellosis and Salmonella. It is *under trial* in peritonitis, gram-negative pulmonary infections and tuberculosis.

Urinary Tract Infections.—Streptomycin is the most effective agent against gram-negative bacteria. At least 0.8 Gm. should be injected daily, and the urine kept alkaline. It should be continued for three days. The urinary bacteria develop fastness rapidly, and to a high degree, and if the infection is not materially improved in five days, they have probably become refractory and further administration is useless (G. T. Harrell, 1947).

Tuberculosis.—Streptomycin inhibits the growth of Mycobacterium tuberculosis in animals and in man, and so arrests the progress of the disease, although this is not eradicated. These bacteria do not become resistant to the drug till two to four months, giving opportunity for therapeutic results. Clinical improvement is demonstrable in various types of tuberculosis, but the improvement is limited and often not permanent. Large doses must be administered over long periods, 1 to 3 Gm. daily for at least two to four months, a total of 360 Gm. These large amounts generally produce toxic manifestations, especially impaired function of the eighth nerve. Careful laboratory control is necessary. W. McDermott, Muschenheim *et al.*, 1947, report definite and sometimes dramatic effects in all of their forty-one patients, with rapid fall of temperature, symptomatic improvement, and regression of the lesions demonstrable by x-ray. P. A. Bunn, 1947, reporting on ninety patients in Veterans Administration hospitals, found that none became worse or developed new lesions under the treatment; and none was completely cured. Exudative lesions showed the greatest improvement. Streptomycin appears to heal some lesions, and to serve as an adjuvant to other measures. Its field is probably to supplement rather than to displace these.

Leprosy.—Some encouraging results are reported from prolonged administration of large doses of streptomycin, but these result in toxic effects disproportionate to the benefits. It seems more promising for local application to the leprous ulcerations (G. H. Faget and Erickson, 1947).

The *streptomycin unit* represents a much smaller antibacterial potency than the penicillin unit; for instance, 1/12 with one organism (I. G. Anderson and Jewell, 1945).

In vitro, the potency of streptomycin is markedly decreased by salts, and especially by human serum (25 to 50 per cent; S. Berkman *et al.*, 1947).

Absorption of streptomycin occurs rapidly from hypodermic or intramuscular injection, but little is absorbed from oral administration. With 420,000 units by mouth it could not be detected in the plasma, and very little in the urine (B. E. Graham *et al.*, 1946), though more in the feces (H. A. Zintel *et al.*, 1945). It is not inactivated by the gastric juice (Anderson and Jewell, 1945), nor in the intestines.

The *blood concentration* is maintained somewhat better than with penicillin. With 3,000,000 units daily by continuous intravenous injection, the blood concentration ranges between 20 and 60 units per cubic centimeter. After a single intravenous injection of 600,000 units it averages 33 units per cubic centimeter in fifteen minutes, 5 units after six hours. With the same dose hypodermically, the maximal blood level is not attained for two or three hours (Zintel *et al.*, 1945). The curve for intramuscular injection does not differ significantly from the intravenous, except during the first minutes (Anderson and Jewell, 1945). Maximum levels obtain for one to three hours, then decline gradually over ten to twelve hours (C. S. Keefer, Blake *et al.*, 1946).

The streptomycin is *distributed* through most body fluids; the concentration in cerebrospinal fluid is low (Zintel *et al.*, 1945). It passes into the fetus, but in somewhat lower concentration (review, Keefer, Blake *et al.*, 1946).

Streptomycin is *excreted* by the urine, somewhat more slowly than penicillin. From 46 to 87 per cent may be recovered within forty-eight hours (Anderson and Jewell, 1945. In dogs, a fourth to two-thirds of the dosage is excreted by urine; Graham *et al.*, 1946). Its urinary concentration is considerably higher than in the blood. The urine of patients receiving 2 million units daily contains up to 1330 units per cubic centimeter (H. F. Helmholz, 1945). Some is excreted by the bile (Keefer *et al.*, 1946).

Untoward reactions are not infrequent, but are rarely serious. They increase with the dosage. Minor effects consist in skin rashes, malaise, muscle soreness, drug fever and eosinophilia. Some lots produced histamine-like reactions, sometimes severe, with fall of blood pressure and syncope. These are due to impurities and are now rare. A neurotoxic action on the eighth nerve occurs in up to 10 per cent of patients receiving large doses over long periods, with symptoms of vertigo, tinnitus, ataxia and diminished acuity of hearing. It improves after discontinuing the administration, but the recovery is slow and may be incomplete. There is no evidence of renal or hepatic insufficiency (Anderson and Jewell, 1945; Hettig and Adcock, 1946; Molitov, 1946).

In animals, the LD$_{(50)}$ of streptomycin is about 750 mg. per Kg. Monkeys show no toxic effects when 25 mg. per Kg. were injected daily for sixty-six days. Susceptible species develop fatty metamorphosis of the parenchymal cells of the liver, and to a less extent of the renal tubular epithelium. The lesions disappear rapidly after the drug is withdrawn. They are produced by the crystalline as well as by crude preparations (Hettig and Adcock; Molitor, Graessle *et al.*, 1946).

Streptothricin has a delayed toxic reaction on animals, also producing the fatty liver and renal changes (Muskett and Martland, 1946).

Administration of streptomycin must be parenteral; oral administration is useless. Intramuscular injections, repeated every three to four hours, are preferred for systemic effects. In meningitis this is supplemented by intrathecal injection; in empyema, by intraperitoneal; in peritonitis it is sometimes injected intraperitoneally (C. S. Keefer, Blake *et al.*, 1946). Large doses when applied directly to the cerebral cortex produce convulsions (H. C. Johnson, Walker *et al.*, 1946).

For intramuscular injection, streptomycin is dissolved in physiological saline solution, at the rate of 100 to 200 mg. per cubic centimeter. Hypodermic injections must be more dilute. For intravenous drip, it is used at the rate of 1 to 2 Gm. per liter of saline, injected at the rate of about 25 drops per minute. For intrathecal injection, 10 to 20 mg. per cubic centimeter of saline solution.

The dosage for severe fulminating infection is 2 to 4 Gm. daily, in divided doses; for less severe, 1 to 2 Gm. may suffice. The injections should be continued for forty-eight to seventy-two hours after the temperature is normal and all signs of infection have disappeared. It is important to give the full dosage at the start, since fastness may develop rapidly (M. Finland, Murray *et al.*, 1946).

Streptomycin resistance can be produced in gonococci and meningococci by progressive cultivation in media with increasing concentrations of the drug. The resistant meningococci remain fully virulent and produce fatal infection in mice, notwithstanding streptomycin treatment. There is no crossed resistance to penicillin, and vice versa (C. P. Miller and Bohnhoff, 1946, 1947; C. A. Chandler and Schoenbach, 1947).

***Streptomycin,** N.N.R., is the purified antibiotic substance produced by certain strains of Streptomyces griseus when grown on suitable media. It may be prepared as the chloride, sulfate and other salts. It is marketed in airtight ampuls, generally of 1 Gm. It is stable when stored below 15° C. Solutions are less stable and should be freshly prepared for parenteral injections.

OTHER ANTIBIOTIC AGENTS

Tyrothricin is an extract from a soil bacterium, Bacillus brevis, first isolated by Dubos, 1939, which is bacteriostatic and bacteriolytic for several gram-positive organisms. It contains at least two active constituents, *gramicidin* and the much less potent *tyrocidin*. Serum inhibits the latter, but not gramicidin. The bacteriostatic action appears to involve inhibition of the metabolic enzymes of the susceptible bacteria. It is standardized by its protection of mice against intraperitoneally injected pneumococci.

Tyrothricin is used *only locally*, in superficial indolent ulcers, mastoiditis, empyema and some wound infections, and cautiously in body cavities. It is ineffective systemically (H. J. Robinson and Graessle, 1942), and *dangerous by vein*. Its clinical use is in the experimental stage.

Tyrothricin is marketed as a concentrate or as an alcoholic solution, and diluted with isotonic saline so that the solution contains 500 micrograms per cubic centimeter.

Gramicidin S, a bactericidal polypeptide prepared from soil bacteria by Russian investigators, differs chemically from gramicidin Dubos and from tyrocidin. It is reported as a wound antiseptic effective against both gram-positive and negative organisms (Gause and Brazhnikova, 1944).

Clavacin (*Patulin*), a substance which has been isolated in crystalline form, is found in Aspergillus clavatus (Waksman *et al.*, 1942), in Penicillium clavatum and in P. patulum. It is bactericidal in fairly high dilutions to both gram-positive and negative bacteria, and arrests the development of various pathogenic fungi, in 0.5 per cent dilution (J. A. Herrick, 1945). It is highly toxic on intravenous or intramuscular injection, but not with oral or local administration. It is active against gram-negative and positive bacteria and fungi (Katzman *et al.*, 1944). Nasal instillation was reported effective against colds, but thorough and extensive clinical trials by the Medical Research Council of Great Britain failed to demonstrate any value (J.A.M.A., *126*:510).

Bacitracin is an antibiotic substance in the filtrate of B. subtilis cultures, effective against a wide range of bacteria. It is neutral, thermostable, nontoxic, on intravenous injection, nonirritating to the conjunctiva, nonhemolytic, resistant to proteolytic enzymes. It is a polypeptide (B. A. Johnson *et al.*, 1945).

Most of the aerobic and anaerobic cocci of surgical infections, but none of the gram-negative aerobic bacilli, are susceptible to bacitracin as well as to penicillin. Good clinical results are reported from the local application of bacitracin in surgical infections, especially those by staphylococci and nonhemolytic streptococci which resist penicillin and sulfonamides (H. L. Meleney and Johnson, 1947).

Subtilin, isolated from some strains of B. subtilis, is effective experimentally against some infectious diseases caused by gram-positive bacteria. It is relatively nontoxic to vertebrate tissues (A. J. Salle, 1947).

Nocardia, a mold, has yielded a substance that appears to inhibit tuberculosis (E. W. Emmart, 1947).

Tomatin, an antibiotic substance isolated from tomato leaves, inhibits several fungi (T. D. Fontaine *et al.*, 1947).

ANTISEPTIC BENZENE DERIVATIVES

These differ from the antipyretic derivatives by greater toxicity. On local contact they coagulate proteins, thus determining the death of cells, resulting in irritation and inflammatory changes and in antiseptic effects. After absorption they produce some excitement and more pronounced depression of the central nervous system. Many alter the blood pigment to methemoglobin. Their effects are similar in principle, but differ in important details. The high toxicity is due to side chains, such as the hydroxyl and carboxyl groups, by which they can react with protoplasm.

Historical.—In the form of the natural mixtures, the antiseptic properties of this group have been long known empirically, as in the smoking of meat. One of the methods of embalming practiced by the Egyptians utilized largely balsams and products rich in essential oils—the latter closely related to the aromatic series. The isolated substances belong to the achievements of the nineteenth century. Creosote was first made in 1832, phenol in 1834; but almost thirty years elapsed before they were employed to combat infection in surgery. Various antiseptics had indeed been used for centuries in wound treatment, not with the idea of killing living infective agents, but of preventing the putrefaction of the blood and tissues which was supposed to produce injurious matter, the "materia peccans."

The **field of antiseptics** has become considerably restricted since they were introduced by Lister. They can be highly effective outside the body, but they rarely penetrate sufficiently to kill bacteria in living tissues; when they do penetrate, they are generally more effective in killing the tissue cells than the bacteria. They do not really disinfect the tissues, but may kill and embalm the bacteria on the surface. This has a more limited value.

Toxicity and Resistance.—By highly impenetrable cell walls, and by the formation of very resistant spores, bacteria are able to survive conditions which would kill other cells. Under these adverse conditions the microorganisms are unable to grow and multiply; but by passing into a dormant state, particularly by spore formation, they are able to preserve their vitality for a considerable time, and to recover their power of growth as soon as the conditions become more favorable. Substances which merely suspend the vitality of bacteria are *bacteriostatics;* those which kill them outright are *bactericides. Deodorants* obscure or destroy the odorous bacterial products, but have little action on the bacteria themselves.

The Influence of Proteins and Other Organic Matter.—Many substances which are strongly germicidal when acting on the bacteria alone are much weakened by entering into chemic reactions with the medium. Potassium permanganate is *destroyed* by all organic matter; mercuric chloride is *precipitated* by proteins; silver nitrate by chlorides, and so on. These insoluble combinations are no longer germicidal. They *hinder the penetration* of the antiseptic, a condition of considerable surgical importance. The antiseptics of the aromatic series are relatively little affected. From the standpoint of antiseptic efficiency and penetration, the phenols stand high, but they are impeded by serum, even when there is no precipitation (Bechhold and Ehrlich, 1906). The flavine dyes are effective in serum.

The Disinfecting Power of the Commonly Used Antiseptics.—On account of the different resistance of different bacteria, and the ease with which the antiseptic action is modified by circumstances, the results of experiments directed to comparing the different antiseptics cannot be generalized. Tables of antiseptic values are therefore unsatisfactory. Some antiseptics act fairly uniformly on all bacteria; others, especially the dyes, show a high degree of specificity. The relative susceptibility of bacteria and cells was investigated on tissue cultures by R. A. Lambert, 1916.

Penetration of Antiseptics.—The limitations are illustrated by Hirschfelder and Novak, 1938, who injected a small quantity of a staphylococcus culture under the skin of guinea pigs. The bacteria were not killed by any antiseptic applied to the intact skin, or to forty-eight hour granulation tissue. On scarified skin, continuous packs with antiseptics were fairly successful. The penetration increases when the vitality of the cell is lowered, more or less proportional to the injury, as judged, for instance, by the slowing of ciliary motion (V. A. Badetcher, 1933). Dead cells are most permeable and may indeed concentrate antiseptics by adsorption. *Vital stains* penetrate to some extent into living cells, and stain the vacuoles and other inclosures. The cytoplasm proper is generally not stained until it is dead (Dufrenoy, 1933).

Influence of Structure on Action.—Benzene, C_6H_6, has a low toxicity, because it does not readily react with protoplasm. This capacity is given to it by replacing part of the H atoms by other groups, especially by OH (forming phenols) or by CO_2H (forming acids); or by both. The *OH radical* is the most active, the antiseptic and toxic actions increasing with the *number of OH groups* (*i. e.*, progressively from phenol, C_6H_5OH, to resorcin, $C_6H_4(OH)_2$, and pyrogallol, $C_6H_3(OH)_3$), but it is also influenced by the position. The para compounds are the most effective, meta least, ortho intermediate. This holds for all substitute groups. The introduction of the *CO_2H group alone* (*i. e.*, benzoic acid, $C_6H_5.CO_2H$) does not render the substance very active. The antiseptic quality may also be brought out by *other acidyl groups* ($COCH_3$, and the like), the activity being proportional to the size of the introduced radical. NO_2 develops the antiseptic action, but adds its own toxicity to that of the phenols. The substitution of an H of the C_6H_5 in phenol by *alkyls* (*cresols*, $C_6H_4{<}^{OH}_{CH_3}$) leads to an increase of the antiseptic power, and diminishes at the same time the toxicity to tissues. The *substitution of halogens* increases the antiseptic action, according to the number of atoms. The toxicity is diminished by the lower, increased by the higher numbers (Bechhold and Ehrlich, 1906). The violence of the action may be moderated by using esters ("Nencki's salol principle") which develop their action when decomposed into their phenol. Combinations which are so firm as to prevent this liberation (*e. g.*, the phenolsulfonates) are neither antiseptic nor toxic: it is by the formation of such compounds that the organism protects itself against these poisons. The antiseptic and local actions of the salicylates or other *salts* are also much less than those of the corresponding acids.

Fate of the Benzene Derivatives in the Body.—The six-carbon ring is relatively resistant to decomposition, and for the most part passes through the body unbroken, although up to one-half may be burned. The hydrogen atoms and side chains undergo more or less oxidation, resulting in new hydroxyl and carboxyl groups (phenols and acids). These enter conjugations before being excreted by the urine; the phenols form esters, chiefly with sulfuric acid (Baumann and Herter, 1876; O. Neubauer, 1901), and to a less extent with glycuronic acid. The aromatic acids combine with glycocoll to form hippuric acid, and so forth.

Extent of Destruction.—Of the phenol normally absorbed from the intestine, about half is oxidized and half conjugated. Paracresol is oxidized more rapidly than phenol (Pelkan and Whipple, 1922). The exclusion of the bile from the intestines, by increasing intestinal putrefaction, increases phenol elimination (Dublin, 1917). The normal phenol excretion (largely paracresol) tends to vary directly with the protein intake (Folin and Denis, 1915).

Distribution.—When phenol is administered orally, the level of the free and especially of the paired phenols of the blood rises, reaching a maximum in half an hour and returning slowly to the normal, which is reached in six to twelve hours. The conjugation is completed in an hour. The tissues take up a higher percentage of phenol than the blood. The urinary excretion parallels the concentration in the blood. If phenol is injected intravenously (500 mg., dog), a sixth disappears from the blood during the injection, and the normal level is restored in an hour (Pelkan and Whipple, 1922).

Protective Function of Conjugation.—The formation of the esters is generally proportional to the toxicity of the phenols (S. Fraenkel). Since the esters are much less toxic than the phenols they constitute an important protection of the organism against poisoning, especially against the phenols arising in intestinal putrefaction.

Origin of Sulfonate.—This is not derived from sulfates or other inorganic sulfur compounds, for the administration of these does not increase the conjugation. The phenolsulfonates may be formed with a purely carbohydrate diet, so that the sulfur must come from the oxidation of tissue protein, presumably from the cystine; and the quantity can be considerably increased by feeding this amino acid (Shiple and Sherwin, 1923). Considerable phenolsulfonate is produced on incubation of phenol with *slices of liver* (F. Bernheim and Bernheim, 1943). The conjugation is inhibited by 0.0003 M. bisulfate, 0.005 fluoride, 0.002 monoiodoacetate, 0.01 azide, 0.02 oxalate (De Meio and Arnolt, 1945).

Role of the Liver in Conjugation.—The liver takes an important part in the oxidation and conjugation of the phenols (Pelkan and Whipple), although other tissues are probably also concerned. The phenol destruction and conjugation are therefore greater with oral than with intravenous administration, and they are diminished by liver injury; for instance, by chloroform poisoning (Pelkan and Whipple). The sulfo-conjugation has been proposed as a test of hepatic function. Thymol, 0.5 Gm., is normally followed by considerable increase of the ethereal sulfates of the urine. This increase is sometimes absent in hepatic disease, but not always (M. Kahn, 1918). Chloroform and carbon tetrachloride poisoning of rabbits decreases the ratio of organic to inorganic sulfate excretion; phosphorus poisoning does not. Glycuronic acid excretion was not affected by liver injury (Deichmann *et al.*, 1945).

Glycuronic acid corresponds to dextrose, with the end chain (CH_2OH) oxidized to ($COOH$). It is probably an intermediate stage in the oxidation of glucose, for very little can be formed in glycogen-poor animals (Dakin). Glycuronic acid is probably not a normal stage of carbohydrate metabolism; for if it is administered parenterally, it appears almost quantitatively unchanged in the urine (Biberfeld, 1914). The *source* of the glycuronic acid is probably from glycogenic substances rather than from mucin, as had been suggested (Ambrose and Sherwin, 1934). It is never excreted free, but always in combination with aromatic alcohols, phenols, ketones and acids. Haemaelaeinen, 1913, supposed that the alcohols first combine with glucose, and that this glucoside is then oxidized to the glycuronate. Slices of liver in saline phosphate medium produce conjugated glycuronic acid in the presence of phenol, borneol or menthol. This is significantly increased by addition of sodium lactate or pyruvate. It is disturbed in phosphorus-poisoned animals, but apparently not by chloroform poisoning (Bueding and Ladewig, 1939). The glycuronic compounds may be mistaken for sugar, since they reduce copper, although more slowly. The principal *drugs which cause the appearance of glycuronic acid in the urine* are: turpentine, chloroform, chloral, camphor, phenacetin, saccharin, salicylic acid, balsams, morphine.

PHENOL

Phenol, carbolic acid, $C_6H_5.OH$, became widely known as an antiseptic through its introduction by Lister, 1867. Some of its derivatives are superior, at least for special purposes.

Antiseptic Action.—Phenol is a general protoplasmic poison and a fairly active antiseptic, although not nearly so potent as mercuric chloride, or even as the cresols. It precipitates proteins, but the combination is so loose that it readily diffuses further, and therefore penetrates more deeply into the tissues than the metallic antiseptics; and its action is not so much hindered by the presence of organic matter. The *disinfectant power* varies greatly for different micro-organisms; spores are especially resistant. Tubercle bacilli are killed by exposure to 5 per cent for twenty-four hours. It is much more effective for checking bacterial growth; ½ to 1 per cent suffices for this purpose. These are the concentrations used on the body, for here it is not necessary to kill the bacteria if their development is effectively prevented. These solutions do not ordinarily injure the tissues.

Antiseptic Uses.—Five per cent solutions are used for the disinfection of the utensils, instruments, the hands, and so forth. The penetration and therefore the antiseptic efficiency are increased by the addition of salt. "Crude Carbolic Acid," which contains the more active cresols and is cheaper, is preferred for the disinfection of excreta. As antiseptic for wounds and mucous membranes, gargles, lotions or injections, ½ to 1 per cent of phenol is used. A drop of undiluted phenol is useful for disinfecting and cauterizing small wounds, bites, and the like. Injections of phenol have been tried against local inflammations, tuberculous bones and lymph glands, boils, erysipelas (5 per cent to scarified surface), and so on. Lotions are used as parasiticide in scabies, sycosis, pityriasis and against pediculosis capitis. Inhalations have been advocated in fetid bronchitis and pulmonary gangrene, but at best are only deodorant. As intestinal antiseptic, phenol has no value, because of its prompt absorption and marked toxicity.

Phenol Injections in Tetanus.—Baccelli used rather large doses, a 2 to 3 per cent solution injected intravenously or hypodermically along the spine every two or three hours, the *daily* dose starting with 0.2 to 0.5 Gm., and increasing rapidly to 0.8 to 1.5 Gm. of absolute phenol in divided doses, according to severity (J.A.M.A., *53:* 2140, 1909). No bad effects have been reported, and it is said to cause improvement and to decrease the mortality, even in severe cases (Ascoli, 1913). McClintock and Hutchings, 1913, stated that it has only a limited value, as a simple sedative. Joffe, 1914, commended it. Fielder, 1914, obtained negative results in *rabies*.

Pediculosis Capitis.—Whitfield, 1912, advised soaking the scalp in a 2.5 per cent phenol solution for ten minutes and leaving the solution on the hair for an hour.

Actions on Ferments.—Phenol, salicylic acid and other coal tar antiseptics retard *ferment action*. A 5 per cent solution of phenol suffices to weaken materially the action of most ferments.

Solutions of phenol in fatty oils are not antiseptic (Koch, 1886), because its solubility in fats is so much greater than its solubility in protoplasm that it prevents its transference to the bacteria or tissues. "Carbolated Oil" is merely a mild local anesthetic and dermal irritant. Alcohol and glycerin have a similar restraining action. The solubility in petrolatum is small, so that ointments made with this base are more actively antiseptic and irritant.

Local Actions.—Concentrated phenol applied to the skin or mucous membranes produces prickling, burning and pain, then numbness and anesthesia, wrinkling and softening of the epidermis; the color of the skin becomes first white, then red and finally brown. There is no direct corrosion, but a local necrosis. A dry scab forms, which separates without pus. Short applications of weaker solutions determine merely some wrinkling and blanching of the epidermis and the sensory phenomena, but a 5 per cent solution of the acid may cause necrosis, especially when applied continuously to the extremities. This enjoins caution in the use of carbolic dressings. Even dilute solutions should not be covered with dressings that preclude evaporation. Systemic poisoning may result from prolonged application to extensive surfaces. Good solvents of phenol, such as glycerin, alcohol and volatile or fatty oils (but not mineral oils) diminish the degree, but prolong the duration, of the local actions. The analgetic action of phenol solutions (1 per cent) or ointments (2 to 4 per cent, *f. i.*, in cold cream) is used against *itching* and *herpes;* but menthol (1 per cent in alcohol, 1 or 2 per cent in cold cream) is less toxic and more effective.

Undiluted phenol may be used for quick *local anesthesia of the skin*. A scalpel wet with phenol is drawn over the proposed incision, which may be made after a few seconds (Soresi, 1919). A minute drop applied to a *carious tooth* relieves the pain. A small and harmless amount penetrates to the pulp cavity (B. O. A. Thomas, 1941). A 5 per cent watery solution applied to an exposed nerve causes *anesthesia* (Schleich).

The ratio of toxicity of antiseptics to tissue cultures in comparison to antiseptic potency is reported as 0.29 for iodine, 0.64 for azochloramide, 2.7 for phenol, 3.4 for zephiran, 3.9 for merthiolate, 4.1 for saponated cresol (G. H. Paff *et al.*, 1945).

Phenol Camphor.—When camphor and phenol are rubbed together they liquefy. Mixtures of this kind (phenol 30, camphor 60, alcohol 10, known as "Chlumsky's Solution") have been employed on suppurating wounds and abscesses, with the claim that the caustic action is diminished and the analgetic and antiseptic efficiency increased. The latter is doubtful, but the decrease of irritation agrees with the effects of all good phenol solvents. There is no chemic combination (Yvon, 1876; Lemberger, 1906), but F. Müller, Günther and Peiser, 1927, claimed that the mixture used in surgery is a loose molecular compound which is destroyed on contact with water or watery secretions, separating (experimentally) into a 1.3 per cent aqueous phenol solution and finely divided camphor. Chlumsky, 1905 and 1913, recommended phenol camphor in superficial inflammatory conditions, especially erysipelas, painting it on and around the affected area. F. Pohl, 1913, and Schiele, 1914, injected 2 to 5 cc. into diseased joints, without bad effects; 30 to 50 cc. were used for irrigating abscesses. It has been recommended against *athlete's foot* (E. Francis, 1941), but perspiration may render it caustic (H. G. Calvery, 1942).

Absorption.—Phenol is absorbed from all mucous membranes and wounds, and from the intact skin. In the intestinal canal its absorption is at first rapid, but soon becomes almost arrested, apparently by interference with the local circulation (Sollmann, Hanzlik and Pilcher, 1910). It is distributed through all the tissues.

Fate.—A part of the phenol (¼ to ⅔) is completely burned in the body (Tauber, 1878). The remainder is excreted in the urine, largely as ethereal sulfates and glycuronates of phenol, hydroquinone and pyrocatechol. The oxidation products impart the smoky color to the urine.

Normal rabbit tissue contains from 0 to 39 mg. of free phenol per 100 Gm., and 1.15 to 19 mg. of conjugated. Small amounts of *administered phenol* are conjugated and excreted. With doses that exceed this capacity, about half is destroyed by oxidation, chiefly to carbon dioxide and water; the excreted undecomposed phenol, pyrocatechol and hydroquinone are largely conjugated. These hydrolyze on exposure to air, forming substances of *smoky color* (W. B. Deichmann, 1944). Folin and Denis, 1915, found that 30 to 90 per cent of the urinary phenol is not conjugated. With a rise of total phenol, a greater proportion is conjugated, except when bile is excluded from the intestines (Dubin, 1916). A trace of phenols is found in the sweat (Tachau). *Surviving tissue slices* of liver, and kidneys to a less degree, form conjugated glycuronic acids from phenol, menthol, borneol and avertin. The oxidation necessary for this is catalyzed by heavy metals, inhibited by cyanide, iodo-acetic acid, fluoride and hypnotics (Lipschitz and Bueding, 1939).

Central Actions.—Very small doses of phenol produce at first an *analgetic and antipyretic action.* This is so fleeting, and passes so readily into the graver effects, that it cannot be used in therapeutics. It is followed by more pronounced symptoms resembling the "toxic" effects of salicylates. Dangerous doses produce prompt collapse and coma. Frogs and mammals exhibit characteristic muscular tremors, twitchings and convulsions, persisting until the blood pressure falls very low. These are absent, or at most very faint, in man (Husemann, 1871).

Phenol Convulsions.—Salkowski, 1872, showed that these are located in the spinal cord (division of sciatic; decapitation). Morita, 1915, also found that the convulsions occur in rabbits after ablation of the hemispheres. Baglioni, 1900 and 1909, by the methods explained under strychnine, concluded that the convulsions depend on increased excitability of the spinal motor cells. Direct application of dilute phenol solutions to the exposed spinal cord produces anesthesia. The excitability of the *motor cortex* is lowered by its local application (Baglioni and Magnini, 1910), without convulsions (Amantea, 1913). *Muscle and nerve fibers* are paralyzed by local contact with strong solutions, but do not seem to suffer if the drug acts systemically. In *frogs,* phenol produces successively local reflex irritation, short stupor, a medullary cry, then gradually the twitchings and irregular and incoordinated contractions. The reflexes are preserved, but naturally ineffective because of the interference and interruptions of the convulsions (Baglioni; Arloing and Thevenot, 1920).

Circulation.—Intravenous injections of phenol, even with small doses, cause marked fall of blood pressure, usually with rapid recovery until a certain dosage is exceeded. The fall appears to be both cardiac and vasomotor. When phenol is given by stomach, the blood pressure remains low because of the continuous absorption (Sollmann and Brown, 1906).

The *vasomotor center* is usually depressed, probably directly. This may be modified by indirect stimulation through the convulsions or ischemia. The center may therefore be stimulated, or a period of stimulation may precede or follow the depression period (Pilcher and Sollmann, 1915). Phenol causes an increase of *secretions,* especially of saliva, sweat and tears, not yet explained.

Respiration, Temperature and Collapse.—The *respiration* becomes slow and shallow, and finally stops. The *temperature* falls. Since the collapse affects all the medullary centers, and the cardiac muscle as well, it cannot be removed by artificial respiration. The *sensibility to pain* is often *preserved* far into the collapse. The local effects of the phenol play no important part in the production of the collapse (Sollmann and Brown, 1906).

Toxicology.—Suicidal poisoning by "carbolic acid" is common. Accidental poisoning may result when the phenol is applied to the intact skin; its liberal application to open surfaces has frequently led to toxic symptoms. The *fatal dose* by mouth varies between 8.5 and 60 Gm. (Lewin); 0.8 Gm. has been given therapeutically without bad effects. The systemic toxicity is about the same by mouth and hypodermically (Hale, 1913). It depends on the dose; and for the skin, on the area exposed, not on the concentration (Deichmann and Witherup, 1944). The course of carbolic acid poisoning is *rapid.* In almost all fatal cases death ensues inside of twenty-four hours. The *local symptoms* consist in burning of the mouth and throat, nausea and vomiting, abdominal pain. Carbolic burns generally heal promptly, with small tendency to scar formation. The *systemic symptoms* are those of a speedy *collapse,* starting in a few minutes, even when the drug is taken by mouth. It is manifested by faintness and muscular weakness; rarely twitching and convulsions; pulse small, weak and slow; face livid; cold sweat; respiration slow and shallow; unconsciousness; coma; death by stoppage of respiration. The *urine* is scanty and often contains albumin and casts, sometimes hemoglobin or the bile pigments. It has a dark, smoky color, especially on standing, from the oxidation of the hydroquinone, pyrocatechin, and the like, that are formed from phenol. It gives little or no sulfate precipitate with barium chloride. These points are of diagnostic importance. The urine rarely contains traces of uncombined phenol. *Surviving patients* may show vesical and renal irritation, and sometimes prolonged weakness and unstable temperature.

Chronic Phenol Poisoning.—In the days of the Lister spray, chronic phenol poisoning was common among surgeons. It showed the general symptoms of marasmus. Two Gm. of phenol were recovered from the urine of a surgeon who had assisted for two and one-half hours at an operation under a 2 per cent spray (Falkson, 1881) Minor grades may occur from carbolic applications. They often show skin eruptions (Lewin) and renal irritation (kidney changes, Uyeno, 1909). Chronic phenol poisoning sometimes occurs *in industry*. The symptoms consist of digestive disturbances, skin eruptions, nervous disorders with headache, faintness, vertigo and mental changes (H. Zangger, 1928). Dogs tolerate oral administration of 0.4 Gm. twice a week for nine months. Larger doses may produce dyspnea and sudden death (M. Biebl, 1934). Deichmann *et al.*, 1944, found that oral and hypodermic sublethal toxic doses cause pulmonary injury, and later damage to the heart, liver and kidneys. *Inhalation* of 0.1 to 0.2 mg. per liter of air for seven hours daily produces chiefly progressive pulmonary irritation in guinea pigs and rabbits. Rats are relatively resistant.

Phenol-Contaminated Drinking Water.—Heller and Pursell, 1937, reported that the addition of 0.5 to 0.8 per cent of phenol to the drinking water does not interfere with the growth, reproduction or lactation of rats. Nutritional disturbances appear when 1 per cent of phenol is added. The low toxicity is apparently due to conjugation. However, Deichmann and Oesper, 1940, found that 0.2 per cent resulted in retardation of growth and diminished resistance to intercurrent pulmonary infections. Goldfish tolerate 0.0025 per cent (Sollmann).

Treatment of the Local Effects.—These are removed by *promptly* washing with alcohol (or whisky) and applying an oil dressing. Alcohol, fats, glycerin, turpentine and ether act simply by their solvent affinity for phenol, preventing its penetration into the tissues or dissolving it from them (Sollmann, 1906). Soap with plenty of water is recommended by Deichmann and Witherup, 1944.

Treatment of Internal Poisoning.—The best success is obtained by *lavage* of the stomach with warm water, or first with 10 per cent alcohol, taking care that the fluid does not enter the trachea. The washing must be continued till the phenol odor disappears. It should be attempted even if an hour or more has elapsed since the poison was swallowed (D'Hotel, 1907), because a large part of the phenol remains for a long time unabsorbed in the stomach (Sollmann, Hanzlik and Pilcher, 1910). Olive or cottonseed oil are distinctly beneficial; as large a quantity as possible should be swallowed. This checks the local action and the absorption and also facilitates the passing of the stomach tube. There should be further extensive gastric lavage with oil, finally leaving some clean oil in the stomach (L. Goodman and Geiger, 1935). Chemic antidotes, alcohol and sulfates are practically useless. Intravenous saline infusions have some value against the circulatory depression; and heat has some against the collapse.

Lime forms an insoluble compound and is fairly effective (Husemann and Ummethun, 1870). Syrup of lime may be given freely; lime water is too weak. *Permanganate* destroys phenol, but the ordinary doses are not efficient. Tincture of *iodine* was suggested by Maberly, 1909. Schoville, 1913, claimed that charcoal is useful. *Alcohol* was formerly considered a chemic antidote, supposedly effective even when left in the stomach. Both the clinical and experimental evidence disprove this view (Clarke and Brown, 1906). Its solvent action is useless if it is left in the stomach to be absorbed. It does not diminish either the severity or the duration of the symptoms (Dunn and Perley, 1931). *Sulfates* have been given with the object of forming the nontoxic phenolsulfonates. This combination does not occur in the alimentary canal, and the sulfates are slowly absorbed, so that oral administration is useless except in chronic poisoning. The combination is so slow that it is practically not available in acute poisoning, even if the sulfate is injected intravenously (Brown and Sollmann, 1906).

Preparations.—***Phenol**, U.S.P. (Hydroxybenzene, Carbolic Acid), C_6H_5OH, occurs as needle-shaped crystals, colorless, but acquiring a reddish tinge by oxidation of traces of the phenol to quinone and other derivatives (Gibbs, 1909). Characteristic odor and sweetish caustic taste. Melts at about 38° C.; sol. in water (1:15); miscible in all proportions with alcohol, glycerin and fats; dissolved by alkalis. The solubility in water diminishes with the temperature, and can be increased by the addition of alcohol or glycerin. Phenol is sometimes faintly acid to litmus, but this is due to impurities (E. Schmidt, 1911). It is not a true acid, either chemically or physiologically. It is *incompatible* with iron and collodion. Dose, 0.06 to 0.2 Gm., 1 to 3 grains, diluted. *Liquefied Phenol*, U.S.P. (Phenol Liquefactum), contains 10 per cent water. It is more convenient for dispensing. When diluted with an equal volume of glycerin, the mixture is miscible with water. Dose, 0.06 cc., 1 minim. *Phenol Ointment*, U.S.P., contains 2 per cent each of phenol and of glycerin in White Ointment. *Carbolized Oil* usually contains 5 per cent. *Compound Solution of Sodium Borate* (Dobell's Solution), contains 0.3 per cent of phenol, and 1.5 per cent each of sodium bicarbonate and borate.

Phemerol Chloride, N.N.R., is a complex phenyl and ammonium compound, sold as a 1:1000 aqueous solution and 1:500 Tincture. It is used as antiseptic and germicide, undiluted except in the eye and nose; for these it should be diluted with four volumes of water.

Phenolsulfonates or Sulfocarbolates are less toxic and irritant, but also much less antiseptic than phenol. They have little value.

CRESOLS

The introduction of alkyl groups into phenol greatly increases the germicidal efficiency. The most important of these derivatives are the cresols, $C_6H_4OH.CH_3$, obtained from "crude carbolic acid." Attention was directed to their properties by Fraenkel, 1889. The three isomers, ortho-, para- and meta-cresol, differ somewhat quantitatively, the meta being the most antiseptic and least toxic, and para the most toxic; but they are all contained in variable proportions in the commercial products usually employed. The *germicidal power* averages three or more times that of phenol; preparations containing higher homologues (N.N.R.) may be fifteen times more potent than phenol. The *toxicity* of the cresols is of the same order of magnitude as phenol (Tollens, 1905; Hale, 1913; toxicity and fate, Jonescu, 1906), and they produce almost identical effects and lesions with relatively less convulsions and more collapse (Deichmann and Witherup, 1944). They are excreted for the most part conjugated, but otherwise unchanged. The *treatment* of poisoning would be similar. In practice, they are less toxic than phenol, because they are used *more diluted*, but they are far from being "nonpoisonous." Another advantage over phenol is their lower cost. Their *disadvantages* are the disagreeable odor, which depends mainly on impurities; their limited solubility in water; and their variable composition and activity. Organic matter slows their action rather more than with phenol. Acid and hard and salty water hinder them by precipitating the soap by which they are usually dissolved (Hamilton, 1914).

The *toxicity of ortho-n-alkyl phenols* by oral administration to rats decreases with the length of the alkyl chain. This holds true also for alkyl-meta-cresols and alkyl resorcinols (H. W. Brown and Lamson, 1935).

Solutions and Application.—The cresols may be rendered soluble by the addition of soap, as in the official Compound Cresol Solution, and in other ways. The soap mixtures partake of the slippery nature of soap and are therefore less useful in operating, but they are well adapted to cleansing the hands (brushing for two or three minutes with ½ to 1 per cent solution) and for other purposes. A dusting powder containing 3 per cent of tricresol has been recommended for pediculosis (Herxheimer and Nathan, 1915).

Serum Preservation.—Tricresol, 0.25 per cent, is often added to secure the preservation of serums. This is harmless with the usual hypodermic injections, but may be a factor in the collapse that sometimes follows *intraspinal injection*, especially of the antimeningitis serum (Voegtlin, 1914; Livingston, 1920). The experiments of Auer, 1914, on monkeys render it improbable that the ordinary concentrations do any harm. Clinically, it has marked advantages, being more bactericidal than chloroform, and markedly analgetic (J. B. Neal and Abramson, 1917).

With *antipneumococcic serum*, a further danger might arise from the intravenous injection of relatively large doses. However, Voegtlin, 1918, found no danger of toxicity if the concentration does not exceed 0.5 per cent and if the injections are made slowly.

Phenol Coefficient.—The variability of the cresols may be discounted by the determination of the "phenol coefficient," *i. e.*, the ratio of the germicidal power of the disinfectant to the germicidal power of phenol, both being tested under identical conditions, as described in U. S. Public Health Reports, 1921, page 1559. A disinfectant three times as potent as phenol would have the coefficient 3, and so on. The phenol coefficient is valuable only for the disinfectants related to phenol; not for metals, iodine, chlorine, and so forth. Criteria for the evaluation of skin disinfectants were set down by the Council on Pharmacy and Chemistry, 1943, J.A.M.A., *121*:593.

Benzene Derivatives on Insects.—W. Moore, 1917, tested the vapors of a series on house flies. He found that all the benzene derivatives tested had a higher molecular toxicity than carbon disulfide; the physical characters are more important than the chemical composition.

PREPARATIONS.—*Cresol*, U.S.P. (Tricresol, Cresylic Acid), $C_6H_4CH_3OH$, is a mixture of the three isomeric cresols obtained from coal tar. Colorless, yellowish or pinkish refractive liquid, of phenol-like odor, darkening on exposure to air. Sol. in water (1:50), usually forming a cloudy solution; miscible in all proportions with alcohol, ether or glycerin, and dissolving in alkalis. Dose, 0.06 cc., 1 minim, diluted. The following concentrations are employed *for local use: in surgery*, ¼ to 1 per cent; gargles or cystitis, ¼ per cent; cuspidors (tubercle bacilli) or stools, 1 to 1½ per cent; for sponging rooms or soaking clothes, ½ to 1 per cent. To make a 1 per cent solution, add 2 teaspoonfuls to a quart of water. Cresol is generally used in the form of: *Compound Solution of Cresol*, U.S.P., contains 50 per cent of cresol dissolved with a potash-vegetable oil soap. It has a phenol coefficient of about 3, and serves all the uses of the proprietary solutions, with the advantage that it is not advertised under exaggerated and dangerous claims, such as being "nonpoisonous."

Metacresyl acetate is very little soluble in water, and therefore less toxic (Greenwald, 1911). It was tried as a mild antiseptic for mucous membranes.

Commercial Cresol Preparations.—These contain varying amounts of cresol. They may be grouped according to the dissolving agent as (1) *Emulsions* with resin soap or petroleum oils; and (2) *Solutions* with potash soaps (*lysol*) or with sulfo-acids.

Phenoloid Disinfectants.—Cresol mixtures containing the higher homologues are described in N.N.R.

Diphenyl derivatives have been studied for toxicity on animals by Deichmann, Kitzmiller *et al.*, 1947.

TRI-ORTHO CRESYL PHOSPHATE

This produces a peculiar multiple neuritis, which was discovered in the United States early in 1930 as a result of drinking fluid extract of ginger ("Jake") which had been adulterated with this compound (M. I. Smith *et al.*, 1930). It also occurred abroad by similar adulteration of "apiol" (parsley extract). The neuritis involves chiefly the legs and distal muscles. It develops after a latent period of several weeks, even if the drug is administered by vein. The lesions, which are usually permanent, consist mainly in degeneration of the myelin sheath of the peripheral nerve and anterior columns of the spinal cord, and of the pyramidal cells.

Clinical Phenomena.—The characteristic symptoms, bilateral foot drop and wrist drop with loss of Achilles reflex and plantar response, but only occasionally of the patellar reflex, develop in from one day to three weeks (usually four to ten days) after the extract has been taken. The paralysis is preceded by soreness in the affected muscles. In some cases, transient gastro-intestinal disturbance occurs soon after the taking of the extract. The paralysis is always more marked in the feet and legs than in the hands and forearms. There is no sensory disturbance and no involvement of the cranial nerves (C. R. Bennet, 1930; S. Harris, 1930; H. H. Merritt and Moore, 1930; B. Burley, 1930). The autopsy findings are chiefly those of peripheral neuritis (R. H. Goodale and Humphreys, 1931). M. L. Weber, 1937, who followed up thirty-five cases that had been poisoned six years previously, found little restoration of motor function. The disability remained greatest in the legs. Sensation was little impaired, even in severe cases.

Experimental Studies.—M. I. Smith *et al.*, 1930, found that calves and chickens reacted to the suspected extract similarly to humans, and that tri-ortho cresyl phosphate produced the same phenomena. Dogs and monkeys were apparently immune to large doses by oral administration, but developed the characteristic symptoms after intramuscular or subcutaneous injection. Oral administration to rabbits resulted in the phenomena of systemic poisoning by phenol or cresol. These variations in the action on different animals are believed to be due partly to differences in the absorbability from the digestive tract. Typical phenomena are produced by the hypodermic administration of pure tri-ortho cresyl phosphate to cats. The effects are cumulative. The latent period shortens inversely to the dose, the degree of paralysis increases with the dose. Large doses cause rapidly fatal flaccid paralysis (J. G. Kidd and Langworthy, 1933).

Neuropathology.—The lesions are confined chiefly to the myelin sheath of the ventral roots of the spinal cord and to the motor cells of the anterior horn. With longer survival, they may involve also the cells of the dorsal ganglia and the fibers of the dorsal roots (R. D. Lillie and Smith, 1932; Kidd and Langworthy, 1933).

Ortho tricresyl phosphate (but not the meta and para compounds) inhibits *serum choline esterase in vivo* and *in vitro;* this may be the basis of the neurotoxic action. Triorthochlorphenylphosphate also produces this effect (H. Bloch, 1943).

Related Compounds.—Ortho cresol and tricresol are devoid of the neurotoxic action of the phosphate esters. *Mono-ortho cresyl phosphate* also produces only the ordinary phenol actions; *diortho cresyl phosphate* does not produce even these. Both are hydrolyzed fairly rapidly by phosphatases (M. I. Smith, 1934). *Tri-para-cresyl phosphate* is but slightly neurotoxic. Gross and Grosse attribute this to poor absorption. *Triphenyl phosphate* is more extensively neurotoxic than the tri-ortho cresyl phosphate (R. D. Lillie and Smith, 1932). The *phosphite esters* act essentially like the phosphate, but with more rapid and wider extension, even to the bulbar, cerebellar and mesencephalic centers (M. I. Smith, Lillie *et al.*, 1933).

Trimethyl phosphate also has somewhat similar neurotoxic actions (Deichmann and Witherup, 1946).

Hexaethyl tetraphosphate, "HTP," used as insecticide, has a strong inhibitory effect on mammalian and insect choline esterase, *in vitro* and *in vivo*, which accounts for some of its physiologic effects (K. P. DuBois and Mangun, 1947). Great care must be observed in spraying with hexaethyl tetraphosphate, as it is highly toxic to mammals, and is readily absorbed through the skin; 1 mg. per Kg. may produce poisoning, and 5 mg. per Kg. are fatal to some species. It acts chiefly by destroying cholinesterase. The symptoms in man begin with dyspnea and a feeling of tightness in the chest, which should serve as a warning. Severe poisoning in animals produces gastrointestinal symptoms, serious diarrhea, great muscular prostration and apathy (Interdepartmental Committee on Pest Control, April 3, 1947).

POLYATOMIC PHENOLS

The introduction of further OH groups tends to raise the antiseptic, but also the irritant and toxic effects of phenol. The modifications depend largely on the position of the groups: of the three isomers with the two OH groups, *Resorcin*, 1:3, is perhaps somewhat more antiseptic than phenol, and rather less toxic and irritant. *Hydroquinone*, 1:4, is more toxic; and *Pyrocatechin*, 1:2, is much more so. They act as reducing agents, especially in alkaline solutions. Pyrocatechin is not used in medicine. Hydroquinone is not used directly, but is formed from arbutin, contained in Uva ursi. *Pyrogallol*, containing three OH groups, is highly toxic, while its isomer, *phloroglucin*, is practically inactive.

RESORCINOL

Resorcin coagulates albumin. Strong solutions irritate, soften and slowly cauterize the skin; weak solutions are merely antiseptic. It is employed externally in skin diseases, and internally in gastric fermentation and in diarrhea. After absorption, it produces the same effects as phenol, but with more prominent convulsion, occurring even in man; 8 Gm. have caused severe poisoning, but with recovery (Murrel, 1881). Smaller doses are antipyretic, but the action is too short to be useful. They produce "toxic" effects resembling those of salicylates. The fate and excretion are similar to those of phenol.

PREPARATIONS.—***Resorcinol** (Resorcin), U.S.P., $C_6H_4(OH)_2$, 1:3. Colorless, needle-shaped crystals, of peculiar faint odor, and sweetish, then bitter taste

Acquires pinkish tint on exposure to light and air. Very sol. in water (1:1) or alc., freely sol. in glyc. or eth. Dose, 0.06 to 0.3 Gm., 1 to 5 grains; maximum, 1 Gm., 15 grains. On the *skin*, 1 to 50 per cent ointment or 10 to 20 per cent solution in glycerin; 1 to 10 per cent is used as antiseptic and keratoplastic in chromic eczema; 20 per cent is keratolytic. For urethral or vesical irrigation, ½ to 2 per cent. In alopecia, 1 to 2 per cent; however, resorcin discolors light or red hair to a greenish tinge; it does not appreciably alter the color of black hair (H. N. Cole). Resorcin stains may be removed from the skin by citric acid (Mankiewicz, 1916). *Resorcinol Monoacetate*, N.N.R., C_6H_4. (OH) ($OOCCH_3$), tends to liberate resorcinol and has a similar but milder and more persistent action. It does not discolor the hair. It is applied as 5 to 20 per cent ointment or 3 to 5 per cent lotion.

HEXYLRESORCINOL

The introduction of an alkyl radical into resorcinol (analogous to the cresols) increases the germicidal activity and decreases the toxicity. V. Leonard, 1924, introduced hexyl resorcinol, $C_6H_3(OH)_2.(CH_2)_5CH_3$, as an internal antiseptic for the urinary tract, but its action is uncertain (E. Davis and Sharpe, 1932), and it is liable to produce considerable gastro-intestinal disturbance. It is an effective anthelmintic against ascaris and hookworm (P. D. Lamson and associates, 1930, 1931, 1932). It is also advertised as local antiseptic. Its phenol coefficient is high (45), but it has no special advantage, is somewhat irritant and occasionally causes severe local allergic reactions, even with 1:1000 solution (C. W. Walter, 1935).

As anthelmintic, hexylresorcinol is a preferred agent against ascaris and intestinal flukes, and a second choice against hookworm. The crystalline hexylresorcinol in friable capsules of 0.2 Gm. is administered, fasting, as a single dose—5 capsules above twelve years, 2 capsules below six years—followed by water, but no food is taken for the following four hours, as food combines with the drug and renders it inactive. Water may be taken freely and a purgative should be given after twenty-four hours. This treatment usually kills the parasites outright, but repeated treatment may be necessary. It is difficult to administer because of the gastro-intestinal irritation it produces. This is much less with higher alkyl phenols, for instance, heptylphenol and hexylmetacresol, but their clinical efficiency is also much less (Lamson, Mallory and Brown, 1935). The systemic toxicity of hexylresorcinol is negligible, as only a third of the drug is absorbed. *Heptylresorcinol* is less absorbed, about 96 per cent being recovered from the feces (Robbins, 1931).

As urinary antiseptic, hexylresorcinol is administered in gelatin capsules containing 0.15 Gm. in oily solution, to minimize gastro-intestinal irritation. One to 5 capsules are administered daily. There is often decided catharsis, but this usually subsides after a few days, even if the administration is continued. Hexylresorcinol is not suited for hypodermic administration since it would produce local necrosis. The clinical results in some types of urinary cystitis and pyelitis are quite good, but not uniformly so, and B. coli infections are notably resistant. Large doses of sodium bicarbonate diminish its activity, but this is not affected by the natural range of urinary reaction (Leonard and Wood, 1925). There is no evidence of irritation of the urinary tract even with large doses. Rabbits have received 0.5 Gm. daily for six weeks, without toxic symptoms.

Hexylresorcinol, U.S.P., "*caprokol*," is sparingly soluble in water (1:2000), freely in organic solvents. Average dose as anthelmintic, 1 Gm.

Dihydranol (dihydroxyphenyl heptane) seems curative against the natural Balantidium coli infection of guinea pigs, but the effective dose is too close to the toxic (N. A. David and Leake, 1930).

HYDROQUINONE

This compound, paradihydroxybenzene, $C_6H_4(OH)_2$, occurs among the end products of the oxidation of many benzene derivatives, and as it is actively leukopenic, Kracke and Parker suggested that it may be chiefly responsible for *granulocytic neutropenia;* but the evidence is not convincing. Hydroquinone is formed in the cleavage of *arbutin*, a crystalline glucoside which occurs in *Uva ursi*, a plant formerly used as diuretic, acting perhaps by renal irritation. Hydroquinone is employed in photography as a reducing agent. It is a potent bacteriostatic. In *industrial poisoning by hydroquinone*, Velhagen, 1931, observed a peculiar brown coloration of all the corneal layers in the area of the palpebral fissure. He assumed the penetration of crystal dust and its oxidation to paraquinone. Feeding of hydroquinone to black cats was reported to turn their fur gray (quoted from L. Schwartz, 1939). The addition of a small quantity of hydroquinone to *fats* materially delays the onset of rancidity, acting as an "*antioxidant*"; but it remains to be shown that its continued consumption in food is safe. Its employment as a "stabilizing" agent for preparations containing vitamin A is not countenanced (J.A.M.A., 1937, *109:*1454).

Uva Ursi.—This plant has been used for its diuretic and antiseptic effects in vesical catarrh. It contains arbutin, tannic acid and other constituents. *Arbutin* is a crystalline glycoside, yielding glucose and hydroquinone on decomposition. It is decomposed completely in the body (Lewin, 1883; Grisson, 1888); with large doses the hydroquinone appears in the urine (Bass, 1912) and is supposed to be the active agent. Lewin and others found it beneficial in cystitis, and so forth; Paschkis and Feibes, 1884, doubted its efficiency; Bass found no action on healthy men, even with 20 Gm. The usual dose is 1 Gm., three to six times daily.

Quinone, $C_6H_4O_2$, was studied for toxicity by Labes

1929. The *naphthoquinones* (see Index) are discussed in connection with prothrombin formation and vitamin K.

Pyrocatechol.—The systemic toxicity for oral administration to cats and rats was investigated by Dietering, 1938: 50 mg. per Kg. of body weight produces convulsions followed by paralysis, with death in forty-eight hours, by respiratory and circulatory failure. Daily administration of 30 mg. per Kg. results in anemia, icterus, damage to the renal parenchyma, and death in a few weeks. Each dose causes marked hyperglycemia.

PYROGALLOL

The powerful reducing action overshadows the phenol effects. *Locally,* it is a mild caustic for wounds and mucous membranes; it produces but slight irritation of the intact skin, passing into erythemas on continued use. *Absorbed* into the blood, it forms methemoglobin, disrupts the corpuscles and leads to intense acute nephritis. Concentrated solutions acting on blood *in vitro* (not in the body) produce a peculiar insoluble substance, hemogallol. Fatal poisoning may occur even when the drug is applied to the intact skin; and may set in suddenly after it has been used for some time without effects. The *symptoms* consist in diarrhea, and vomiting, chills, prostration, feeble pulse; nephritis with scant dark urine containing blood or hemoglobin derivatives (Neisser, 1881); sometimes icterus and glycosuria. The rapid cases show cyanosis, dyspnea, convulsions and collapse. The *treatment* would be symptomatic. Pyrogallol increases the inhibitory response of the heart of cats and rabbits to stimulation of the divided vagus (Danilewsky and Wjalkowa, 1931).

Pyrogallol (Pyrogallic Acid), $C_6H_3(OH)_3$, is freely sol. in water (1:1.7), alc. (1:1.3), or eth. Solutions turn brown, especially in the light; very rapidly if alkaline. Used externally (but dangerous) as 1 to 10 per cent ointment in skin diseases; and as 1 to 3 per cent solution to deodorize ozena and discharging wounds. The danger of poisoning and the black staining limit its employment. It is used like chrysarobin in psoriasis, lupus, ringworm and other parasitic skin diseases, and in hair dyes.

CREOSOTE AND GUAIACOL

The empyreumatic products of the distillation of wood smoke, and the creosote and tar which may be condensed from it, contain benzene derivatives of considerable antiseptic potency. Medicinal creosote is obtained chiefly from beechwood (first by Reichenbach, 1830). Its principal constituents are *guaiacol,* $C_6H_4.OCH_3.OH$; and *creosol,* $C_6H_3.OCH_3.CH_3.OH$. These are related to the cresols. They are more strongly antiseptic and antipyretic, and rather less irritant and toxic, than is phenol. Creosol should be superior theoretically, but practically does not differ sufficiently from guaiacol to offset its higher cost. Guaiacol constitutes from 60 to 90 per cent of the creosote, and shares all its properties, with the advantage of constant composition.

Uses.—Creosote and guaiacol are becoming obsolete. They were employed in *tuberculosis,* having been introduced especially by Sommerbrodt, 1887; but the clinical benefits are not definite, and the laboratory results are quite negative (L. M. De Witt *et al.,* 1920). Hospitalized patients with pulmonary tuberculosis show no improvement when treated with calcium creosotate, and no change in the sputum or expectoration. Neither the sputum nor the expired air contains the creosotate (E. J. Fellows, 1939).

Bronchitis and *pneumonia* were said to be benefited, especially by inhalation. When guaiacol is injected hypodermically, the major part is contained in the blood, liver and spleen, much less in the lungs and kidneys (Hofbauer, 1915). In *pleuritic effusions,* it hastens the absorption of the exudate when it is rubbed into the chest. As an *antipyretic,* guaiacol, 10 to 30 drops, dissolved in an equal volume of oil or alcohol, may be rubbed into the clean and dry skin of the abdomen for ten to fifteen minutes, thus avoiding intestinal irritation. It causes considerable diaphoresis, and has no advantage over other antipyretics. Guaiacol was classed as an *intestinal antiseptic,* but its action is difficult to demonstrate (Harris, 1912). Creosote water was sometimes given to check *gastric fermentation.* The *local anesthetic action* is utilized, especially *in dentistry.*

Administration.—In tuberculosis, creosote or guaiacol is given in the largest doses which can be tolerated without too much gastro-intestinal irritation, beginning with 1 drop and increasing to 5 or 10 drops, in extemporaneous capsules, three times daily after meals. If they are not tolerated, guaiacol carbonate should be substituted.

Poisoning by creosote resembles that by phenol, but the effects are less convulsive. The local actions are also similar. Death has occurred after 7 Gm. (Schulze, 1894). Hypodermically, guaiacol produces dangerous collapse and cardiac depression. The chief lesions in rabbits are nephrotoxic, mainly tubular, but also somewhat glomerular (Benoit, 1928). The *excretion,* as with phenol, is mainly in combination with glycuronic and sulfuric acid (Knapp, 1911) Guaiacol (but not its carbonate) causes, in very large doses, the appearance of an undetermined, viscous substance in the urine, which is said to be capable of obstructing the uriniferous tubules.

Guaiacol Carbonate is an insoluble ester which liberates guaiacol slowly and incompletely in the intestines. It was introduced to secure local intestinal antisepsis and avoid the taste and systemic toxicity; but too little is liberated to be effective. As much as 6 Gm. of guaiacol carbonate have been given to phthisical patients, as much as 75 Gm. (2½ ounces) to dogs, without producing toxic symptoms. With these large doses, a great deal of the substance is passed in the feces, without having undergone decomposition. *Other guaiacol esters* were also introduced, but have no advantage.

Thiocol is potassium guaiacolsulfonate, analogous to sodium phenolsulfonate. Like the latter, it has little effect. It is exploited as an expectorant, but it neither propels nor liquefies the mucus (roentgenologic observations), nor could any free guaiacol be demonstrated in the lungs even after large doses (Gordonoff and Wyss, 1933).

Preparations.—*Creosote* (Wood Creosote) consists of a mixture of phenols and derivatives, chiefly guaiacol and cresol, obtained during the distillation of wood tar, preferably that derived from beech. Almost colorless or yellowish, highly refractive, oily liquid having a penetrating, smoky odor; burning, caustic taste. Slightly sol. in water. Miscible with alc. and fixed or volatile oils. Dose, 0.12 to 0.25 cc., 2 to 4 minims; maximum, 0.5 cc., 8 minims. *Guaiacol,* $C_6H_4(OH)(OCH_3)$, is a nearly colorless refractive liquid, crystalline at low tempertaures. Odor, aromatic; sharp taste. Sol. in water (1:60 to 70); freely miscible with glyc., alc. or oils. Dose, 0.3 to 0.5 cc., 5 to 8 minims.

TAR

This is a complex product obtained by the destructive distillation of pine woods, especially Pinus palustris. It contains phenols and other aromatic derivatives, resin acids, acetic acid, and the like. Tar is strongly irritant to the skin; it is used in scabies and other parasitic skin diseases, and eczemas. It is said to be healing, antipruritic and drying, but has now been displaced largely by the less disagreeable naphthol and resorcin. Skin that has been treated with tar should not be exposed to the sun or to roentgen rays for several days.

Internally, pine tar has been employed in chronic bronchitis and cystitis, acting similarly to turpentine and copaiba. The official syrup is little more than a flavoring vehicle. Toxic doses of tar produce effects similar to those of phenol: vomiting, colic, diarrhea and collapse. Sezary and Wornes, 1928, reported acute leukopenia after application of juniper tar to the human skin.

Juniper tar has a more pleasant aromatic odor and is often substituted in dermatology. Crude *coal tar* (as 2 to 6 per cent ointment) acts similarly and is twice as effective as pine tar (C. J. White, 1921, 1927), but more malodorous. The odor and color may be partly removed by purification, but with some loss of therapeutic activity.

Oil of Tar.—When tar is subjected to redistillation, it can be separated into a fixed portion—pitch—consisting mainly of rosin; and a volatile portion which separates into *Oil of Tar* and pyroligneous (crude acetic) acid. Oil of tar consists of various coal tar derivatives, mainly cresols, guaiacol, phenol, xylene, toluene, and pyrocatechin. It also contains methyl alcohol and acetone.

PREPARATIONS.—*Pine Tar,* U.S.P. (Pix Pini), is a viscid blackish-brown substance obtained by the destructive distillation of Pine wood. Empyreumatic odor and sharp taste. Miscible with alc. and fixed or volatile oils, only partly sol. in water. *Pine Tar Ointment,* U.S.P. (Unguentum Picis Pini), contains 50 per cent of Pine Tar, 35 per cent of Yellow Ointment and 15 per cent of Yellow Wax. *Syrup of Pine Tar,* 0.1 per cent; average dose, 10 cc. *Juniper Tar,* U.S.P. (Pix Juniperi; *Oil of Cade, Empyreumatic Juniper Oil*), is a dark brown, clear, thick empyreumatic oil obtained by the dry distillation of the wood of Juniperus Oxycedrus; of warm, faintly aromatic and bitter taste. Used externally like pine tar. *Coal Tar,* U.S.P. (Pix Carbonis), a byproduct of the destructive distillation of bituminous coal, is employed as *Coal Tar Ointment,* U.S.P., containing 5 per cent of coal tar, 25 each of starch and zinc oxide and 45 of white petrolatum. *Solution of Coal Tar,* N.F., is to be diluted with 9 volumes of water, as a lotion.

CHEMICAL CARCINOMAS

Tar and Paraffin Epitheliomas.—Workers whose skin comes into frequent contact with coal tar and with crude paraffin may develop chronic dermatitis, eczema, eruptions and papillomas, which may eventually turn into true epithelioma. The susceptibility varies considerably. Pure paraffin does not produce this effect, but paraffinomas may sometimes take a cancerous direction.

Paraffin dermatitis and cancer were first described by Volkmann, 1895. The acute stage begins with eruptions and abscesses, *"wax boils."* These last several months and then pass into a chronic dermatitis, with seborrhea resembling psoriasis, pigmentation, dry fissures, horny thickening, resembling ichthyosis, and so forth. In the terminal stage, multiple warts or papillomas develop, turning finally to true epithelioma (Davis, 1915). The wax cancer affects only a fraction of the workers, and is therefore influenced by predisposition (B. F. Davis, 1920).

Chemical Carcinogenesis.—Cancerous tumors are produced by prolonged application of tar or certain of its constituents to the skin of mice, rats or rabbits, and also by hypodermic injections continued over long periods. The tumors are malignant, form metastases, and are transplantable to animals of the same strain (for over twenty passages; Z. K. Cooper *et al.*, 1944). They are inherent in the anthracene fraction of the tar (Norris, 1914). J. W. Cook and associates, 1935, isolated the pure carcinogenic substances and synthesized these and others. They are nitrogen-free aromatic hydrocarbons containing the phenanthrene ring. The most active are derivatives of benzanthracene 1.2, although this itself is not carcinogenic (Barry and Cook, 1934). Methyl cholanthrene, which is structurally related to desoxycholic acid and to cholesterol, is especially active. These substances are related in structure to the estrogenic hormones, and they are indeed mildly estrogenic, and vice versa, but the transposed actions require much more than the therapeutic dosage (W. Cramer and Horning, 1937).

Agents credited with producing occupational cancer include: arsenic, chromates, nickel carbonyl, dyes, ultraviolet rays, roentgen rays, radium, mesothorium, asbestos, crude mineral oils, pitch, tar, soot, anthracene oil, creosote, aromatic amino-compounds (aniline, naphthylamine, benzidine), substances from parasitic worms.

The carcinogenic activity, structure and chemical reactivity of the polynuclear aromatic hydrocarbons are reviewed by L. F. Fieser, 1938. The phenanthrene nucleus is not essential to carcinogenesis, for this is also produced by benzacridine (Barry, Cook *et al.*, 1935), and by triphenylbenzene and tetraphenylmethane (Morton, Branch and Clapp, 1936); but most of the active substances have a number of benzene rings linked together (G. M. Badger, Cook *et al.*, 1940). Some 150 chemicals, including inorganic substances, coal tar derivatives and dyes, were studied by B. T. Simpson and Marsh, 1931, in relation to spontaneous mammary cancer of mice, the greater number with negative results. *Benzene* is not carcinogenic; *oleic acid* occasionally produces benign tumors (Bottomley and Twort, 1934).

Development of the Chemical Cancers.—The scientific study of tar cancer was started by the observation of Yamagiwa and Ishikawa, 1915, that local cancerous changes are initiated by applying tar externally to rabbits' ears over long periods, half a year or a year. Tsutsui, 1918, showed that mice (and rats) are more suitable, with a larger proportion of takes. The incidence varies greatly with the strains of mice (Kreyberg, 1934); but there is no correlation with susceptibility to spontaneous tumors. The chemical tumors, like the spontaneous, can be transplanted successfully only into mice of the same strain (Andervont, 1934). The dosage has a limited influence in shortening the latent time (Dunning, Curtis and Bullock). With a single application of 20-methylcholanthrene, nearly half of the mice developed malignant tumors in thirteen to forty-two weeks (Cramer and Stowell, 1943). The interval between applications and cancer development is materially longer in long-lived animals, approximately proportional to the life span. The delayed actions of a single application set in long after the agent is no longer detectable at the site. The application must therefore have started a self-perpetuating abnormality that is transmitted through generations of cells (review, E. V. Cowdry, 1943). The effects of a second course of carcinogenic hydrocarbon are additive even after an interval of four months (Lavik *et al.*, 1942).

The precautions which must be followed in cancer experimentation on mice are reviewed by C. Voegtlin, 1937. Results obtained with one type of neoplasm can not safely be transferred to other types. Dibenzopyrene produces cancer in man as well in animals (review, F. C. Wood, 1937). Passey, 1938, obtained tar tumors in dogs. Not all strains of mice are susceptible to chemical *breast cancer;* those that are, are also susceptible to its spontaneous occurrence. Guinea pigs are much less susceptible than mice; rabbits are almost insusceptible. In man and primates, cancer production by these agents is not definitely established. The immunity of rabbits is probably due to detoxication; they oxidize dibenzanthrene to dihydroxy dibenzanthrene, which is not carcinogenic even for mice (C. P. Roads, 1942).

Experimental brain tumors, gliomas or meningeal fibrosarcomas are produced in eight to seventeen months by intracerebral implantation of pellets of 20-methylcholanthrene (Seligman and Shear, 1939) or of 3.4 benzopyrene in mice (H. M. Zimmerman and Arnold, 1943). *Pulmonary cancer* may be produced by injection of tobacco tar into the pulmonary parenchyma of rats (A. H. Roffo, 1943). Intrapleural injection of benzopyrene causes a condition resembling *leukemia* with malignant cells resembling monocytes, in 9 per cent of the injected mice (J. Furth and Furth, 1938). Leukemia, usually of lymphoid type, is also produced by painting the skin of mice with methylcholanthrene and other carcinogenic agents (review, J. Furth, 1946).

With direct application to the skin, the immediate effect is injury to the epithelium, which develops into cell proliferation, keratosis and chronic hyperemia (Cramer and Stowell, 1942). The cancer formation appears to be caused by direct stimulation of growth, rather than by irritation, for it may start distant from the site of application; thus in the *liver* after hypodermic administration of diamino anthracene, in the *lung* after dibenzanthracene (Andervont). *Dimethylamino azobenzene* (*"butter yellow dye"*) produces an orderly of sequence changes, with proliferation of bile ducts, liver parenchyma and supporting tissue, terminating in complex malignant tumors (E. L. Opie, 1944). (Its metabolites were studied by E. S. Stevenson *et al.*, 1942.) *Testicular* interstitial tumors may be induced in mice by administering triphenylethyline, 5 mg. weekly for fifty weeks or more (W. U. Gardner, 1943). Carcinoma develops in rats when 2-acetaminofluorene (*"AAF"*) is added to their diet (De Eds and Wilson, 1946). Dibenzopyrene and methylcholanthrene produce tumors in any organ in which tumors are known to occur naturally, including the gastro-intestinal tract, kidney, bladder and lung. The result may be either carcinoma or sarcoma, or mixed, according to which type of cells happens to yield and form a new race. Once started, the characteristics are retained; for instance, for over 440 generations of mice transplants. "The grafted tumors are merely a race of cells under cultivation" (Wood, 1937), a permanently altered race originating from a previously normal race (W. H. Lewis, 1935). The rate of growth of the tumor cells in tissue cultures correlates with their growth in the animals (Ludford, 1934).

Protozoa subjected to prolonged exposure to polycyclic hydrocarbons or other blastogenic agents, develop increased viscosity of the cytoplasm which interferes with division and results in morphologic abnormalities, similar to those of cancer cells, which are then perpetuated indefinitely in the progeny (J. C. Mottram, 1942, 1944). Continued exposure of many successive generations of protozoa or bacteria increases their susceptibility to its toxic actions (R. R. Spencer and Melroy, 1942). Methylcholanthrene has marked effects on *yeast cultures,* increasing the total growth by a third, with the appearance of many giant cells, after two months (C. W. Dodge, 1937). The photosensitivity of paramecia is increased by cholanthrene and several other carcinogenic agents, in dilutions greater than with any noncarcinogenic light sensitizer (Doniach, 1939). Light rays have some restraining effect on the development of benzopyrene tumors in mice (J. J. Morton *et al.*, 1940). In *higher plants,* the carcinogenic chemicals induce the formation of numerous adventitious roots on the stems of tomato and nicotiana (Kisser and Lindenberg, 1940); but nothing analogous to neoplasm; plant tumors appear to require the constant stimulation of a living parasite (M. Levine, 1942).

Anticarcinogenic Actions.—Certain dyes, Nile blue and methylene blue, when fed to rats, diminish the incidence of liver cancer from ingestion of O-aminoazotoluene (M. Hashida, 1941; S. Ito, 1941); similarly β-sitosteral with "butter yellow" (Sato and Morigami, 1941). *Plant hormones,* if permitted to act on minced tumor before its inoculation into mice, markedly decrease the number of takes and the subsequent growth rate; but if the tumor is already established, it is not affected by hypodermic injection of the plant hormones (B. E. Kline and Rusch, 1943).

Distant Effects of Coal Tar.—Rabbits to whose ears coal tar was applied once or twice a week, and which were killed after seven to twenty days, showed focal necrosis of the liver, ascites, edema of the subcutaneous tissue, fatty changes in the myocardium and liver, degeneration of the bone marrow, and emaciation (C. H. Hu and Wu, 1936). Oral administration of methylcholanthrene and of benzopyrene to rats decreases the rate of growth. This is counteracted by cystine, methionine and glutathione (J. White and White, 1939). *1.2.5.6 dibenzanthrene,* when introduced into the tail tissue of young rats so as to produce continued absorption, causes progressive inhibition of growth, resulting in permanent dwarfing (H. Alapy, 1941).

Bladder Tumors of Aniline Workers.—A high incidence of hemorrhagic cystitis, recurrent papillomas and cancers of the urinary bladder was reported by Rhein, 1895, in workers employed in the manufacture of aniline dyes, especially fuchsin, benzidine and naphthohydramine. H. Curschmann, 1920, estimated the incidence as high as 1:500. Lessenberger, 1912, found it thirty-three times as high as in nondye workers. People living in the vicinity of the factories do not show an abnormal cancer rate. The tumors are discovered from two to thirty-six years after starting the employment (Nassauer, 1919; Schwerin, 1920; Oppenheimer, 1920). The average is about twelve years. Half to two-thirds become carcinomatous (Gehrmann, 1936). Once noted, the tumors progress rapidly and the prognosis is unfavorable, even with radical operations. The effect appears to be due to the nitro and amino groups of aromatic intermediates (A. Mueller, 1933). Suspicion attaches especially to phenyl hydroxylamine, a metabolic decomposition product of aniline which irritates the bladder even in high dilutions.

Experimental Bladder Tumors.—Papillomas and cancerous changes can be produced by the introduction of pellets of equal parts of coal tar, scarlet red and paraffin into the bladder of rats (Maisin and Picard, 1924; Watanabe, 1934), and by the long-continued hypodermic or oral administration of commercial betanaphthylamine ($C_{10}H_4NH_2$) to rabbits or dogs (Perlmann and Staehler, 1933; Hueper, Briggs and Wolfe, 1938). It is conceivable that the effect may be due to impurities (Voegtlin, 1938). Prolonged administration of this drug also causes blood destruction, degeneration of the renal tubular epithelium and of the hepatic parenchyma (Ranta, Leming and Blood, 1938). 2-acetyl-aminofluorene, when fed to mice for fifty-two weeks, results in epithelial tumors in the urinary bladder of about half of the animals; also in neoplasms in the liver and uterus and other organs of rats and mice (R. H. Wilson *et al.*, 1941; E. P. Armstrong and Bonser, 1944).

Bladder hyperkeratosis and papillomas may also be produced in rats by administering azotoluene with a diet of rice flour (J. P. Strömbeck, 1946).

BENZENE

Benzene (benzol), C_6H_6, is an important industrial poison, generally as vapor, from its extensive use as a rubber solvent, motor fuel, and so forth. It acts acutely as a lipolytic narcotic and asphyxiant convulsant. Chronic poisoning involves the bone marrow, decreasing first the white and then also the red corpuscles. It has been used in leukemia, but is unreliable and dangerous. It is somewhat antiseptic. It causes local irritation; subcutaneous injection results in edema, induration and abscess (Chassevant, quoted by Ellinger, 1923). Benzene must not be confused with "Purified Benzin," U. S. P., which is a gasoline fraction.

Fate.—Benzene is partly oxidized in the body to phenol (15 to 30 per cent), catechol and quinone and excreted as phenolsulfates (Baumann and Herter, 1877); a part is completely destroyed to muconic acid (Jaffe, 1909), and a considerable portion is excreted unchanged by the lungs. The brain and spinal cord contain more than other organs (Joachimoglu, 1915).

Acute Benzene Poisoning.—Fairly large doses are tolerated by mouth; 9 to 12 Gm. have caused serious collapse (Perrin, 1861; Averill, 1889). The acute symptoms are restlessness, excitement, high rise of temperature, narcosis, and death by paralysis of respiration. Sublethal doses are followed by good recovery. The technical article is somewhat more toxic than the pure (Lehmann, 1911).

Acute clinical poisoning by benzene vapor occurs by absorption through the lungs. *Small amounts* produce euphoria and inebriation similar to that of alcohol. This passes rather rapidly into drowsiness, giddiness and motor incoordination which interferes with escape. Fuehner found benzene about as narcotic as chloroform. Vomiting may set in, with collapse, pallor of the face and cyanosis of the extremities. Larger amounts cause twitching and convulsions, passing into paralysis. The respiration becomes slowed, the blood pressure falls, unconsciousness and coma supervene. Death may occur suddenly in the convulsions, or more gradually in coma. The *necropsy findings* are those of suffocation, including edema of the cerebral meninges and lungs. The blood remains fluid for a long time; there are often small hemorrhages in various organs. Patients who recover sometimes develop skin changes (Lewin, 1907; Wolf, 1911; Heffter, 1915). *Acute poisoning in animals* by pure or impure benzene shows the same symptoms, the impurities having but little effect, so that "crude" benzene is less toxic than the "pure" and "commercial"; these are about equally toxic for dogs and guinea pigs (Schrenk, Yant *et al.*, 1940). *Ventricular extrasystoles* set in promptly. With fatal doses these pass into ventricular tachycardia and fibrillation. This may be prevented by the injection of mecholyl, not by quinine. There is also peripheral paralysis of the blood vessels (Dautrebande, 1933; Nahuen and Hoff, 1934). *Epinephrine,* 0.02 mg. per Kg., injected intravenously into dogs inhaling benzene, generally evokes ventricular fibrillation. This "*benzol-adrenalin test*" has been used by Wégria and Nickerson, 1942, to confirm the protective action of quinidine.

Acutely Toxic Concentrations.—Slight symptoms occur after several hours' exposure to 1500 to 3000 parts per million of air. The maximal concentration that can be inhaled for an hour without serious disturbance is 3000 to 5000:10^6; 7500:10^6 is dangerous in one-half to one hour. With 19,000:10^6 (2 per cent) death occurs in five to ten minutes. The toxic concentrations were determined on cats by Bamesreiter, 1932. With rats, narcosis occurs above 0.1 per cent (volume); 0.16 per cent is fatal in less than six hours (H. Taylor, 1939).

Chronic benzene poisoning may result from therapeutic oral administration, or from inhalation in the industries. It constitutes an important industrial hazard. Its history and symptomatology were reviewed by Winslow, 1927, for the National Safety Council. A group of papers appeared in the Journal of Industrial Hygiene, 1939. Workers gradually (after two or three months or later) develop leukopenia, alpastic anemia and purpura haemolytica, without other marked symptoms. They generally recover slowly but completely when removed from exposure. L. J. Goldwater, 1941, observed the frequent occurrence of anemia, macrocytosis and thrombocytopenia in rotogravure workers, but leukopenia and prolonged bleeding and coagulation time were exceptional. The susceptibility varies greatly, and some workers show no apparent effects (Legge, 1920). Young persons and especially pregnant females are said to be more susceptible; but, women in general are not more susceptible. Corresponding phenomena are produced by dilute vapors in animals (Santesson, 1897; Selling, 1912). Their susceptibility increases with repeated exposure, thus explaining the deferred outbreak in workers. The effects are greatly diminished by dilution, *i. e.*, by liberal ventilation, and this is indispensable to protection. Contact of the liquid benzene with the skin adds materially to the danger. Leukocyte counts and determinations of the urinary sulfur partition should be made periodically on exposed workers, to detect the poisoning at its inception. The toxicity of the vapors of pure benzene is as high as that of the impure, if not higher (Pugliese, 1922). It is also the dominant toxic ingredient in benzene-toluene-xylene (Svirbely *et al.*, 1944).

Mechansim of Action.—The benzene effects are attributed to destruction of leukocytes in the circulating blood, and to damage of the bone marrow, lymph glands, spleen and the whole hematopoietic system. The formation of blood platelets is first stimulated, then depressed (Duke, 1913). The uric acid is not increased, and this speaks against destruction of leukocytes. Pappenheim, 1913, believed the decrease to be only apparent, asserting that the leukocytes accumulate in the dilated capillaries of the liver and other internal organs. He found marked hepatic and renal lesions in rabbits after repeated large doses. Duke, 1915, attributed the platelet changes to irritant, then toxic, action on the bone marrow. This shows the reddish-yellow gelatinous appearance of aplastic anemia in autopsies of patients with chronic benzene poisoning (bibliography, Engelhardt, 1931). The human series of Mallory, Gall and Brickley, 1939, ranged from severe hypoplasia to extreme hyperplasia.

Blood Changes in Animals.—Subcutaneous injections of benzene (2 to 40 cc.) into rabbits or dogs produce death in three to twenty days, with marked destructive changes in the hematopoietic organs, especially the myeloid tissue. There is a corresponding diminution of the leukocytes and blood platelets. With large doses, the platelets show a preliminary increase in rabbits, not in dogs (Duke, 1915). Recovery may be followed by a second fall (Weiskotten *et al.*, 1916). With rabbits, hypodermic injection of small doses (0.01 Gm. per Kg.) daily for eighty-five days produced transient leukocytosis, terminal anemia, marked thrombosis, decreased resistance, degenerative changes in leukocyte structure (G. Bayer, 1933). *Erythrocytes* decrease progressively in number; abnormal forms appear, including punctate basophilia (W. D. Paul, Friedländer and McCord, 1927), but no reticulocytes. The acute blood destruction causes increased pigment deposition in the liver and spleen. Rabbits exposed for two hours to 1 per cent vapor respond with immediate fall of erythrocyte count, by 25 per cent, followed in two or three days by a sharp rise, and then a second drop, which may go below the first; and finally a slow return to normal, generally in two weeks (E. J. Robinson and Climenko, 1938).

Hemorrhages, similar to purpura, into the skin and mucosae, including the stomach and intestines, occur frequently in chronic benzene poisoning. Uterine hemorrhage may be so severe as to cause death. The bleeding also favors fatal infection. The production of antibodies is diminished (Hektoen, 1916). The hemorrhages are due to decreased clotting power of the blood, involving lowered prothrombic content (Hurwitz and Drinker, 1915), thrombopenia and leukopenia, and damage to the endothelial cells (Dautrebande, 1933).

Dermatitis.—Chronic exposure to benzene may lead to extensive eczema, with irritation of the skin follicles, cornification of the sebaceous glands, increased pigmentation and keratosis. This may involve damage to the cornea.

Neuritis develops in some cases, and may include retrobulbar optic neuritis and blindness.

Safety Limits of Benzene Exposure.—The National Safety Council suggested 100 parts per million of air as a safe limit; 75 parts are distinctly safer, and even this may be fatal to susceptible persons (Bowditch and Elder, 1939; F. T. Hunter, 1939). Poisoning occurs in factories with air concentrations of 200 to 5000 parts per million. The *partition of sulfur in the urine* appears to be a better and safer criterion of excessive exposure because it is more individualized. Normally, 80 to 100 per cent of the urinary sulfur exists as inorganic sulfate. On exposure to benzene, this conjugates with part of the sulfate, and the ratio of inorganic sulfate is correspondingly reduced to 25 per cent and less often to 0. The reduction shows long before the blood changes, and if excessive exposure is promptly corrected, rapid recovery results (H. H. Schrenk *et al.*, 1936). *Low protein diet* renders the liver of animals more susceptible to the toxic effects; leukopenia is greater on high fat diet (T. W. Li *et al.*, 1944, 1945).

Risk of Industrial Poisoning from Benzene Derivatives.—H. F. Smyth, 1931, claimed that the risk of accidental poisoning is slight with substances whose M. L. D. lies between 0.1 and 0.25 Gm. per Kg. of body weight, if the toxicity is realized and proper precautions are taken.

Use in Leukemia.—The destructive action of benzene on leukocytes led to its introduction by v. Koranyi, 1922. Numerous reporters (Kiralyfi, 1912; Billings, 1913; Morawitz, 1914; and others) described more or less favorable, but rather inconstant, results. The changes are noticed only after continued administration (5 to 15 minims, four times daily), often requiring some weeks. The leukocyte count falls, more profoundly and persistently than with arsenic, but never to normal, as in x-ray treatment. In a considerable number of cases, especially the advanced, the benzene is unsuccessful. In others, toxic effects supervene, and this has discouraged its use; ordinary doses cause eructations, but the appetite is not disturbed. There may be some dizziness, sometimes bronchitis. Occasionally, late symptoms of chronic benzene poisoning develop, which may be fatal (Neumann, 1913; Klemperer and Hirschfeld). It is therefore advisable to discontinue the benzene as soon as the leukocytes start to decline (Kiralyfi, 1913), or at least when they have fallen to 20,000. Liver, kidney and intestinal disturbances contraindicate benzene (Hahn, 1914).

METHYLBENZENES: TOLUENE AND XYLENE

Toluene (toluol), $C_6H_5CH_3$, and xylene (xylol), $C_6H_4(CH_3)_2$, resemble benzene in their actions (Baumann and Herter, 1877), and have about the same acute toxicity; but they are much less deleterious under ordinary factory conditions, especially to the bone marrow (Halsgren, 1926). *Toluene* is used in paints, where it has largely displaced benzene. It is employed as a laboratory antiseptic, especially to preserve ferments. It is more irritant than benzene, somewhat more narcotic in lower concentrations, and has considerably less effect on the blood picture. *Toluene fumes in industry* produce irritation of mucous membranes, depression of the central nervous system, and depression of the bone marrow. Susceptibility differs markedly. Enlargement of the liver and macrocytosis are usually the first signs of chronic industrial poisoning. They are followed by decrease of red cells, usually moderate, and lymphocytosis. Leukopenia is exceptional. Exposure of men for eight hours daily to 200 parts per million produces some impairment of coordination and reaction time. The inorganic sulfate in the urine is not affected, in contrast to benzene. The more susceptible individuals should not be employed. Treatment would consist in blood transfusion followed by liver and iron administration (R. H. Wilson, 1943; von Oettingen *et al.*, 1942; L. Greenberg *et al.*, 1942). *Xylene* is used extensively in printing. A 25 per cent ointment in equal parts of hydrous woolfat and petrolatum is effective against pediculosis pubis (C. Ferguson, 1930). *Cumene*, isopropyl benzene, a higher homologue of the benzene series, produced slow and prolonged narcosis. It is toxic in considerably lower concentrations than benzene or toluene, but its higher boiling point (152° C.) makes it easier to control (H. W. Werner *et al.*, 1944). "*Solvent naphtha*," consisting chiefly of xylene with small amounts of toluene and thiophene, has largely taken the place of benzene in industry.

Fate.—A methyl group is oxidized in the body. Toluene is thus converted into benzoic acid, which is excreted as hippuric acid. Xylene is oxidized to toluic acid, $C_6H_4CH_3COOH$, which pairs with glycocoll to toluric acid.

NAPHTHALENE

This represents the union of two benzene rings, $C_{10}H_8$. It occurs as a colorless, crystalline powder, of coal tar odor and hot taste. It is practically insoluble in water, soluble in alcohol (1:13).

Uses.—It is employed as insecticide (moth balls), but is not very potent (W. E. Fleming and Baker, 1934). It has been used as antiseptic dusting powder in skin diseases and as intestinal antiseptic and anthelmintic, especially against oxyuris. *Dose*, 0.1 to 0.5 Gm. (2 to 8 grains). For children, 0.05 Gm., 1 grain, at one and one-half years; to 0.2 Gm., 3 grains, at twelve years, three times daily. Fumigations have been tried against pertussis.

The **toxicity** is usually rather low, because but little is absorbed, the greater part being eliminated unchanged by the feces. That absorbed is excreted as naphthol, naphthoquinone, and the like, and produces renal and vesical irritation and hemorrhage, and damages the blood-forming organs, resulting in anemia (S. Mayer, 1920). However, the absorption is sometimes greater (Kaminer, 1920), especially when it is vaporized, and orally in the presence of oil: 2 Gm., administered in the course of two days, proved fatal to a six-year-old child (Prochownik, 1911). Heine, 1913, reported poisoning in a woman after 2.8 Gm., distributed over three days. *Milder cases* show headache, nausea, vomiting, profuse perspiration, hematuria, slight edema, optic neuritis; sometimes damage to the cornea, retina and lens, similar to naphthol (Takamura, 1913). The cholesterol content of the tissues may be altered (Michail and Vancea, 1927).

Naphthalene Cataract.—Lens changes appear within one to three days after daily administrations of naphthalene to rabbits by stomach tube, 1 Gm. per Kg. of body weight. They progress so that the lens becomes completely opaque within twenty days. The initial lesions and the course resemble those of human cataract. The mechanism is not known, except that the glutathione content of the lens diminishes, and this is probably concerned in the lens metabolism. There are also severe lesions of the retina and signs of general intoxication (review, M. C. Bourne, 1937). All these effects are more marked in rabbits on a diet of bran, carrots and oats; they may be entirely suppressed by adding cabbage to the feed (Bourne, 1933).

Hydrogenated Naphthalenes.—Tetrahydronaphthalene (tetralene, $C_{10}H_{12}$) and decahydronaphthalene (decalene, $C_{10}H_{18}$) are used as solvents for resins and fats in the dye and lacquer industry, and also in motor fuel mixtures. Their toxicity is relatively low (Leschke).

Pentachlorinated naphthalene, used as coating of wire cables, produces papular rash in exposed skin. The dust and the fumes may cause fatal acute atrophy of the liver (L. H. Cotter, 1944; E. Collier, 1943).

NAPHTHOL

Alpha- and betanaphthol, $C_{10}H_7.OH$, are phenols, formed by the introduction of an OH group into naphthalene. *Betanaphthol* is the less toxic of the isomers. It is more germicidal than phenol. It is almost insoluble in water, and is employed as an ointment in alopecia (1 to 2 per cent), psoriasis, acne, parasitic skin diseases, pruritus, 3 per cent for adults, 1 per cent for children. A 10 per cent ointment is keratolytic. Caution is necessary lest the action become too violent and cause peeling which may be followed by persistent pigmentation. Betanaphthol is also employed to deodorize ozena. Internally, it is used as an intestinal antiseptic and anthelmintic. It is effective in hookworm disease, but inferior to thymol (Freeman, 1908). The local irritation and toxicity may be lessened on the salol principle, by transforming it into esters.

Toxic Effects.—Naphthol is especially irritant to the kidneys. Severe nephritis has been caused by its absorption from the intact skin in the therapeutic dose (Kaposi, 1881; Baatz, 1894). Death has been reported from its external application in scabies (L. Burger, 1919). It is especially contraindicated in the presence of renal diseases. Changes in the retina and opacity of the lens have also been described after its use (*e. g.*, Howe, 1913).

Betanaphthol, U.S.P. (*Naphthol,* B.P.), $C_{10}H_7OH$, occurs as colorless or buff-colored, crystalline laminae or powder; faint phenol odor; pungent taste. Very slightly sol. in water (1:1000); very sol. in alc. (1:0.8) and in oils, glycerin and alkalis. Dose, 0.25 Gm., 4 grains; against hookworm, 1 to 4 Gm., by special technic (Freeman, 1908).

Beta-tetralol, 1,2,3,4 tetrahydrobetanaphthol, which is used as insect repellant, produces cataract in rats in four to six weeks, if 1 to 2 per cent is added to their diet (O. G. Fitzhugh, 1946).

PARADICHLOROBENZENE

This is a by-product of the manufacture of picric acid. It resembles naphthalene in physical properties, and is chemically indifferent. It is a potent insecticide (Konantz, 1918). It is also toxic to worms. Oral administration to dogs produces no apparent deleterious effect, even in the dosage of 1 Gm. per Kg. (Sollmann, 1919). It is inferior, however, to carbon tetrachloride, and its use on stock animals taints the meat (Dikmans, 1927). It is used as a moth repellant. Several young workers exposed to this vapor for one or two years developed toxic hepatitis and cataract. Inhalation of fatal concentrations by animals results in vacuolization and necrosis of the liver cells, but no changes were observable in the lens (Berliner, 1939).

Orthodichlorobenzene is used extensively as solvent for lacquer, and in protecting wood against termites. *Orthodichlorophenol* is also employed as wood preservative. Both may produce vesication (Downing, 1939). The chlorophenols are more toxic to rats by mouth than hypodermically. They produce restlessness, increased rate of respiration, rapidly developing motor weakness, tremors, clonic convulsions, dyspnea, coma and death (W. B. Deichmann, 1943). *Para chlorophenol* is a potent bactericide for gram-negative organisms, effective in clinically safe concentrations. F. L. Meleney *et al.*, 1946, recommended an ointment containing P-chlorophenol, 0.25 per cent, and penicillin, 250 units per Gm., in a water-soluble carbowax and propylene glycol base.

INDOLE

This substance, benzopyrrole, , has a peculiar action on the motor elements of the spinal cord and especially the pons, in rabbits and mice, so that any impulses from the higher centers result in fascicular twitchings and clonic convulsions (Feinberg and McCulloch, 1944). Intravenous injection into dogs produces brief apnea followed by hyperpnea; immediate fall of blood pressure; increased mucous and salivary secretion, convulsive movements, and death by cardiac dilatation (Ets and Feinberg, 1942). The toxicity of indole acids, according to A. Berthelot and Dieryck, 1939, is considerably less than had been reported by Anderson, Shimkin and Leake, 1936, the difference being due to the toxicity of the solvent. In frogs, the action is more on the cord than on the pons (Yanai, 1935). Methylindoles paralyze the central nervous system in frogs, especially the sensory cord.

Dichlorophenol indophenol, the dye used for estimating ascorbic acid, is reported to be carcinolytic: Infiltration of human cancers with N/400 solution, twice daily for two weeks, was followed by disappearance of cancer cells and formation of fresh granulation tissues (H. Rotter, 1939). Confirmation should be awaited. *Phenol-indophenol dyes* produce pallor in amphibian larvae by inhibiting the tyrosinase in their melanophores (F. H. J. Figge, 1938).

Indole Acids as Phytohormones.—Indolyl-3-acetic acid (and the corresponding propionic and butyric acids, and a number of other ether-soluble unsaturated fatty acids) act as "*hetero-auxins*": dilute solutions ($1:10^8$) markedly increase the growth of plants by stimulating them to synthesize solid material (reviews, K. V. Thimann, 1946; P. W. Zimmerman, 1943). Haloid derivatives of weak organic acids are especially effective—dichlorophenoxyacetic acid is three hundred times more potent than indolebutyric acid (Zimmerman and Hitchcock, 1942).

Auxins occur naturally in plants, most abundantly in the developing buds and young leaves where they are produced. The naturally occurring auxins are easily oxidized, and leaves contain enzymes for their destruction.

Auxins have several distinct actions: (1) They intensify photosynthesis (Cholodny and Gorbovsky, 1939); (2) they promote elongation of the plant; (3) they stimulate root growth, so that seeds start roots earlier, and rooting may be produced in unusual locations on the plant (Zimmerman and Hitchcock, 1935). Thiamine and its fraction thiazole are essential to root growth and enable tomato roots to grow without tops in culture solutions (W. J. Robbins and Schmidt, 1938); (4) they induce fruit formation in the ovary; (5) they inhibit the growth of lateral buds; (6) they inhibit autumnal leaf fall; (7) higher concentrations are fatal to plants, much more so to broad-leaved plants than to grasses.

Indole acetic acid and a number of other auxins inhibit the growth of certain *bacteria,* but varying greatly with the species (R. J. Dubos, 1946).

Phytohormones are used in horticulture to stimulate the rooting of cuttings. Spraying of orchards reduces the premature dropping of fruit by half, and has become standard orchard practice. They are used extensively as *weed killers,* especially *2,4-dichlorophenoxyacetic acid* ("2,4-D") and the trichlorocompound ("2,4,5-T"). These are beneficial at 10 per million, but at 100 to 1000 ppm they stimulate abnormal growth and kill the entire deep root system when applied to the foliage. They are highly selective; tomato plants are killed by spraying with 100 ppm of 2,4-D. It is nonirritating to the skin and relatively nontoxic to animals. Fish survive concentrations that kill water hyacinths. Sodium dinitro-ortho-cresylate ("sinox"), a yellow dye, also kills broad-leaved annual weeds with little effect on grass (review, E. M. Hildebrand, 1946). The estimation of phytocidal action is outlined by H. R. Offord, 1946.

Beta-indolylacetic acid, $1:10^7$, suppresses the germination of clover, but it has a much lower *toxicity in soils,* where it is decomposed by the soil bacteria. The 2,4-dichlorophenoxyacetic acid is toxic to clover and sugar beet with $1:10^6$ in soil, and retains its toxicity much longer (Nutman *et al.*, 1945).

In animals, parenteral administration of *2,4-dichlorophenoxyacetic acid,* 150 to 200 mg. per Kg., produces myotonia lasting eight to twenty-four hours. Repeated injections did not produce any functional or morphologic changes, with the doses studied (N. L. R. Bucher, 1946).

Phytohormones do not affect the growth, development and estrus cycle of rats, or the incubation of chicken eggs (W. S. Dye *et al.*, 1944).

QUINOLINE

Quinoline, C_9H_7N, is derived from naphthalene by the substitution of a N for a CH group. It is highly toxic and strongly antiseptic (Donath, 1881). In rabbits, the hypodermic or intravenous injection of 0.2 Gm. per kilogram produces retinitis, similar to that from naphthalene; the lens, however, remains clear (Jess, 1916).

Oxyquinoline Sulfate, $(C_9H_7ON)_2.H_2SO_4$, is strongly bacteriostatic, but feebly germicidal. It seems to be nontoxic and is used as an antiseptic lotion for mucous membranes and the like, under the name of **chinosol.** Its fate was studied by Brahm, 1899, and Grabbe, 1928. It is rapidly absorbed from the intestines of dogs, and as rapidly excreted by the urine (almost completely conjugated with sulfate; a small part free) and by the bile. Several iodated derivatives are used as effective amebicides in dysentery, especially Vioform and Chiniofon (Yatren); see Index. Various *dioxyquinoline* derivatives were investigated by Mancini, 1932.

ANILINE

Aniline, $C_6H_5NH_2$, is used extensively in the arts and gives rise to industrial poisoning, with methemoglobin formation, headache, weakness, dyspnea, cyanosis, convulsions and psychic disturbances. Acute effects on dogs involve methemoglobin formation; and results of the anoxia are essentially on the central nervous system and heart (B. B. Clark *et al.*, 1943). Its excretion was studied by Rambousek, 1913.

Chronic poisoning sometimes develops vesicular miliaria and other skin eruptions. The blood changes are less marked than in the acute. It has been asserted that the *methemoglobin formation* is increased by alcohol, clinically, and this has been confirmed in cats. The explanation is not clear. It is not due to more rapid absorption or to increased oxidation of the aniline (Schwedtke, 1938). It has been suggested that impurities may play a large share in industrial poisoning (review, Luce and Hamilton, 1916).

Heart; Curare Action.—Aniline and its methyl derivatives (*toluidine* and *xylidine*) are toxic to the *frog heart*, increasing the chronaxia markedly (R. Bonnet and Lelu, 1933). They have little effect on the frog sciatic nerve, but a strong curare action (Bonnet, Faye and Monrot, 1933).

Xylidine, with moderate concentrations, produces jaundice and fatty liver in dogs. Prolonged administration results in precirrhotic changes, with parenchymal injury, but with unimpaired reticulo-endothelial function (Svirbely, Monaco and Alford, 1946).

Shoe-Dye Poisoning.—Black dyes for leather commonly contain aniline oil and nitrobenzene, and numerous poisonings have been caused by recently dyed shoes. They are characterized by marked cyanosis, with blue lips and ears, and gray face, noticeable in one to three hours, often preceding the subjective symptoms of anoxemia: faintness, vertigo, headache and nausea. More severe cases resemble ordinary acute aniline and nitrobenzene poisoning. Polyuria and severe thirst are frequent. Fatalities are rare and recovery is fairly rapid (Stifel, 1919). The effects are probably due to aniline, for nitrobenzene is not so readily absorbed through the skin (Schwedtke, 1938).

Aniline dye poisoning with cyanosis has been reported in infants from skin absorption of the dye from freshly stamped pads (Graubarth *et al.*, 1945).

PHENYLHYDRAZINE

This is employed as the hydrochloride, $C_6H_5NH.NH_2HCl$, against polycythemia vera. It produces striking and peculiar changes in the blood picture, which may advance to profound anemia.

The effect is not shared by its components, hydrazine and phenyl, which as such do not alter the blood picture (E. V. Allen and Page, 1930); and the action and its mechanism are quite different from those of benzol. The latter produces aplasia of the bone marrow and spleen, with decrease of the leukocytes and erythrocytes and platelets. Phenylhydrazine, as studied in animals, has little effect on hematopoiesis; it does cause hyperplasia of the spleen and slight hyperplasia of the leukoblastic elements of the bone marrow, but it has no primary effect on the erythroblastic elements or on the platelets, and the reticulocytes tend to increase. Its anemia is due essentially to hemolysis of the mature red cells, but the mechanism is obscure (Evenson, 1938). Destruction of hemoglobin occurs presumably within the red blood cells, since these contain *basophilic masses;* similarly with other hydrazines and hydroxylamines (O. Warburg *et al.*, 1931). The effect is not altered by removal of the spleen (Giffin). The hemolysis results in increased deposition of iron in the liver and spleen, in bilirubin in the blood, and in large amounts of urobilin and urobilinogen in the urine, sometimes also hematoporphyrin. The urine may turn darker on standing. The nitrogen of the urine and blood is high, the blood calcium is low.

The *therapeutic response* is satisfactory in somewhat over half the cases of polycythemia. It becomes manifest after some days, with rise of the leukocytes to 50,000 or more, followed by a decline of hemoglobin and erythrocytes, with disappearance of the other symptoms. The effects are cumulative and continue for a week or two after the administration has been stopped, partly because the excretion of the drug is slow.

Phenylhydrazine hydrochloride is *administered* by mouth in capsules, 0.2 Gm. (3 grains) daily, for three to

four days, then 0.1 Gm. daily until the leukocytes rise, or until the hemoglobin falls below normal, usually in three to four weeks, when a total of 1 to 3 Gm. have been administered (Brown and Giffin estimated that 1 Gm. of phenylhydrazine would reduce the hemoglobin by about 6 Gm.). The administration is suspended temporarily if immature red cells increase. If the effect is incomplete another course may be given after an interval of a week or two, as a precaution against cumulation. After the normal level is reached it may be maintained with smaller doses which may be tried out for each patient, using 0.1 Gm., one to three times per week. Stealy and Sumerlin, 1944, reported a patient whose polycythemia was kept under control for eleven years without bad effects. (Acetyl phenylhydrazine, "Pyrodin," has also been used in polycythemia.) *Untoward symptoms* appear as a rule when the total dosage of the course exceeds 2.5 Gm.: jaundice, anorexia, nausea, slight bladder irritation, pruritus (Giffin and Conner). Others have reported dermatitis (eczema, erythema nodosum and papulosum), excessive hemolysis and increased tendency to thrombosis. On account of this, phenylhydrazine is generally avoided when patients are confined to bed or are elderly with advanced arteriosclerosis, as also in diseased conditions of the heart, kidney or liver.

Industrial poisoning has occurred, usually in minor degree, from repeated contacts with the skin whence it is more readily absorbed than from the digestive tract. It causes local irritation (pustules, edema) and systemic effects: headache, diarrhea, anorexia, lassitude, pallor, loss of weight; the urine may contain protein and blood.

Toxic Effects in Animals.—Doses proportionate to the clinical, continued for eight months, did not produce untoward effects in dogs (Allen and Giffin). Larger doses (rabbits or guinea pigs, 0.04 to 0.12 Gm. hypodermically) cause acute poisoning, with hemolysis, fall of blood pressure, asthenia, increased respiration, fall of temperature, albumin and urobilinogen in the urine (Lande *et al.*). With fatal doses, especially intravenous, necropsy shows hepatic swelling, degeneration and necrosis, pneumonic infiltration and degenerative changes in the other viscera (Wells; Underhill). Phenylhydrazine produces rapid formation of *methemoglobin* and other unidentified hemoglobin derivatives in life, more slowly in the test tube. When it is injected hypodermically into a rooster, the color of the comb turns to brownish-black in two or three minutes (L. Lewin, 1901). The hemoglobin of frogs forms a peculiar "hemoverdin."

NITROBENZENE

Nitrobenzene, $C_6H_5NO_2$, is used extensively in the manufacture of aniline. Its odor resembles that of hydrocyanic acid. It is employed in cheap perfumery and soaps, under the name of Artificial Oil of Almonds or Oil of Mirbane, but it is highly toxic; 1 Gm. may be fatal.

The *toxic symptoms* are usually rather delayed, sometimes for twelve hours, and are said to be accelerated by alcohol. They resemble those of aniline poisoning, and consist in nausea and prostration, burning, headache, intense cyanosis from methemoglobin, beginning in the lips and spreading over the entire body, air hunger and increased heart action, vomiting with characteristic odor, sensory skin irritation, convulsions and coma, ending in death after a few hours. The prognosis is generally good even in severe cases; the mortality is about 20 per cent; but with prompt treatment, 30 cc. were survived (Zuccola, 1918). In protracted cases, temporary improvement and relapses occur. The methemoglobin persists for many days.

The cyanosis is a striking feature, the face turning almost black; the blood, when withdrawn, is also dark, owing to the formation of methemoglobin. The blood corpuscles undergo rapid and intensive destruction. The urine may contain hemoglobin, methemoglobin, porphyrin, urobilinogen, urobilin, albumin and casts. In case of recovery the anemia is followed by active regeneration, with marked hyperactivity of the bone marrow (Zuccola). Polycythemia to six or seven millions may develop. The other symptoms result largely from the asphyxia; but the motor centers are probably affected directly. The respiration and circulation undergo relatively little disturbance. The reported cases of nitrobenzene poisoning were reviewed by S. S. Adams, 1912. Nitrobenzene has been taken to produce *abortion*, but even large doses are ineffective (Spinner, 1917). *Treatment* of poisoning consists in evacuation and stimulation. No fat should be given. Transfusion of blood results in marked improvement (Zuccola).

Inhalation of Nitrobenzene Vapor.—The symptoms differ in detail with the species of animals. They generally begin three or four days after exposure, with vomiting and marked digestive disturbance; then loss of muscular coordination, generally starting with the hind legs; forced movements or extensor rigidity. Consciousness is preserved. Death occurs through respiratory failure (Dresbach and Chandler, 1917). The motor symptoms are of cerebellar type; histologic examination shows changes in the cerebellar Purkinje cells, while other nerve cells are unaffected (Dresbach and Chandler, 1918).

Subacute and chronic nitrobenzene poisoning shows icterus and cyanosis, the clinical picture resembling that of pernicious anemia. The liver damage may be fatal. Otherwise, the prognosis is favorable, but the blood regeneration is much slower than after acute poisoning.

Nitrotoluene presumably acts similarly to trinitrotoluene.

Methemoglobin production by aromatic amino and nitro compounds (aniline, nitrobenzene, etc.) occurs much more rapidly and readily in living man and many animals than in shed blood; and not at all in rabbits, even with fatal doses, although these form methemoglobin with nitrites. Apparently the methemoglobin formation is not due to the aniline and nitrobenzene as such, or to the final products of their metabolism, paraminophenol and nitrophenol, but to intermediate products, especially to phenylhydroxylamine, C_6H_5NHOH, or aminophenols (Heubner, Lipschitz). These are oxidized by the oxygen of oxyhemoglobin, and this process liberates active oxygen, which oxidizes the oxyhemoglobin to methemoglobin. This may again be reduced by more of the phenylhydroxylamine. Paradinitrophenol can transform a hundred times its equivalent of hemoglobin, so that the action is catalytic (Heubner and Lo-Sing, 1938). Differences in this metabolism may explain the differences in the process.

With acute nitrobenzene and aniline poisoning of dogs, methemoglobin appears in spectroscopic traces in one and one-half hours, becomes distinct in two and one-half hours and increases for about six hours (Dietrich, 1892). The methemoglobin percentage rises higher in the blood of splenectomized dogs than normally (Ray and Stimson, 1927), perhaps because the circulating blood is normally diluted with spleen blood, which is less exposed to nitrobenzene. Methylene blue, 1 to 2 mg. per Kg. intravenously, or 65 to 130 mg. by mouth every four hours, restores methemoglobin to oxyhemoglobin, clinically (A. F. Hartmann, 1938) and in animals (A. P. Richardson, 1939).

TRINITROPHENOL (PICRIC ACID)

The saturated aqueous solution is used *externally* as a dressing for burns and superficial wounds, weeping eczemas, and so forth, exerting anesthetic, antiseptic, astringent and protective actions, and stimulating the reproduction of epithelium, in contrast to most other antiseptics (Ehrenfried, 1911). It is less painful than tannic acid. Stronger alcoholic solutions are irritant and, when absorbed, become toxic. This may also occur when aqueous solutions or dusting powders are applied to large surfaces, so that it should only be used on small burns. *By mouth,* 1 to 2 Gm. produce severe poisoning, generally with recovery under treatment (Lewin). It stains the skin, conjunctiva and tissues yellow, even on systemic administration, simulating icterus. This may persist for two weeks after taking 1 Gm. The urine is colored a peculiar red (Walko, 1901).

The toxic effects were investigated on dogs by Rapp and Foehr, 1827. Braconnet, 1830, introduced it against intermittent fever; it was also used as anthelmintic; but its internal administration was soon considered too dangerous. It was employed in surgery by Cheron, 1876.

Application.—Trinitrophenol is used on burns and the like as a saturated aqueous solution, whose antiseptic efficiency is about seven times that of 1 per cent phenol. It is prepared by dissolving 6 Gm. in a pint of hot water and filtering when cold. Cloths saturated with this solution are applied, covered with dry cotton, and left in place for several days. Stronger alcoholic solutions should not be used. *Picric stains* may be removed from the skin by applying powdered potassium sulfate for a minute, then washing with soap; or by a paste of magnesium carbonate (Mankiewicz, 1916).

The **toxicology** is practically important, especially in munition factories (Alice Hamilton, 1917). The common belief of its use in beers seems to be unfounded (Gadamer). Locally, the handling of the dry powder produces eczematous dermatitis, "picric itch." A measles rash also occurs sometimes in poisoning. Systemically, toxic doses destroy the red corpuscles and produce gastro-enteritis, hemorrhagic nephritis and acute hepatitis. There may thus be a true icterus, although the yellow coloration is mainly due to picric staining (Malmejac, 1917). Industrial exposure to *ammonium picrate dust,* 0.008 mg. per cubic meter, produced no systemic effects, but a tenth of the workers had dermatitis (Sunderman *et al.,* 1945).

Toxic symptoms which arise from its use on burned surfaces include headache, vertigo, nausea, vomiting, diarrhea; erythematous, papular or vesicular rashes; yellow coloration of the skin and conjunctiva; darkened green or port wine-colored urine; albuminuria. These should be checked so that the applications may be promptly discontinued.

The toxic effects on rabbits and dogs are described by Koizumi, 1914; those on frogs by E. D. Brown, Ahlfs and Howard, 1920.

Fate.—A part of the picric acid may be excreted unchanged by the urine, but most is transformed by the liver into picramic acid. This confers the diazo reaction on the urine (Pecker, 1916).

Trinitrophenol, U.S.P. (Picric Acid), $C_6H_2(NO_2)_3OH$, acid to litmus, explosive on percussion, is a yellow crystalline powder, odorless, of bitter taste and intense staining power. Sol. in water (1:80) or alc. (1:12).

TRINITROTOLUENE

This is important as an explosive ("T.N.T."). It is $C_6H_2(NO_2)C_3H_3$. Other nitro and amino derivatives of benzene which are also used as explosives, produce similar effects with differences in detail (Alice Hamilton, 1917). Poisoning arises by inhalation of the dust, in a proportion of the munition workers, generally between the fifth and sixth week of the employment; young and old subjects are more susceptible than vigorous adults (Martland, 1917). It is readily *absorbed* through the respiratory and gastro-intestinal tract, a small amount also through the skin. The *urine* contains dinitroaminotoluene and probably other amino derivatives (von Oettingen *et al.,* 1944; R. K. Snyder, 1946). Slices of muscle and liver convert trinitrotoluene into a compound that inhibits tissue respiration, and then further into a compound that lacks this inhibition (E. Bueding and Joliffe, 1946).

Untoward effects in munitions workers are usually minor: The most frequent is mild *dermatosis* of the hands. The skin of the hands is stained a light yellow, the hair reddish (L. Schwartz, 1944); there is irritation of the respiratory mucosae, sneezing, sore throat and irritant cough. Systemic effects begin with gastro-intestinal irritation, distress, nausea, anoxia, vomiting and diarrhea. The most serious but infrequent complication is *hepatic necrosis* (Livingstone *et al.,* 1916). It occurs even with good working conditions (W. L. Palmer *et al.,* 1943) in about 0.2 per cent of munitions workers, but a fourth to a third of the cases are fatal (von Oettingen *et al.,* 1944). Its infrequency indicates that it requires special susceptibility, probably by *sensitization,* as it occurs only after some months of exposure; but the actual onset is usually sudden. None has been reported after six months of exposure (J. H. Eddy, 1944). *Other occasional clinical effects* include blood destruction, aplastic anemia and purpura (Panton, 1917; B. Moore, 1917); cyanosis of the lips and ears; a deep blue alveolar line (L. Schwartz, 1939); leukocytosis or leukopenia; central nervous changes of varying degree, probably resulting from anoxia; peripheral neuritis and muscle pains which may be early symptoms; cardiac muscular and menstrual irregularities, urinary and renal irritation (von Oettingen *et al.*, 1944). R. F. Sievers *et al.*, 1946, report three cases of aplastic anemia, two with fatal outcome, after exposure to TNT. Necropsy showed hypoplastic bone marrow and subacute atrophy of the liver.

Toxic Effects on Animals.—Dogs and cats are more susceptible to trinitrotoluene than are rabbits and guinea pigs (C. Voegtlin *et al.*, 1921). Administration to dogs over several months produced irritation of the digestive tract and urinary bladder; ataxia, nystagmus, circus movements; and moderate anemia (von Oettingen *et al.*, 1944). The chief pathologic finding in various animals is general hemosiderosis; sometimes moderate fatty degeneration of the liver and perhaps of the kidneys, attributable to methemoglobinemia (R. D. Lillie, 1943). M. I. Smith *et al.*, 1943, found no changes in the glycuronic acid excretion; porphyrin may be somewhat increased. H. J. Channon *et al.*, 1944, studied the *fate* of TNT in rabbits.

Effects of Diet.—H. P. Himsworth and Glynn, 1942, reported that the chronic toxic effects for rats are greater on a diet rich in fat, and are decreased by high protein or carbohydrate feeding. Addition of milk to a well balanced diet had no effect on the toxicity; nor did the addition of ascorbic acid; although scorbutogenic diet increases the susceptibility in guinea pigs. Ascorbic acid is slightly protective with cats (M. I. Smith *et al.*, 1943).

Treatment.—Little can probably be done for the fully developed disease, but administration of methionine, 3 to 5 Gm. daily, appears to reduce the mortality (J. H. Eddy, 1945). The workers should be withdrawn from exposure with the first appearance of any symptoms. *Protection* offers the only satisfactory solution of the problem. It involves proper ventilation, cleanliness, and so forth. The subject is discusesd by Schereschewsky, 1917.

Tetryl, trinitrophenylmethylnitramine, used extensively as "sensitive" explosive, produces *dermatitis* in nearly half of the workers, generally after about three weeks of exposure, but most of those affected become "hardened". The palms and fingers stain yellow, the hair red (L. Schwartz, 1944). The dermatitis involves especially the face around the eyes, with erythemia and edema similar to that from second degree burns. The nasal mucosa is also affected, with epistaxis from small ulcerating points. *Systemic effects*, rather rapidly developing secondary anemia, irritability, anorexia, are less frequent. Renal and hepatic damage have not been demonstrated. *Prophylaxis* consists chiefly in control of dust. Protective casein hand creams reduce the incidence to half. Severely affected workers should be eliminated; lighter cases may try to develop tolerance (L. J. Witkowski *et al.*, 1942). *Synthetic antigens*, sensitizing guinea pigs to skin tests, have been prepared from tetryl and related compounds *in vitro* by coupling them to serum proteins (G. P. H. Gell, 1944).

Hexite, hexanitrodiphenylamine, produces vesicular dermatitis in munition workers. Its systemic effects resemble those of nitroglycerin (L. Schwartz, 1944).

COAL TAR DYES

The quality of dyeing generally implies that the dye has a high adsorption affinity, *i. e.*, that it accumulates in high concentration on the surfaces. This increases the concentration in contact with the cell, and modifies its surface properties, and indeed those of intra- and extracellular colloids, similarly to the albumoses, saponins, and the like. The actions of the dyes therefore have similarities independent of their chemical composition. They generally have rather high antiseptic value, often with specific differences that go parallel with the staining action. Protozoa are generally more susceptible than bacteria. Intravenous injection produces acute anaphylactoid phenomena, which have been employed similarly to the foreign protein injections against septicemias, and so on (Churchman, 1925). The injected dye often gives selected concentration in inflamed and injured tissues; for instance, in necrotic tuberculous and cancerous areas (Cecil and Weil, 1917). The excretion is also generally rather selective, either by the urine or more often by the bile (Salant and Bengis, 1916). The rate of the excretion is utilized for studying the functional efficiency of the kidneys and liver. Colloidal dyes leave the blood plasma so slowly that they can be used to estimate the volume of the circulating blood. The greater number of the medicinal dyes belong to a few chemical types. Commercial dyes are often impure and indefinite mixtures.

Intravenous Injections of Colloidoclastic Antiseptics.—Improvement of staphylococcus, gonococcus and other infections may occur after the intravenous injection of antiseptic dyes, arsphenamine, mercurochrome, mercuric chloride, formaldehyde and a number of other antiseptics (H. H. Young *et al.*, 1924; J. S. Simmons, 1929). Directly bactericidal concentrations in the blood would be fatal; but all these agents tend to alter the colloidal equilibrium of the blood, and therefore produce more or less allergic reaction, which may be responsible for the improvement, but also implies an element of danger.

The *penetration of dyes into cells* presents interesting problems (A. P. Mathews, 1910). Basic dyes diminish, acid dyes increase the imbibition of gelatin. This may be a factor in the penetration, but is not a complete explanation (Traube and Koehler, 1915). The vital staining and the toxicity of acid and basic dyes are not parallel (Hoeber, 1914). The addition of dyes to other poisons often modifies their toxicity (Sellei, 1913).

Yeast.—Basic dyes (methylene blue) stimulate yeast growth in dilute solutions and inhibit with moderate concentrations. Acid dyes have little effect (Somogyi, 1916). There is no correlation between the effects on yeast and excised frog heart or mammalian intestine. (Axmacher, 1933).

Tissue Cultures.—The growth of cultures from embryonal chick lung is accelerated by weak solutions of various dyes, and inhibited by stronger concentrations (Kamon, 1928).

Effects of Dyes on Cancer.—Selective staining of cancers by dyes does not imply selective toxicity; it is generally due to the presence of necrotic tissue. Indeed, injection of trypan blue (or colloidal metals) increases the susceptibility of mice to transplantation carcinomas (Ludford, 1932). Zahl and Waters, 1941, suggested the possibility of using the localization of Evans blue or lithium carmine in the semi-necrotic zone of tumors for introducing radioactive substances.

METHYLTHIONINE CHLORIDE, METHYLENE BLUE

This dye (tetramethyl thionine chloride) and its colorless reduction derivatives furnish an oxidation-reduction system with interesting reactions in the test tube and in organ emulsions, resembling somewhat those of the cellular respiration ferments. It has been suggested that it may substitute for these, but this is doubtful for intact animals. It forms methemoglobin, on intravenous injection as well as in shed blood, the latter with hemolysis; this is probably the explanation of its antidotal action in cyanide poisoning. It penetrates cells fairly readily and is used for intravital staining of nerve tissue. It has a variety of actions, but its therapeutic applications have generally turned out inferior to other agents. It was tried as an analgetic in neuralgia and neuritis, as an antipyretic and parasiticide in malaria, and as an antiseptic in cystitis, urethritis, conjunctivitis and skin diseases. It colors the urine green or blue and may be used as a kidney function test (Tachau, 1911).

Fate.—Methylene blue is distributed through all tissues (localization in kidneys, G. D. Shafer, 1908), but it is rapidly reduced to colorless leuko compounds. These are oxidized when the tissues are exposed to air (Herter, 1904), or are in contact with hydrogen peroxide, thus restoring the blue color. Prolonged ingestion (as analgetic) gives a blue tint to the vitreous humor; this is the only tissue in the body which is blue before exposure to the air.

Excretion occurs by the urine and feces (traces in the sweat and sputum), partly unchanged and partly as "methylene azure." The latter is also present in medicinal methylene blue, being formed from it by alkalis. Both exist in a colored and colorless (reduced) form in the urine (Underhill and Closson, 1905). This is therefore rendered more blue by oxidizing agents, especially in acid reaction, and paler by reducing agents (dextrose, and so forth).

Test of Kidney Function.—After hypodermic injection of 0.02 to 0.5 Gm. the excretion begins normally between fifteen to twenty-five minutes later. The usefulness of the test is more limited than that of the phenolsulfonphthalein test.

Urinary Antisepsis.—Methylene blue (1:150,000) is antiseptic for pure cultures; but it is a slow and weak germicide and practically inactive in the leuko form, in which it is excreted in the urine. In doses of 0.4 to 0.6 Gm., four times daily for several days, it perhaps is of some use in staphylococcus cystitis, but useless in urethritis (Hinman, 1915).

Methylene Blue Oxidation-Reduction Reactions.—The dye is readily reduced to a series of colorless (leuko) compounds (four have been demonstrated in the urine), and these may be reoxidized to the blue dye. Through these reactions it acts as an oxidizing and reducing "carrier" in some rather peculiar reactions, probably through its sulfhydryl group, and it may to some extent take the place of glutathione (review, Harrop and Barron, 1928).

The oxidative effects (with decolorization of the blue) include the incomplete oxidation of glucose (Warburg), and the oxidation of hemoglobin to methemoglobin. *As a reducing agent* it prevents the oxidative effects of blood charcoal (Warburg) and the spontaneous oxidation of ethers. It checks the oxidation of succinic acid by hashed muscle (Battelli and Stern). In this it inhibits not the dehydrogenation but the oxidation of the hydrogen (Thunberg). It greatly increases the respiration of mammalian erythrocytes, and Meyerhof believed that it increases tissue respiration; but the evidence for its action on living cells is not satisfactory.

Its use in carbon monoxide poisoning was based on a theory that it would take the place of hemoglobin as a conveyor of oxygen to the tissues. It appears to be not only useless, but toxic, for it augments the phenomena of anoxia in animals (Crisler, 1935). It is reported to improve efficiency of performance at *high altitudes*, if 0.2 to 0.04 Gm. is administered about two hours before the ascent (M. M. Brooks, 1945).

Actions on Hemoglobin.—Methylene blue can oxidize hemoglobin to methemoglobin or again (in its leuko form) reduce methemoglobin to hemoglobin, according to circumstances. In severe methemoglobinemia, from nitrite, acetanilide or sulfanilamide, in man or animals, intravenous injection of small doses of methylene blue (1 to 2 mg. per Kg.) promptly decreases the methemoglobin and increases the oxygen capacity of the blood, or it may be administered orally, 65 to 130 mg. every four hours, for man (W. B. Wendel, 1938; A. F. Hartmann *et al.*, 1938; A. P. Richardson, 1939; D. Campbell and Morgan, 1939). On the other hand, methylene blue injection is effective in cyanide poisoning (although not so effective as nitrite) by forming methemoglobin to bind the cyanide. Methylene blue is also *hemolytic.*

Experimental Tumors.—The injection of methylene blue into rat and mouse tumors increases the number of egressions from 3-8 per cent to 25-44 per cent. Other dryes are ineffective (M. M. Brooks, 1934).

Malaria.—Methylene blue, 0.1 to 0.15 Gm., is recommended by Froes, 1934, as adjunct to quinine or atabrine (in their usual dosage).

Leprosy.—Rozental, 1935, claimed diminution of the bacteria and marked clinical improvement from the intravenous injection of aniline dyes that have selective affinity for the leprous lesions: 1 per cent methylene blue or 0.5 per cent of "brilliant green," 5 to 30 cc. every five to six days for several months.

Tsutsugamushi infections of mice are reported to respond remarkably well to treatment with methylthionine chloride (W. F. McLimans, 1947).

Toxic Actions.—Therapeutic doses sometimes cause slight vesical or gastro-intestinal irritation. Hypodermically, it may produce ulcers and abscesses. Its toxicity is low, the fatal dose for dogs exceeding 1 Gm. per kilogram. Intravenously, 0.5 Gm. per kilogram kills by respiratory paralysis; considerably smaller doses may produce marked circulatory disturbances. Its continued oral use is harmless (Tanfiljeff, 1907). Rats tolerate 500 mg. per Kg. as 5 per cent solution by mouth, or 150 mg. per Kg. as 1 per cent solution hypodermically, but are killed by 200 mg. per Kg. hypodermically, and by 50 to 100 mg. per Kg. intraperitoneally (H. H. Anderson *et al.*, 1934).

Peripheral Autonomic Actions.—In general, small concentrations of methylene blue produce parasympathetic stimulation, perhaps by inhibiting cholinesterase. Moderate concentrations paralyze the parasympathetic receptive mechanism, similarly to atropine (R. P. Cook, 1926).

Blood Pressure and Respiration.—Intravenous injection of 4 mg. per Kg. produces marked rise of blood pressure, followed by fall (Garfounkel and Gautrelet, 1913) by direct action on the vessels (Addarii and Freundlich, 1937). Perfused blood vessels are first constricted and then dilated. The *respiration* is stimulated by small and arrested by large doses (Lundberg). It shortens the time when exposure to oxygen results in pulmonary edema (Gregoire, 1931). The *heart rate* is slowed by intravenous injection and by perfusion of the excised heart with dilute solutions of methylene blue (Lundberg, 1924). On the other hand, it is antagonistic to drugs that stimulate the vagus, although it is less potent than atropine (C. Heymans, 1922). This is a reversible effect on the cell surface, before the protoplasm is stained (R. P. Cook, 1926). Methylene blue also inhibits the *cholinesterase* of the serum, in low concentration, but much less effectively *in vivo* (E. Rentz, 1940). The excised frog's heart is stimulated by small doses; large doses destroy its irritability.

Hyperthermia.—Moderate doses raise the temperature, as was first shown by Ehrlich. The action is central, and results in increase of gaseous metabolism and decrease of liver glycogen. With rats, these effects do not occur if the environmental temperature is below 24° C. (Gregoire, 1931).

Intestine is stimulated by 1:10^6; with 1:10^4 this is followed by inhibition. Atropine antagonizes the stimulation only imperfectly (Lundberg).

Uterus is also stimulated, irrespective of its response to epinephrine. It can then be inhibited by large doses of atropine, but not by ergotoxine (Lundberg). High concentrations are depressant (R. P. Cook, 1926).

Somnifacient Adjuvant.—Konzett, 1938, reported that pretreatment of rats and other animals with small intraperitoneal doses of methylene blue or other liposoluble dyes (neutral red, and so forth) considerably strengthens the action of soporifics (chloral, phenobarbital, and the like). The dyes alone are not somnifacient even in larger doses. Congo red, which is not liposoluble, is ineffective. Intravenous injection of methylene blue intensifies the *electrical activity of the cerebral cortex* (Moruzzi, 1938).

Preparation.—*Methylene Blue,* U.S.P.; *Methylthionine Chloride,* (not to be confused with *methyl blue*), occurs as dark green crystals; freely soluble in water (1:25) and alcohol. Dose, 0.06 to 0.3 Gm., 1 to 5 grains; externally, 0.5 per cent solution on mucous membranes, 2 per cent on skin.

PHENOTHIAZINE (THIODIPHENYLAMINE)

This substance, prepared by the action of sulfur on diphenylamine, is an effective *insecticide,* in concentrations which are not toxic for higher animals and man. It is more toxic than rotenone to mosquito larvae (F. L. Campbell *et al.*, 1934). It is also an effective *anthelmintic* against oxyuris (1 to 4 Gm. per day, according to age, for five successive days, N. Sisk, 1943), but it sometimes produces *anemia* and *toxic hepatitis* (D. Hubble, 1941). It gives rise to local irritations of the *skin,* and its oxidation products sensitize the skin to irritation by light (also with pigs; Swales *et al.*, 1942).

Properties.—Phenothiazine is a pale yellow crystalline powder, practically tasteless, soluble in fat solvents and in alcohol, practically insoluble in water, oxidizing slowly in moist air. It is the parent substance of many "thiazine" dyes, especially thionol, Lauth's violet and methylene blue.

Fate.—Phenothiazine is rapidly excreted by the urine, partly as such and partly as the more soluble oxidation product thionol, a red dye related to methylene blue. In acid urine this is reduced to leukothionol, which is bactericidal in both acid and alkaline reaction (below *p*H 4.5 and above 8), but not in neutral solutions (De Eds, Eddy and Thomas, 1938; J. O. Thomas *et al.*, 1938). Rabbits excrete about 50 per cent in the urine as colorless conjugate (G. H. Benham, 1945). Leukothionol is oxidized to thionol when exposed to sunlight under anaerobic conditions (De Eds, Wilson and Thomas, 1940).

Urinary Tract Infections.—Good results are reported with daily doses of 1.3 to 2 Gm. by mouth, the total course not to exceed 15 Gm., when it should be intermitted. The urine should be kept at *p*H 4.5 to 5.5 by ammonium chloride, With this dosage no untoward effects were observed; but long continuation of excessive doses may produce secondary *anemia,* apparently hemolytic, similarly to methylene blue (De Eds, Stockton and Thomas, 1939). It accelerates saponin hemolysis of horse erythrocytes *in vitro,* but does not produce photodynamic hemolysis (H. B. Collier and Allen, 1942).

TRIPHENYLAMINE (ROSANILINE) DYES

The basic dyes of this group, especially *gentian violet, crystal violet* and *methyl violet,* have a selective toxicity for gram-positive bacteria, especially staphylococcus, B. pyocyaneus and B. diphtheriae; and a much weaker action on the gram-negative species. They have a low toxicity for tissues, and penetrate them readily. The acid dyes (acid *fuchsin*) act selectively on gram-negative organisms.

Composition.—These dyes are derived from triphenyl methane, $H.C:(C_6H_5)_3$. *Pararosaniline* is triamine-triphenyl-carbinol, $(C_6H_4NH_2)_3COH$, and *rosaniline* is triamino-diphenyltolyl-carbinol, $(C_6H_4NH_2)_2(C_6H_3.CH_3.NH_2)COH$. *Fuchsine* (magenta, aniline red) is a mixture of rosaniline and pararosaniline chloride. *Basic fuchsine* is a corresponding acetate; and *Acid fuchsine* (ruby S) is the acid sodium salt of fuchsine disulfonic and trisulfonic acds. The introduction of methyl groups into para-, rosaniline-fuchsine results in a series of violet dyes grouped in the U.S.P. as *Methylrosaniline Chloride: gentian violet* is a mixture of penta- and hexa-methyl pararosaniline chloride; *methyl violet* consists mostly of the pentamethyl, and *crystal violet* of the hexa-derivative. Crystal violet is most readily obtained in pure form; but so far gentian violet has been most extensively used. In fact, many of the statements refer to dyes that had been diluted with indefinite quantities of dextrin. *Brilliant green* (malachite green) also belongs to the triphenylamine group.

Gentian Violet.—The selective action on *bacteria* was investigated especially by Churchman, 1914. Its relative harmlessness to tissues is illustrated by the observations of Russel, 1914, that tissue cultures are not injured by the concentrations which kill bacteria. The oral minimal fatal dose for rabbits is 22 mg. per Kg. daily for six days. Dogs are more tolerant (W. H. Wright and Brady, 1940).

Local Application.—Gentian violet is a rather good superficial antiseptic for wounds, burns, ulcers and inflamed mucous membranes. It is applied as $\frac{1}{10}$ to 1 per cent solution. The latter, used on burns as a spray or in tragacanth jelly, forms a tough, pliable film and eschar, which is less subject to infection than is the tannic acid eschar, though it has similar limitations (R. H. Aldrich, 1933; J. H. Cornell *et al.*, 1933; R. D. McClure, 1939). Devine, 1939, treats burns with a three-dye solution, 1 per cent of gentian violet and brilliant green, and 0.1 per cent of neutral acriflavine. This keeps indefinitely and is applied with a swab, without scrubbing or dressing. The staining is the chief objection.

Oral Use.—Gentian violet has been used in *colitis*, 0.065 Gm., 1 grain, three times daily, in capsules. It is an effective *anthelmintic*. For *oxyuris*, W. H. Wright and Brady, 1940, found it superior to all other treatments. The dosage for adults is two tablets of 30 mg., $\frac{1}{2}$ grain, three times daily, before meals. They may be enteric coated. Some patients react with nausea, vomiting and diarrhea, but these subside quickly if the dosage is reduced or temporarily discontinued. *Contraindications* are ascaris, and fairly severe cardiac, hepatic, renal or gastro-intestinal disease, and alcohol. Gentian violet is also effective against *Strongyloides stercoralis, Clonorchis sinensis* and other liver flukes. It is administered as enteric-coated tablets of 0.06 Gm., three times daily immediately after meals, for one or two weeks. It is usually well tolerated, but some patients have temporary intestinal discomfort and nausea (E. C. Faust, 1926, 1937).

Intravenous Injection.—Young and Hill, 1924, claimed good results in septicemia, in chronic cystitis and in osteomyelitis, when caused by staphylococcus. They inject 5 mg. per Kg. of the body weight, as 0.5 per cent dilution, repeated in five hours if necessary. The skin immediately takes a markedly blue tint from the dye, which disappears in a few hours. It has been shown on animals that the intravenous injection of gentian violet produces marked but brief fall of blood pressure, which may be preceded by a sharp rise. These effects occur also after pithing, so that they are peripheral (presumably of the allergic type). The respiration is not affected (Pindar and Donnelly, 1925).

Methylrosaniline Chloride, U.S.P. (*Gentian,* Methyl or Crystal Violet), is a mixture of hexa, penta and tetramethyl pararosaniline chlorides. It occurs as a dark green powder or pieces, with metallic luster. Soluble in 40 parts of water and in 10 parts of alcohol, insoluble in ether. Dose, 60 mg., $\frac{1}{2}$ grain, in enteric-coated tablets.

Brilliant Green (*Malachite Green*).—Leitch, 1917, claimed high antiseptic power and satisfactory results in wounds.

Acid Fuchsine.—Churchman found that this kills gram-negative organisms (Bacillus prodigiosus) in concentrations that had no effect on the gram-positive (B. anthracis); but this selective action occurred only at a temperature (50° C.) materially above that of the body.

Basic Fuchsine (Gruebler), pararosaniline acetate, was advised by May, 1912, and Donnelly, 1914, as a lotion or ointment (1 per cent) for ulcers and burns. It is antiseptic, nonirritant, nontoxic and seems to encourage epithelial growth and granulation. The color may be removed from the skin by alcohol.

AZO DYES

Azo- and diazo-compounds, derived from $C_6H_5.N=N.C_6H_5$ and $C_6H_5\text{—}\underset{\substack{|\\ Cl}}{N}\equiv N$, are important intermediates of many dyes and organic chemicals.

Congo red (diphenyl p-o-bis sodium azonaphthionate) is a colloidal dye with detoxicant actions, perhaps due to adsorption of the toxic substances. It also produces peculiar effects on blood coagulation and formation. Because of its slow diffusion, it may be used to estimate the blood plasma volume. Different samples vary materially in colloidal properties.

Toxicity and Systemic Effects.—With intravenous injection of 1 per cent solution of congo red 4 B (Coleman and Bell), dissolved in 5 per cent dextrose, which gives a more stable solution than sodium chloride, the LD_{60} for various mammals and for pigeons ranges from 150 to 250 mg. per Kg. The toxic symptoms consist in general depression and collapse; death occurs by circulatory collapse, the result of cardiac depression. Perfused hearts react with increased tonus and systolic arrest. Smooth muscle of the bladder, uterus and intestines is stimulated. Their reaction to autonomic drugs is not altered (A. P. Richardson and Dillon, 1939).

Detoxicant Actions.—Ishigami, 1928, found that congo red and other colloidal dyes which have practically no effect on gastrocnemius preparations when used alone, weaken materially the action of curare and guanidine, not that of nicotine, very slightly that of oxalate. They do not affect the actions of pilocarpine, epinephrine, cocaine and strophanthin on the excised frog heart or excised rabbit intestine. These results were confirmed and extended by Thienes, 1930: Injection of congo red into frogs several hours before or simultaneously with the poison antagonizes the "curare action" of curare, tetramethylammonium, sparteine and brucine, and the spinal convulsant actions of strychnine and brucine. The dye is generally ineffective if injected after the onset of the symptoms. It does not affect the action of atropine on the vagus. It also inhibits the convulsions of descending galvanic currents; but it has no effect on the narcosis of ascending galvanic currents, nor does it enhance the paralyzant action of other drugs, nor is it in itself paralyzant. Methylene blue and neutral red, on the other hand, are directly depressant (Köllensperger, 1938).

Brilliant vital red has been used as *anticonvulsant in epilepsy,* with variable success. A 1 per cent solution is injected intravenously, at first 10 to 15 cc., then 30 cc., daily, with omission every third or fourth day to avoid renal irritation (S. Cobb, Cohen and Ney, 1938; R. Osgood and Robinson, 1938).

Antihemolytic Action.—The addition of 0.1 per cent of congo red protects human corpuscles against hemolysis by hypotonic saline, hypertonic urea in saline, bile salts and saponin. This is attributed to the formation of a film of congo red on the cells. It increases hemolysis by hypotonic dextrose solutions, ether and urea in water (A. P. Richardson, 1939).

Blood coagulation is affected by several colloidal dyes, being generally hastened by small doses, and delayed by large doses. With intravenous injection of *congo red* (as 1 per cent solution) into rabbits, Taliaferro and Haag, 1937, found that 10 to 20 mg. per Kg. diminishes the coagulation time, while this is greatly increased by 200 mg. or more; the M.L.D. being 300 mg. per Kg. Coagulation is also delayed by adding it in the test tube. In dogs, 5 to 25 mg. per Kg. does not shorten the coagulation time, but rather delays clotting time (Richardson, 1939). In man, it is shortened by 10 to 15 cc. of 1 per cent, by vein. This dosage repeated daily as needed was recommended by Wedekind *et al.*, 1930, as clinically *hemostatic* in various persistent hemorrhages involving diminished blood coagulation. Acute traumatic hemorrhage is not affected, nor is oral or hypodermic administration effective. The mechanism of the hemostatic action is not understood; but it is accompanied by increase of fibrinogen, platelets and monocytes (Nikolajew and Gusewitch, 1935). Daily intraperitoneal injections for three to eight days raise the plasma prothrombin (W. A. Barnes, 1942). It does not occur in rabbits (Richardson, 1939). *Chlorazol Sky Blue* F F (Chicago Blue) prevents clotting by inhibiting the effect of calcium and thrombokinase on the fibrinogen-prothrombase complex (Huggett and Silman, 1932). *Chlorazol fast pink* B K S is injected in physiological experimentation to check blood coagulation (Modell, 1939). It is more effective than heparin (Huggett and Rowe, 1932).

Reticulocytes.—Intravenous injection of congo red into patients with pernicious anemia, or into guinea pigs, evokes a shower of reticulocytes. The effects of repeated injections may resemble those from liver extract, but they often fail. The clinical dosage is stated as 10 cc. of 1.5 per cent "congo red 4 B" in 6 per cent dextrose, daily for five to ten days (Mermod and Dock, 1935; Massa and Zolezzi, 1935).

Fate.—Congo red practically disappears from the blood within twenty-four hours after intravenous injection. It is distributed chiefly to the organs that contain large amounts of extracellular fluid. The kidneys retain a rather high concentration. The excretion occurs chiefly by the bile (Richardson, 1939).

Dye Method of Determining Plasma Volume.—The dyes that have been used for this purpose include congo red, vital red, trypan red, blue azo dyes and numerous others (Dawson, Evans and Whipple, 1920). "*Water blue,*" a nontoxic triphenylmethane dye, is especially slow to leave the blood stream (Hemingway *et al.*, 1935). The rate of disappearance of congo red from the blood is utilized diagnostically. It is slowed by impaired liver function (Ninomiya, 1928) and quickened in amyloid disease—the latter because congo red is selectively absorbed by amyloid (E. Wallace, 1932). *Evans blue* (Dye T-1824) is fatal to cats and dogs if 10 cc. per Kg. of 0.5 per cent solution are injected intravenously; delayed death may occur with 3 to 5 cc. (Hueper and Ichniowski, 1944).

Toluidine blue, alizarine blue S and indigo carmine increase the *oxygen uptake* by slices of rat kidney, and partially counteract cyanide (Axmacher, 1935).

Indigocarmine is used for coloring Mercuric Chloride Poison Tablets, and also as a kidney function test. It occurs as a blue powder or paste, sparingly sol. in water; insol. in alc. Dose, subcutaneous or intramuscular injection, 0.05 to 0.1 Gm., ¾ to 1½ grains; intravenous injection, 0.008 to 0.016 Gm., ⅛ to ¼ grain, B.P.

"Scarlet red" is a rather complex toluylnaphthol derivative with two azo links. It is used as 4 to 8 per cent ointment, to stimulate the growth of epithelium on clean granulating wounds, especially on burns and on clean ulcers (Schmieden, 1908; Morawitz, 1909). It may also be employed as solution in oil and as dusting powder (diluted with talcum). Its application should be confined to the areas of active epithelial proliferation. The 8 per cent ointment often produces irritation and even erosion and should therefore be alternated with a soothing ointment. Systemic effects (violent gastro-enteritis, Lyle, 1912) have been reported. Although scarlet red has been in use for many years, clinical opinions as to its value are still divided. It is conceded to be ineffective in chronic ulcers, if the local circulation is impaired. O. Sachs, 1911, claims that a number of other aniline dyes also stimulate epithelial growth, but the property is especially prominent in the compounds allied to amido-azo-benzene (Martinotti, 1914).

In *cancer,* the necrotic areas accumulate diazo dyes, but no therapeutic effects have been attained (R. Weil, 1916). The toxicity of diazo dyes was studied by Cecil and Weil, 1917.

Orthotoluene-azobetanaphthol is used as an oil-soluble dye for citrus fruit. Climenko, 1937, found 1 to 5 mg. in the peel of dyed fruit, none in the pulp or juice. Its toxicity for animals is low, acutely or chronic.

Pyridium, an azo dye (phenyl-2-6-diamino-pyridine monohydrochloride), was introduced as an oral urinary antiseptic (0.2 Gm. in capsules, three times daily), but it was found to be practically ineffective (Report, with bibliography, Council on Pharmacy and Chemistry, J.A.M.A., 1933, *101:* 2118). With clinical administration of 0.6 Gm. per day, an eighth to half is *excreted* by the urine, and this becomes somewhat bacteriostatic against Staphylococcus aureus and against coli (Goerner and Haley, 1932). Rapid intravenous injection of pyridium causes transitory fall of blood pressure. Massive oral doses form methemoglobin. Prolonged oral administration to dogs produces liver damage and erythropenia (Walton and Lawson, 1934).

BENZIDINE DYES

Trypan red and **trypan blue** are complex derivatives of benzidine (paradiamino diphenyl),

Ehrlich found that these have a high toxicity for trypanosomes. Repeated small injections of trypan blue into mice result in mitosis of the liver cells, with reduction of glycogen storage (H. W. Deane, 1944).

Suramin Sodium (*naphuride sodium Germanin,* "Bayer 205," moranyl, naganol, antrypol), the sodium salt of a complex aromatic aminosulfonic acid carbamide, was introduced as *trypanocide* in African "sleeping sickness" from T. gambiense infections. It is highly successful clinically, producing a temporary "clinical cure," even in advanced cases, but with later relapse. It is *excreted* very slowly and meanwhile gives protection against infection for several months, making it especially effective for prophylaxis. The slow excretion also tends to cumulative action, and its concentration in the blood and cerebrospinal fluid should be controlled by the Wormall test, as a routine of treatment (F. Hawkin, 1940).

It is also used in *pemphigus,* with varying results (Wells, Humphrey and Wells, 1937).

Its *toxicity* is relatively low, but it has a tendency to produce renal irritation, with casts and albuminuria, lasting some six weeks and generally disappearing spontaneously. Hemolysis, dermatitis and fever occur occasionally, agranulocytosis rarely. A few fatalities have been erported. Toxic doses of suramin sodium produce intense zonal degeneration of the adrenal cortex in guinea pigs, and there are indications that this may occur clinically (E. M. Humphreys and Donaldson, 1941). *In animals,* the most striking phenomenon is the duration of the effect: a single injection not only frees the blood from trypanosomes, but renders the animal resistant to infection for days to months, and during this period the serum is curative when injected into other animals. The substance itself, however, has little effect on the parasites *in vitro;* in animals, also, the action is delayed for several days; and the therapeutic response is greatly influenced by the species of the infected animal. It appears therefore that some complex cooperation of the host is involved in the production of the parasiticidal substance. This is not an ordinary immune substance, for this activity is not destroyed by heating. *Plasma globulin* and probably other proteins combine with germanin, perhaps by adsorption. This causes prolonged retention of the substance in the plasma and tissues (Boursnell and Wormall, 1939). The serum proteins undergo a marked change on the addition of germanin (2 per cent); they become incoagulable by tannic acid, metallic salts or heating to 60° C. (Kocian, 1936; references, Dale, 1923); and fail to provoke anaphylactic shock in sensitized animals (Makarowa and Zeiss, 1923), owing to denaturation (Steppuhn *et al.,* 1923) in which the sulfonic group is probably involved (Roehl, 1926). It tends to prevent flocculation of congo red, mastic and benzoin by electrocytes (O. Jirovec, 1943). It forms complex compounds with *calcium* and thereby decreases the calcium ion concentration in solution (Mulli *et al.,* 1933). This may be concerned in its inhibiting effect on blood coagulation.

Suramin Sodium, U.S.P., *naphuride sodium,* is a white, odorless, slightly bitter powder, readily soluble in water, forming a neutral solution. It is administered *intravenously* as a freshly prepared solution, made by sprinkling the powder on the surface of water, to prevent lumping. The initial *dose* for treatment of trypanosomes or pemphigus is 0.3 to 0.5 Gm. in 10 cc. of water, followed by 1 Gm. in 10 cc. every four days until 10 Gm. have been administered. Caution should be used if renal irritation develops. The course should not be repeated until four months have elapsed. The prophylactic dose for protection against trypansomiasis is 1 Gm. every two or three months.

Diamidino Stilbene is reported highly effective in Indian Kala Azar, with 98 per cent of immediate cures and few relapses. However, it is often followed by serious toxic reactions, paresthesia and partial anesthesia of the trigeminal area, with degenerative lesions in the principal sensory pontine nucleus of the trigeminal nerve, developing sometimes months after the administration (S. Gupta, 1943).

Pentamidine (4.4′-diamidino diphenoxypentane) is used against trypanosomes. A death has been reported, following three doses of 0.1 Gm. (McComas and Martin, 1944).

PHTHALEIN DYES

Phthalic anhydride furnishes two series of dyes of medical interest, (1) the phenolphthaleins and (2) the resorcinolphthaleins or fluoresceins.

Fluoresceins.—Sodium fluorescein (*uranin*) retains its color in extremely dilute solutions and has an intense fluorescence: this is true also of the tetrabromine compound, *eosin,* and of the tetraiodine compound, *erythrosin.* Fluorescein is used locally for revealing abrasions and foreign bodies on the cornea and conjunctiva; and by oral administration to test the permeability of the ocular vessels, in the diagnosis of intra-ocular inflammation; and as a renal function test. It is also used to tint solutions, for instance, of local anesthetics; and to trace water supplies. Its toxicity is low; but the fluorescence of eosin and erythrosin sensitizes to the longer light rays, which are irritant and destructive to protoplasm.

Eosin and Erythrosin.—Rost, 1915, found the oral administration of eosin harmless in man and animals. On intravenous injection, the toxic effects of eosin and erythrosin are much higher than those of fluorescein (Salant and Bengis, 1917). Hypersusceptibility to tetrabromfluorescein in lipsticks has resulted in contact dermatitis and gastro-intestinal irritation (R. Hecht *et al.*, 1939).

Diagnosis of Corneal Injury.—Two per cent of fluorescein is dissolved in water by the aid of 3 per cent of sodium bicarbonate. When dropped on the eye, this does not stain the tissue protected by living epithelium; but where this has been injured by abrasions or ulcers, the dye penetrates and produces a green stain. Foreign bodies appear surrounded by a green ring. Loss of substance in the conjunctiva leads to a yellow stain. These phenomena were discovered by Ehrlich, 1882, and introduced into practice.

Diagnosis of Intra-Ocular Inflammation.—When fluorescein is administered by mouth, the whole body takes on a jaundice color, which appears in twenty-four hours. Here also the normal eye is not colored, the dye being retained in the posterior chamber; but in the presence of intra-ocular disease, glaucoma, iritis, and the like, the aqueous humor is colored bright green in about twenty minutes, thus differentiating these diseases from conjunctivitis, in which there is no coloration. The dose by mouth for adults is 3 to 6 Gm.; for children, 1.5 to 2 Gm., in water. This presents no danger (Hamburger, 1909).

Renal Function Test.—This was described by Strauss, 1913. Fluorescein sodium, 1 Gm. in a cup of tea, is given on an empty stomach. Normally, it appears in the urine (best seen when alkaline) in ten to twenty minutes, and lasts thirty-five to forty hours. In renal disease, it appears later and lasts longer. The skin may be stained slightly yellow, but there are no other side effects.

Diagnosis of peripheral vascular disorders is facilitated by long wave ultraviolet illumination after intravenous injection of fluorescein sodium (K. Lange and Boyd, 1944).

Leprosy.—Ryrie, 1936, reported marked improvement with phthalic acid and fluorescein but frequent relapes.

Fluorescein Sodium, U.S.P. (Fluorescein Soluble, Resorcinolphthalein Sodium), is freely sol. in water and in alc. It has strong fluorescence even in extreme solution, but it disappears on acidulation.

Fluorescent Substances and Light.—V. Tappeiner and Rabb (1903) showed that fluorescent substances are destructive to all forms of life and to ferments and toxins, but that the effects appear only in the presence of the specific light rays which induce the fluorescence (review, Tappeiner, 1909; Iodlbauer and Haffner, 1921).

Clinical Manifestations.—Rats or guinea pigs can be photosensitized by intraperitoneal injection of 1 mg. of eosin, or by feeding ripe buckwheat, or an alcoholic extract of the hull, or by the injection of hematoporphyrin, and by other fluorescent substances. Exposure to sunlight causes erythema, pruritus, lacrimation, edema of the face, opacity and ulceration of the cornea, and nervous disturbances (F. P. Mathews, 1938).

Smooth Muscle.—All forms are stimulated by ultraviolet light directly and by strong daylight after sensitization with fluorescent substances (for instance, an hour after the intravenous injection of 6 cc. of 10 per cent eosin into a rabbit). The action appears to be directly on the contractile mechanism. Excessive ultraviolet irradiation injures excised intestinal muscle (Adler, 1920).

If the excised stomach of a frog is treated with a dilute solution of eosin, it goes into tonus when exposed to light, and relaxes in the dark; mammalian intestine is permanently paralyzed (Kolm and Pick, 1920).

Isolated Heart.—When this is sensitized by small doses of eosin or benzoflavin, its tonus is increased by exposure to light, and relaxed by darkness. Larger doses of the sensitizants, or prolonged exposure to light, also depress (Viale, 1923).

Plants.—Eosin and erythrosin are toxic in the light, not in the dark (Shanz, 1923).

Phenolphthalein is discussed under the Cathartics. *Phenolsulfonphthalein,* which is used as a test of renal function, is formed by substituting SO_2 for the CO in phenolphthalein. Delayed and diminished excretion indicates the existence and degree of renal impairment (Abel and Rowntree, 1909; Rowntree and Geraghty, 1910; Chesney, Marshall and Rowntree, 1914). In *Phenoltetrachlorphthalein,* used as a test for hepatic function, the four H atoms in the phthalic ring have been replaced by Cl. These dyes are injected intramuscularly, and their concentration in the excretions is measured colorimetrically, after the addition of alkali which produces a molecular rearrangement that results in the red color. In *Tetrabromphenolphthalein,* two Br atoms are introduced into each phenol ring (not into the phthalic ring, as with the tetrachlor compounds.) The bromine atoms render this compound opaque to roentgen rays; and as it is excreted in the bile, it is used to outline the gallbladder. Details of these tests may be found in N.N.R.

Phenolsulfonphthalein.—In dogs, Arbuthnot *et al.*, 1917, found that with intramuscular injection the urinary excretion varies greatly according to the rate of absorption. With intravenous injection, about 80 per cent is excreted in an hour, regardless of the amount injected (between 3 and 30 mg.). The amount excreted is practically independent of the quantity of urine (beyond a certain minimum). A considerable part is temporarily stored in the tissues before it goes into the urine (Bernheim, 1926). Some is excreted by the bile, and some is lost by reduction, so that the recovery is not quantitative (Kendall, 1917). Suppression of the biliary output by *hepatic injury* increases the total urinary output. *Subdural injections* are normally followed by the appearance of the drug in the urine within ten minutes, but it may be considerably delayed in diseases of the central nervous system, especially when the meninges are involved (Mehrtens and West, 1917) *Other compounds related to phenolsulfonphthalein* are also excreted by the kidneys. These may be somewhat antiseptic (E. J. Davis, 1918).

Phenolsulfonphthalein, U.S.P. (Phenol Red), is slightly sol. in water (1:1300), readily soluble in dilute alkalis. Dose, by intravenous or intramuscular injection, 6 mg., $\frac{1}{10}$ grain. *Phenolsulfonphthalein Injection,* U.S.P., in alkalinized sodium chloride solution; usual size, 6 mg. in 1 cc.

Phenoltetrachlorphthalein Test of Hepatic Function.—The disodium salt is injected intravenously (not intramuscularly or subcutaneously), 5 mg. per Kg., as 2 per cent solution (marketed as ampuls), and its excretion determined either by the quantity in the stools (Rowntree, Hurwitz and Bloomfield, 1913) or by the duodenal tube (Aaron, Beck and Schneider, 1921), or its disappearance from the blood stream (S. M. Rosenthal, 1922). The effect of shock conditions and anaphylactoid drugs on the rates of disappearance of dyes was studied by Hanzlik and De Eds, 1926.

The **tetrabromine** and **tetraiodine** derivatives are discussed under bromine and iodine compounds (see Index).

Dibutylphthalate is used as a plasticizer for cellulose nitrate and acetate lacquers. No toxic effects, external or internal, have been reported, and it is probably harmless. It does not volatilize readily (J.A.M.A., 1934, *103:* 860). **Diallyl phthalate,** used in the manufacture of plastics, produces some local irritation in the workers, and enough may be absorbed from the skin to cause toxic effects (W. A. McOmie, 1946).

Cumarin is directly depressant to the smooth muscle of rabbit uterus and intestine, and to frog heart (Bergstrom, 1928).

ACRIDINE DYES (FLAVINES)

derivative of the coal tar base acridine was introduced by Ehrlich, 1912, as a trypanocide under the name of "trypaflavine." This is now generally called acriflavine and is used as a local and urinary antiseptic, as are also its neutral base and the closely related proflavine.

Acriflavine is diaminomethylacridine chloride hydrochloride; *proflavine* is diaminoacridine sulfate. It differs by the absence of the methyl group. It also is used as *proflavine base.*

Many other acridine dyes have been studied, but are not bactericidal. The preparation and properties of acri- and proflavine were described by Benda, 1912. *Atabrine* is an effective antimalarial agent (see Index); it is an acridine derivative. The *literature,* to 1919, was reviewed by the Council on Pharmacy and Chemistry, J.A.M.A., 1919, *73:* 1542.

Clinical Uses.—*Acriflavine* and *proflavine* are actively antiseptic even in the presence of wound secretions. They are not very toxic to phagocytes and epithelium and therefore interfere relatively little with wound repair (Browning *et al.,* 1919). They are used to check surface infection of wounds and mucous membranes, especially when sulfonamides are contraindicated. Acriflavine is more antiseptic and more toxic than proflavine, but acts more slowly. Neutral acriflavine may be preferred on sensitive mucous membranes where the acidity of the others is objectionable. The flavines seem to have a distinct field for temporarily checking bacterial growth while a wound is awaiting operation; as in transportation with war wounds or in the interval of two stage operations. The best results are obtained by dusting proflavine directly on the wound, and so minimizing its inactivation by absorption into the dressings (G. A. G. Mitchell and Buttle, 1942).

Toxicity.—Tubby *et al.,* 1919, found that rapid intravenous injections kill cats by paralysis of respiration. For rabbits, 10 to 20 mg. of acridine by vein are nonfatal; proflavine is half as toxic. Injurious effects have been reported from industrial exposure to the solid or vapor of acridine, especially violent irritation, burning and itching and sometimes inflammatory swelling of the skin and mucous membranes. It has been regarded as the irritating principle in tar, creosote and pitch that sensitizes the skin to sunlight. The *erythrocytes* show peculiar effects. Proflavine changes their shape to rods in dogs, but not in humans or rabbits. Proflavine and 9-amino acridine powerfully accelerate saponin hemolysis and inhibit lyso-lecithin laking (H. B. Collier, 1945).

Intravenous injection of 2 mg. per Kg. in cats increases the movements of the *uterus* by a direct action on the muscle, enjoining caution against such injections in pregnancy (Sapeika, 1934).

Reinhardt, 1922, claims that *diphtheria toxin* is destroyed by acriflavine, 1:100.

Stains may be removed from the *skin* by soap and water, followed if necessary by 3 per cent HCl in 95 per cent alcohol; or hydrogen peroxide may be added to the soap solution. Linen may be boiled for several hours in a 3.5 per cent solution of sodium perborate.

PREPARATIONS.—*Acriflavine* occurs as a reddish-brown, odorless powder of bitter taste, forming fluorescent solutions in water. These are not injured by boiling, but are sensitive to light. One per cent solutions may be stored in amber bottles for a week. Dilute solutions must be freshly prepared. The flavines are also soluble in alcohol, but insoluble in fat solvents. *Acriflavine Hydrochloride* is freely sol. in water (1:3), insol. in oils.

◆

MISCELLANEOUS ANTISEPTICS

FORMALDEHYDE

Aldehydes react chemically with a large variety of organic substances, among others with proteins. This probably explains their actions (Liebreich, 1893). Formaldehyde, HCHO, especially is strongly germicidal and is largely used as disinfectant. It hardens the tissues on local contact and thereby produces irritation, especially of mucous membranes. Its systemic toxicity is relatively low. Formaldehyde is a colorless, irritant gas, prepared by the oxidation of methyl alcohol. It is freely soluble in water, and is official in the form of a 40 per cent solution, popularly called *Formalin.* (In making solutions of a given strength, it is necessary to take two and one-half times as much of the commercial solution as would be required of absolute formaldehyde.) The gas may be liberated from this solution by various means, but heating is not economical, as it polymerizes a large part of the formaldehyde into the insoluble and inactive *trioxymethylene* or *paraform* $(HCHO)_3$. The change also occurs somewhat on standing, but this may be prevented by chemic means (calcium salts, methyl alcohol). Trioxymethylene again yields formaldehyde by dry heat. Formaldehyde is converted into *methenamine* (hexamethylene tetramine) by ammonia.

Historical.—Formaldehyde was discovered by Hoffmann, 1867; its antiseptic action by Loew and Fischer, 1886. Aranson, 1894, showed that it also destroys toxins.

Fate.—Formaldehyde is absorbed from all parts of the alimentary tract and lungs (McGuigan, 1914). It is not excreted as such (Blum; Pohl, 1893), even with intravenous injection, unless very large doses are given (McGuigan, 1912; Impens and Rosenberg; Salkowski, 1915). It is mainly oxidized in the tissues, especially the liver (Pohl), to formic acid. The oxidation of aldehydes is not direct, but through the "Cannizzaro reaction," commonly observed *in vitro* when aldehydes are treated with alkalis, $2HCHO + H_2O = CH_3OH + HCOOH$. A part of the formic acid may appear in the urine (Pohl; Klueber and Gerlasch), but small quantities of formic acid are also completely destroyed (Sollmann, 1908). Some of the formaldehyde may be transformed into methenamine (McGuigan).

Reaction of Formaldehyde with Proteins.—Formaldehyde enters into peculiar compounds, which are precipitated under suitable conditions, from which the formaldehyde and the original proteins may be completely regenerated under other conditions. The protein is rendered more acid by binding the free amino groups. With albumoses (Sollmann, 1902) and presumably with other proteins the compound contains definite proportions of formaldehyde, albumose and alkali. It is precipitated in weakly alkaline solutions, dissolved without decomposition by stronger alkalis, and is decomposed, or its formation prevented, by weak acids and by excess of neutral salts. Even under favorable conditions the combination is completed slowly (Schryver, 1911). The precipitate contains a further quantity of formaldehyde mechanically. Formaldehyde retards or *prevents the coagulation and spontaneous laking of shed blood*, when added in the proportion of 1:200 to 400. *Uric acid and urates* are dissolved, or their precipitation is prevented, by the formation of soluble compounds. *Urea*, on the other hand, forms an insoluble compound with formaldehyde. The *digestibility* of fibrin and the coagulability of casein are diminished. Formaldehyde lessens the activity of certain *ferments*, papain, trypsin, ptyalin and amylopsin; while pepsin, rennin and malt diastase are but little altered.

Antiseptic Action.—Formaldehyde is a potent disinfectant, of relatively high penetrating power, harmless to metals, fabrics and colors and of relatively low toxicity. On account of its irritant effects, its use on the body is generally inadvisable. It is employed particularly for the disinfection of rooms and excreta.

Antiseptic Efficiency.—Formaldehyde is much more effective as a bacteriostatic agent than as a germicide. Its activity varies for different organisms. Typhoid bacilli, with exposure of twenty-four hours, are killed by 1:6000 (Hyman, 1914); all the concentrations refer to absolute HCHO. Solutions of ½ to 2½ per cent destroy all bacteria, spores and toxins, in six to twenty-four hours. The gas is similarly antiseptic, especially when it is moist. The activity is increased by acids, presumably by preventing combination with the proteins of the medium (Hinman, 1913). The germicidal efficiency against *spirochetes* is low (Akatsu, 1917).

Practical Application.—*Feces* are mixed with 10 per cent of the commercial solution. This destroys the odor almost immediately, but to insure complete disinfection, they should be left in contact for an hour. *Tuberculous sputum* should be disinfected with 5 per cent of the commercial solution for an hour. *Instruments* and other articles may be placed in 1½ to 5 per cent solutions of formalin.

Fumigation of Rooms.—No method of fumigation is absolutely reliable. Moist formaldehyde vapor is the most efficient fumigant against bacterial diseases, but has little penetrative power. It does not destroy mosquitoes or other insects, and is therefore inferior to sulfur dioxide against malaria or yellow fever (McClintock *et al.*, 1911). Formaldehyde vapor is usually generated by the heat evolved by the interaction of formaldehyde solution with permanganate or cheaper oxidizing agents.

It may also be formed by special apparatus involving the incomplete combustion of methyl alcohol or the vaporization of trioxymethylene. Simple spraying with formaldehyde solution (8 cc. per cubic meter) is also used. Evaporation of formaldehyde solution by heat is wasteful, but may be employed (150 cc. for 1000 cubic feet).

Permanganate oxidation (Evans and Russel, 1915): For a room of 2000 cubic feet, 2 pounds of potassium permanganate are placed in a 3 gallon pail which is set in a large tin can containing water. When everything is ready, 2 quarts of 40 per cent formaldehyde are poured on the permanganate, the room is vacated immediately and left closed for at least twelve hours, then thoroughly aired (Hoxie). With this and the following methods, about 40 to 80 per cent of the formaldehyde is effectively volatilized (Base, 1916; Hamilton, 1917; Storm, 1918). *Chromate method* (S. G. Dixon, 1914): A solution of 1½ fluidounces of concentrated sulfuric acid and 1 pint of U.S.P. Formaldehyde Sol. is prepared in advance. When needed, it is poured on 10 ounces of sod. dichromate crystals, which have been spread in a thin layer in a vessel ten times the capacity of the ingredients. The gas is liberated more rapidly than with permanganate; the operator must therefore withdraw promptly.

Houseflies are both attracted and killed by exposing a 1:20 dilution in saucers. They develop paralysis of the nervous system, progressing forward from the hind end of the abdomen (W. A. Hiestand, 1932).

Application to the body is not recommended because of the local irritant action. It has been employed, however, for the *disinfection of hands* (1 per cent): as a *mouth wash* and *gargle* (½ per cent); in *skin diseases* and *hyperi-*

drosis (2.5 per cent); for painting the throat in *diphtheria* or *tonsillitis* (2½ to 5 per cent). The *evaporation* of a small amount of the solution in the room has also been used in *tuberculosis*. McGuire, 1900, suggested intravenous injections of 1:20,000. They were quickly abandoned.

Formaldehyde as Food Preservative.—Concentrations of 1:33,000 to 1:20,000 have been used, especially for milk. It is both ineffective and dangerous, and is therefore properly prohibited. The ordinary concentration for milk (1:10,000) checks lactic fermentation, but does not kill the tubercle bacilli and is therefore of questionable utility. It may produce intestinal ulcers (Schaps, 1905). It probably causes cumulative effects. Even surface application is said to lead to inflammatory changes in the liver and kidneys (Fischer, 1905). Salkowski, 1915, reported that formaldehyde, 0.6 to 1 Gm. per day, added to the food of a 12 Kg. dog, was well tolerated and did not impair the utilization of protein.

Local Actions.—Formaldehyde solutions or vapor, even when very dilute, produce strong irritation of all *mucous membranes*. The susceptibility to this irritation is diminished by *habituation*. Applied to the unbroken *skin*, it hardens the epidermis, renders it rough and whitish, and produces anesthesia. Repeated application of strong solution leads to superficial *necrosis* of the skin and nails and to persistent eczema (Galewsky, 1905). Its application to broken surfaces is painful. Isolated tissues are promptly hardened. Formaldehyde is therefore used in *histologic technic* in strengths of ½ to 10 per cent. These effects are produced by the *coagulation of proteins*. They are influenced by the concentration and by the time of contact (Meneguzzi, 1913).

Urticaria.—The endermic application of formaldehyde (2 per cent) produces wheals (Sollmann, 1917). General urticaria is also sometimes seen from the systemic use of formaldehyde, in mouth-wash (Heidingsfeld, 1916) or formamint tablets (Glaser-Lipehne). Urticaria is also produced by all other nonconjugated aliphatic aldehydes, but not by conjugated or aromatic aldehydes (B. Z. Rappaport and Hoffman, 1941).

Use against Hyperidrosis.—A 20 to 30 per cent dilution of the official solution relieves excessive perspiration of the feet (Althof, 1914) or axillae. The effect is said to persist for four to six weeks after painting the area daily for three successive days; the treatment may then be repeated. If used too long, however, it tends to cause eczema. The result may also be secured by repeated anodal cataphoresis of 5 per cent formaldehyde (E. A. Pinson, 1942).

Secretin Formation.—When formaldehyde is applied directly to the mucosa of the upper intestine (not the lower), the irritation increases the flow of pancreatic juice. The most favorable concentration is 1 to 2 per cent, 8 to 10 per cent being ineffective (Delezenne and Pozerski, 1915).

Red corpuscles are fixed by dilute solutions similarly to other tissues; strong solutions of commercial (not of pure) formaldehyde may produce laking, by their formic acid (Franchi, 1913).

Spermatozoa are promptly killed by formaldehyde, 1:25,000 (J. R. Baker, 1931).

Poisoning by Swallowing Formaldehyde.—The symptoms are immediate and severe abdominal pains; often sudden and prolonged loss of consciousness and collapse. Death occurs in twenty-four to forty-eight hours. The autopsy shows severe gastritis with erosions. In nonfatal cases, the urine is suppressed for twelve to twenty-four hours, and then generally contains blood and casts. There is often diarrhea and tenesmus, sore mouth and dysphagia (MacLachlan, 1909). The recovery is curiously rapid, the patients being well within a week. The prognosis is generally favorable. Few fatilities are found in recent bibliographies (review, U. S. Public Health Reports, 1945, Suppl. 181). The fatal cases all took over 3 ounces of the commercial solution. The largest quantity from which recovery is reported is 60 cc. The *treatment* should consist in dilution and evacuation, preferably by lavage, and the administration of ammonium chloride solution, together with sodium bicarbonate or sodium phosphate as alkaline buffer. *Inhalation of formaldehyde vapor* may cause bronchitis and pneumonia, but even prolonged inhalation has little systemic action.

Intravenous injection of solutions in normal saline of a strength of 1:5000 generally produces no immediate effects, even in man, but there may be rather mild colloidoclastic reactions, which have been used against bacteremias.

Neuromuscular and autonomic reactions are modified by formaldehyde. *Striated muscle* responds to stimulation with a prolonged veratrine-like contracture, but with the action-potential persisting throughout (G. H. Bishop and Kendall, 1929). The modifications of *smo th muscle* responses were studied by Thienes. The contractibility of *heart muscle*, in frogs, is lowered by formaldehyde and acetaldehyde. The irritability is not changed (Sasaki, 1921). The antagonism to the cardiac toxicity of *nicotine* is described under methenamine.

PREPARATIONS.—***Formaldehyde Solution,** U.S.P. (Liquor Formaldehydi; Formalin); a clear, colorless, watery solution of pungent odor and caustic taste, containing not less than 37 per cent of HCOH, and some methanol to prevent polymerization. Miscible with water and alcohol. A tablespoon in a quart of water makes about 1 per cent of absolute formaldehyde. *Paraformaldehyde* (Paraform, Trioxymethylene), $(HCOH)_3$, occurs as white friable masses, or as a powder, having a slight odor of formaldehyde. Slowly sol. in cold water; insol. in alc. or ether. Dose, 0.5 Gm., 8 grains. It sublimes slowly at

100° C. and melts at 171° C. Heated under proper conditions, it is decomposed into formaldehyde and is used for the *disinfection of rooms*. Two Gm. of paraform are required per cubic meter (35 cubic feet of space). Formaldehyde is also slowly liberated at body temperature: paraform has therefore been suggested as an *intestinal antiseptic* (0.05 to 0.1 Gm. every two hours, for children), but its irritant action renders it objectionable. Larger doses (3 to 4 Gm.) are *cathartic*, small doses are rather constipating. It will not cause serious poisoning even in large doses.

FORMALDEHYDE COMPOUNDS

These are generally inactive and nonirritant in themselves, but regenerate formaldehyde under suitable conditions. It was therefore thought that they would prove valuable antiseptics. Most of them, however, liberate it either too slowly or too readily. Methenamine alone has proved really valuable.

Glutol (Schleich, 1896) is an insoluble compound of formaldehyde and gelatin, which holds the greater part of the formaldehyde so firmly that it is practically useless (Sollmann, 1908). *Other protein compounds* were also disappointing. Classen introduced compounds with *carbohydrates:* starch (amyloform), dextrin, milk-sugar, and so forth. Their fate was studied by Jacobson, 1906. There were also combinations with phenols, urea (Cohn, 1897), and others. Anhydromethylenecitrate (*citarin*) splits off CH_2O too readily (Nicolaier, 1906); methylenedisalicylic acid is not decomposed in its passage through the body (Sollmann, 1908).

METHENAMINE

Methenamine (hexamethylene-tetramine, $N_4(CH_2)_6$) is formed by the action of ammonia on formaldehyde. It is itself devoid of antiseptic, irritant or toxic actions. Its solutions, however, dissociate slowly with the evolution of formaldehyde, according to the reversible reaction $N_4(CH_2)_6 + 6H_2O \rightleftarrows 4NH_3 + 6HCHO$. This decomposition is favored by the presence of free acid; it becomes practically negligible at neutral reaction and is arrested by relatively mild alkalinity (Hanzlik and Collins, 1913; De Eds, 1924). From one-sixth to one-third of the methenamine is decomposed by the acid reactions of the digestive tract, especially of the stomach. The absorption of the remainder starts promptly, and the methenamine is distributed rapidly through the tissues and secretions, and excreted unchanged mainly in the urine. The acid reaction of the urine sets free a small quantity of formaldehyde, sufficient to be more or less antiseptic, so that methenamine is used in the prophylaxis and treatment of urinary infections (introduced by Nicolaier, 1895, 1899), especially in Escherichia coli infections that resist mandelic acid, sulfonamides and penicillin. It is useless if the urine is alkaline. Occasionally, especially in susceptible individuals, it may produce irritation of the bladder and hematuria. This is minimized by liberal dilution. Even larger doses do not cause systemic poisoning. Insignificant traces of formaldehyde are liberated in the blood and tissues; even under optimal conditions the concentration would remain far below the antiseptic level. Before this limitation was realized, methanemine was tried against infections of the bile passages, meninges, respiratory tract, accessory sinuses, and other parts. The liberated formaldehyde is oxidized to formic acid.

Time of Excretion and Distribution.—Methenamine appears in the urine within eleven minutes after oral, rectal or hypodermic administration, reaches its maximum in one to three hours, and practically ceases in four to eight hours, according to the dose. After twelve hours only small amounts are excreted, although the blood may contain faint traces after twenty-four hours (Sollmann, 1908; Crowe, 1908; Burnham, 1912; Falk and Sugiura, 1916). Approximately the same time relations obtain for its concentration and disappearance from the other secretions and tissues. Its distribution is universal, since it has been demonstrated in all parts of the body in which it was sought.

Quantitative Excretion.—With doses of 1 to 5 Gm., from 32 to 85 per cent of the methenamine is excreted by the urine. The percentage is independent of the dose (within these limits), of diuresis and of clinical conditions. It is determined mainly by the reaction that the methenamine encounters in the digestive tract, and the excretion can therefore generally be increased by the administration of alkali (De Eds, 1924). *The concentration of methenamine* depends on the dose, the time, and in urine largely on the ingestion of fluid. With continued administration three times daily, the concentration in the urine ranged from 1:1400 to 2800 for doses of 0.67 Gm.; from 1:24,00 to 14,000 for 0.33 Gm. (Falk and Sugiura, 1916). In other secretions and in the tissues the concentration is probably lower.

Excretion in Eye.—Gradle, 1911, found methenamine in the anterior chamber, its excretion being hastened by mydriatics; its concentration, however, is not sufficient to be antiseptic. In cats, Remelé, 1916, found it in the aqueous humor shortly after the intravenous injection of 2 Gm. *Excretion in milk* was announced by Bucura, 1905, and confirmed by Crowe, 1908; Woldewijn, 1910; and by J. Schmid and Schroeter, 1910. Reider, 1912, found that the highest concentration was reached after an hour. *Excretion in saliva* reaches its maximum in half an hour (Hanzlik).

Presence of Free Formaldehyde in the Urine.—The amount of formaldehyde liberated depends upon the acidity, the concentration, the time of standing and perhaps on other, unknown conditions. The liberation may occur in the kidney (Burnham) and increases in the bladder (Hinman, 1913). G. G. Smith, 1913, found that

0.5 Gm. always gave formaldehyde in acid urines, while 0.3 Gm. was inconstant. The *concentration of formaldehyde in urine* was estimated by Hinman, 1913, as below 1:40,000 in half the cases; 1:16,000 in 25 per cent; and over 1:7000 in 2 per cent of the urines. Alkaline urines do not liberate formaldehyde; but the formaldehyde liberated in the acid kidney may persist for a short time in the alkaline bladder. Kidney disease does not modify the liberation (Hinman).

Antiseptic Action.—*Methenamine itself is not antiseptic*, if the liberation of formaldehyde is prevented by alkalis (Hanzlik, 1913). A concentration of 5 per cent is required to check the growth of staphylococcus in neutral broth cultures; this may be attributed to the free formaldehyde (Jordan, 1911). The antiseptic action is always parallel to the concentration of free formaldehyde (Hanzlik and Collins). Formaldehyde in concentration of 1:50,000 to 30,000 has a distinct though limited antiseptic effect (Mossa and Paleotti).

Antiseptic effects after administration are especially marked in acid urines. Crowe, 1908, claimed that the administration of 5 Gm. per day renders the bile and other body fluids antiseptic, but exact observations have not confirmed this (Hanzlik and Collins), and the idea of producing "tissue antisepsis" by its use must be abandoned.

Therapeutic Use as Urinary Antiseptic.—Methenamine is one of the most potent urinary antiseptics, provided that the reaction of the urine is acid. It is highly effective against coli or staphylococci introduced into the bladder (E. Davis and Sharpe, 1932); although mandelic acid, sulfanilamide and acriflavine are often more successful against active bladder infections. In neutral or alkaline urine, its efficiency is practically nil (Jordan, 1911). In ammoniacal urines it would be useless. It would be especially valuable as a prophylactic, *f. i.*, in catheterization (Hinman, 1915). It was advised to prevent the spread of typhoid bacilli (Richardson, 1898), but its efficiency is doubtful. It may be used in inflammation or suppuration of the renal pelvis, bladder or urethra. The dosage should be from 0.25 to 0.5 Gm. (4 to 8 grains) in half a glass of water, four or five times a day. If the urine is alkaline, acid sodium phosphate (NaH_2PO_4) should be administered, 1 to 2 Gm. every one to four hours, as a separate prescription, midway between the methenamine administrations, until the urine is acid. This may cause moderate diarrhea.

Incompatibilities.—Methenamine is a fairly strong base, gradually displacing ammonia from its salts. It is decomposed by acids (even acetylsalicylic acid) and by acid salts with the liberation of the irritant formaldehyde. It is also incompatible with tannin, mercuric chloride and oxidizing agents (J.A.M.A., Feb. 8, 1913, p. 465).

Methenamine salts have no great advantage. Boruttau, 1914, claimed that the urinary antiseptic action is somewhat greater with salicylate or camphorate. Jacobs and Heidelberger, 1915, reported experiments with some quaternary derivatives that appear promising. The activity of these does not seem to depend on the liberation of formaldehyde, so that they are not inhibited by protein and do not require acid.

Solvent Action on Uric Acid.—Methenamine was proposed as a remedy for gout and urate calculism. It, as well as formaldehyde, dissolves uric acid, with the formation of a series of paired compounds (Nicolaier, 1906). The solvent action is really slight, however (Stevens and May, 1911), and the experimental and clinical results have been disappointing (Hanzlik, 1916).

Administration for Systemic Disinfection.—Large doses, 5 to 20 Gm. per day, were formerly administered against infections of the biliary and respiratory tracts, meninges, and so on, but critical observations do not show any antiseptic action (biliary tract, Burnham; infantile paralysis, Frazer, 1914; empyema, Shattuck, 1911). The most delicate tests have failed to detect formaldehyde in any of the tissues and secretions, other than the gastric juice and urine: negative results were reported for the milk, Schmid and Schroeter; saliva, Hanzlik; bile, cerebrospinal fluid and sputum, Burnham, 1912; various situations, McGuigan, 1912; blood and cerebrospinal fluid, Voit, 1923; blood, De Eds, 1924. Liberation under certain conditions in the aqueous humor and cerebrospinal fluid of rabbits was claimed by Sherif, 1930. The small excretion of formate is an index to the small quantity of formaldehyde liberated (De Eds, 1924).

Hematuria.—Methenamine itself is nonirritant, so that it may be given hypodermically (Gundrum, 1911) or injected into the bladder in 50 per cent solution (Burnham). After the liberation of formaldehyde, this becomes irritant, but only in specially susceptible individuals or with large doses. This results in painful micturition and eventually cystitis and hematuria. The kidneys may probably also be irritated. The cystoscope shows hemorrhagic cystitis, and postmortem examination, hyperemia of the pelvis (D. L. Simon, 1914). The hematuria has been used by malingerers (Marie and Behague, 1920). These irritant effects are exceptional if the drug is given in sufficient dilution. They disappear promptly and without any permanent damage, if it is discontinued.

I. A. Abt, 1917, believed that its use caused severe and fatal nephritis; this requires confirmation. In dogs, Wiggs, 1910, obtained marked nephritis from relatively small doses. In guinea pigs, hypodermic injections (Frothingham, 1910) produce local necrosis and gastric congestion, hemorrhage and ulceration.

Other Undesirable Actions.—Rubeolar skin rashes, catarrhs of various mucosae, and digestive disturbances have been reported (Coleman, 1903), but they are rare. Urticaria is probably fairly common. Methenamine was the most common cause of *dermatitis* in the rubber industry before 1926, so that this use has been largely discontinued (*cf.* L. Schwartz, 1934, who also discusses the other chemical dermatitis of rubber manufacture).

Intravenous injection does not seem justified in view of the rapid absorption of methenamine, but it has been used (1.5 to 2 Gm. as 25 per cent solution; Loeper and Grosdidier, 1918). Large doses may be injected without direct toxicity (Crowe, 1908; Burnham, 1913); occasional anaphylactoid reactions may be expected.

Antagonism to Nicotine.—Intravenous injection of formaldehyde (20 mg. per Kg., dogs) or methenamine, or most effectively *methenamine iodomethylate* (150 mg. per Kg.), almost immediately suppresses the auricular fibrillation and auriculoventricular dissociation of nicotine (0.1 mg. per Kg.). It also prevents the hypertension and the stimulation of isolated intestine. The action is rather special; it is much more effective than quinidine, but does not apply to other fibrillating poisons (Gautrelet, Halpern and Corteggiani, 1932). It produces some curare action (Gautrelet and Halpern, 1934).

PREPARATION.—***Methenamine,** U.S.P. (Hexamine, Hexamethylenamine, Hexamethylenetetramine), was introduced as *urotropin* and is also marketed under numerous other and confusing trade names. These commercial brands are in no way superior to the official substance (Base, 1907). It occurs as colorless, lustrous, odorless crystals, of sweet, then bitter taste. Solutions react alkaline to litmus. It is freely sol. in water (1:1.5) and alc. (1:12.5). Dose, 0.3 to 1 Gm., 5 to 15 grains. *Methenamine Tablets*, U.S.P.; usually available as 0.3 and 0.5 Gm.

Sodium formaldehyde sulfoxylate, $CH_2OHSO_2Na.2H_2O$, is a very active reducing agent, of low toxicity even with intravenous injection. S. M. Rosenthal, 1934, found it an effective antidote in *mercurial poisoning* (see Index), by reducing the mercuric to the less toxic mercurous salts.

Rosenthal, 1938, also found it effective against one strain of *pneumococci* in mice, but ineffective against other strains. This inefficiency was confirmed by H. H. Powell and Jamieson, 1935. On intravenous injection, it disappears rapidly from the blood; half to two-thirds is *excreted* unchanged by the urine, regardless of dosage, the greater part in two or three hours. *Oral administration* does not give effective blood concentrations (E. Hug, 1936). It is freely soluble in water, decomposed by dilute acids.

Nail polish dermatitis is generally caused by hypersusceptibility to *toluene sulfonamide formaldehyde* and related synthetic resins (Keil and Van Dyck, 1944).

Other Aldehydes.—All aldehydes are irritant. Acetaldehyde and paraldehyde are somewhat antiseptic, but more markedly narcotic. This narcotic action is especially prominent in trichloraldehyde (chloral).

Acroleine.—CH_2:CH.CHO, resulting from the decomposition of glycerol or fats by excessive heat, is but little antispetic. Its injection by various channels produces typical shock (G. F. Kamen, 1943). Its ordinary toxic effects consist chiefly in strong irritation of the skin and exposed mucosae. Habitual exposure seems to lead to some tolerance. No other chronic ill effects have been reported.

Heptyl aldehyde against tumors has given contradictory results. L. C. Strong and Whitney, 1938, and Strong reported softening, liquefaction and regression of spontaneous tumors, and improvement of the general condition, by the daily administration to mice in food, and to dogs hypodermically (0.1 to 1 cc.). This was confirmed by Boyland and Huntsman, 1938. C. Carruthers, 1940, reported that its application to the skin of mice on alternating days diminishes the carcinogenic frequency of methylcholanthrene, but it had no effect on established tumors. He also found (1939) that feeding of heptyl aldehyde tends to produce resorption of embryos in mice. Various other aldehydes had no effect. On the other hand, C. A. Baumann *et al.*, 1938, observed no effect on tumor growth or survival of the animals with five varieties of mouse tumors, except a nonspecific effect when enough was added to render the food so unpalatable as to restrict the caloric intake. W. G. Clark, 1939, noted no apparent effect on spindle-cell sarcoma in rats, even when the aldehyde was injected into the tumor.

OZONE

This is a polymeric form of oxygen (O_3), which decomposes readily with the liberation of active oxygen. It is strongly oxidizing, deodorant and antiseptic, but is easily destroyed in the presence of organic or other oxidizable matter. Efficient concentrations are highly irritant and produce toxic depressant systemic effects. It is used for the sterilization of water. Traces of ozone are contained in the air, especially after thunder storms, but the quantity is much too small to have any effect whatever; in fact, concentrations far beyond human tolerance are of uncertain efficiency (J.A.M.A., *57:* 1370, 1911; A. L. Kendall and Walker, 1936). At most, its persistent presence is an indicator of the absence of organic matter in the air. The odor of ozone is characteristic, disguises other odors, and tends to fatigue the olfactory endings (Wolfhugel, 1875; Erlandsen and Schwarz, 1910).

Effects of Inhalation.—The older methods of preparing ozone developed irritant nitrogen oxides. The modern machines are free from this defect. By their use, concentrations of 5 to 10 per million, inhaled for a short time, produce in man increased amplitude of the pulse, drowsiness, fatigue and persistent headache—the latter probably by irritation of the sinuses. Ten per million inhaled for fifteen minutes produces sore throat. One per million diminishes the oxygen intake and the CO_2 output. *Prolonged exposure* to concentrations below 1 per million does not produce noticeable disturbance; but with higher concentrations there is irritation of the respiratory tract and other mucous membranes, leading to fatal pulmonary edema; or in acute toxic concentrations to initial restlessness followed by depression and coma. Exposure for two hours to 10 or 15 per million is dangerous to life, but the irritant effects, cough, headache, and so forth, give ample warning to avoid the danger. For an antiseptic action, at least 13 per million would be necessary. The air contains at most 0.00015 to 0.158 per million (Jordan and Carlson, 1913).

HYDROGEN PEROXIDE

The peroxides are fairly stable in pure solutions, but on contact with catalyzers, inorganic or organic (catalase), tissues, and so on, they split off active oxygen and are therefore strongly antiseptic and deodorant. The action lasts only so long as oxygen is being evolved, and is brief and superficial. In deep and closed cavities, the rapid evolution of gas presents danger of mechanical injury and embolism. Hydrogen peroxide is employed for washing fetid wounds and ulcers; as injection for gonorrhea; as mouth wash, and for other uses. Used as the full U.S.P. strength (10 per cent of available oxygen), at least four times daily (Farrell and Nichols, 1937), it is especially effective against anaerobic organisms that grow on dead tissues, *i. e.*, fusospirochetosis, Vincent's angina, mercurial stomatitis. It is nontoxic and scarcely irritant, but for most uses it should be diluted with 2 to 10 parts of water. Its continued use as a mouth wash sometimes causes hypertrophy of the papillae of the tongue (C. S. Miller *et al.*, 1938). A stronger (30 per cent) preparation is caustic. In contact with pus it foams, and this aids mechanically in cleansing the wound. Hydrogen peroxide is a chemical *antidote* for cyanide and phosphorus poisoning. It is used for *bleaching* the hair and fabrics. The concentration of 0.35 per cent (absolute) in *milk* inhibits the development of pathogenic bacteria (Budde, 1903), but it also destroys the ferments of milk and is of questionable utility (Heinemann, 1913). Sieber, 1901, claims that it destroys toxins. The germicide action is feeble (Albert and Taylor, 1918).

Phagocytosis is stimulated *in vitro* by hydrogen peroxide, whereas free oxygen is generally depressant (H. J. Hamburger, 1915). Potassium chlorate and ferricyanide proved inactive. *Gastric acidity* is lowered by lavage with ½ to 3 per cent solutions of hydrogen peroxide, the effectiveness increasing with the concentration. The effect may persist for two weeks, but there is generally discomfort and sometimes bleeding, so that it is not a desirable clinical agent. More dilute solutions may stimulate the secretion of acid (Culmer and Atkinson, 1937). *In vitro*, hydrogen peroxide is somewhat more toxic to *ascarids* than is ascaridol (Butz and Lande, 1934).

PREPARATIONS.—***Solution of Hydrogen Peroxide,** U.S.P. (Liquor Hydrogenii Peroxidi; Solution of Hydrogen Dioxide); a slightly acid aqueous solution of H_2O_2 (approximately 3 per cent), corresponding to about 10 per cent (volumes) of available oxygen. It occurs as a colorless liquid, odorless, with slightly acid taste, producing a peculiar sensation and soapy froth in the mouth. It keeps best in bottles stoppered merely with a plug of cotton, and standing in a cool place. It is incompatible with easily oxidizable substances. It decomposes gradually. This is not due to impurities (Clover, 1913). The decomposition is retarded by small quantities of acid or acetanilid. The latter is used in most brands (Kebler, 1910), but in time these acquire a yellow tint and an odor of nitrobenzol, and should then not be used. Dose, 2 to 8 cc., ½ to 2 drachms. *Stronger Solution of Hydrogen Peroxide*, U.S.P., contains about 8 per cent of H_2O_2. It tends to deteriorate on keeping and may be stabilized by the addition of harmless substances.

"Solid Peroxide" consists of easily soluble compounds with urea, containing about 35 per cent of absolute peroxide.

Organic peroxides were introduced by Freer and Novy, 1903. Acetyl-benzoyl peroxide (Acetozone) and succinic dioxide (Alphozone) may be considered as H_2O_2 in which the H has been replaced by organic radicals. In the presence of water they are slowly hydrolyzed, forming organic peracids, with active oxidizing and germicidal properties. They were used as local and intestinal antiseptics, but are of doubtful efficiency for the latter purpose. They should not be mixed with organic liquids, or kept in a warm place, as they tend to explode.

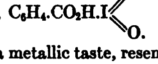
Peroxides of metals are compounds in which the H of H_2O_2 has been replaced by metals. They are readily decomposed with the formation of H_2O_2 or the active oxygen, and have been suggested as substitutes for hydrogen peroxide. The commercial products are usually mixtures containing 15 to 75 per cent of the peroxide. The compounds of the different metals vary considerably in stability and solubility, and in the ease with which their solutions are decomposed. Acids convert them rapidly into hydrogen peroxide; *f. i.*, $MgO_2 + H_2SO_4 = MgSO_4 + H_2O_2$. Water decomposes them more slowly, inversely to their solubility; *f. i.*, $ZnO_2 + 2H_2O + Zn(OH)_2 + H_2O_2$, so that their action is more prolonged. The therapeutic effect is also modified by the nature of the base. *Sodium peroxide* yields a solution sufficiently alkaline to be caustic. It is used as a paste on comedones. *Medicinal Zinc Peroxide*, U.S.P., is a fine white powder, insoluble in water, soluble in dilute acids. It is used on infected wounds, as a creamy 40 per cent suspension in water. It must come into thorough contact with the infected surface, after wide exposure and trimming (B. C. Johnson and Meleney, 1939). Zinc peroxide is also used in skin diseases; *magnesium peroxide* in dentifrices; *calcium peroxide* against gastro-intestinal fermentation.

Sodium Perborate, U.S.P., $NaBO_3.4H_2O$, yields hyrdrogen peroxide on contact with water, being transformed into metaborate which acts as a mild alkali; $NBO_3 + H_2O = H_2O_2 + NaBO_2$. It is used as a substitute for peroxide, as a dusting powder or 2 per cent solution, and especially as a dental antiseptic, and in Vincent infections, applied as a paste and rinsed off in five minutes; but its routine use is not advisable. It is strongly alkaline, producing considerable irritation and even corrosion, so that it often does more harm than good (Hirchfeld, 1937). As a mouth wash, not more than a teaspoonful should be used in a glass of water. Its continued use often produces hypertrophy of the lingual papillae and darkening of the gums (C. S. Miller *et al.*, 1938). It occurs as white crystalline granules or a white powder, soluble in water (1:40); odorless, saline taste; decomposed in moist air with the evolution of oxygen. Contains not less than 9 per cent of available oxygen. Dose, 0.06 Gm., 1 grain, U.S.P.

IODOXYBENZOIC ACID

This has a strong oxidizing action, even in the body (Heinz, 1899). Loevenhart and Grove, 1911, investigated the sodium salts of the 3 compounds: (1) Iodobenzoic acid, $C_6H_4.CO_2H.I$. (2) Iodosobenzoic acid, $C_6H_4.CO_2H.I = O$.

(3) Iodoxybenzoic acid,



$C_6H_4.CO_2H.I \begin{smallmatrix} \nearrow O. \\ \searrow O. \end{smallmatrix}$

The two latter have a metallic taste, resembling that of hydrogen peroxide, presumably due to the active oxygen. They oxidize hemoglobin to oxyhemoglobin. (2) is irritating, (1) and (3) mildly so. The systemic effects were studied by intravenous injection. (1) has little action. The oxygenated compounds (2) and (3) produce the phenomena of apnea; marked and continued fall of blood pressure by depression of the vasomotor center; brief arrest of respiration, also by depression of the medullary center. The vagus center is not affected. These actions are due to the active oxygen. This cannot replace ordinary molecular oxygen for maintaining the cardiac activity; Loevenhart and Eyster, 1913.

Antiseptic Action.—Practical results have been disappointing. (2) and (3) are much more bactericidal than (1) (Arkin, 1911). Iodoxybenzoate increased the production of antibodies in dogs (Hektoen, 1911); also the production of hemolysin and agglutinin in rabbits, when injected intravenously shortly after immunization. It stimulates phagocytosis (Arkin, 1915). Its injection lessens inflammation by mustard oil or allergy, while this is increased by cyanide, indicating that edema is lessened by oxidation and increased by asphyxia (Amberg, 1913). Iodosobenzoic acid was studied by Jahn, 1914. *In vitro* it is more effective than sulfonamides on E. coli and hemolytic streptococcus (F. P. Chinard, 1942). It reduces the toxicity of tuberculin *in vitro* (Arkin, 1916).

Iodoxybenzoic Acid against Chronic Arthritis.—Promising results were claimed, but it is now rarely used. It was reported to arrest the progress of the disease, and to remove the functional disturbances, to relieve the pain, diminish the swelling and tenderness of the joints, to increase their mobility and functional use, and to improve the general health (A. G. Young and Youmans, 1926). The ammonium salt is administered intravenously, 1 Gm. in 100 cc., injected slowly (ten minutes) once or twice a week, for 6 to 8 doses. The toxicity is low, and is determined mainly by the rate of injection. At most, there may be temporary apnea. The solution is irritant, and may produce fibrosis of the vein; if it escapes into the subcutaneous tissue, it is painful, but not escharotic. The mechanism of action is not understood. The injections are often followed by irritation of the mucous membranes and presumably of other tissues; it is possible that it sets up acute inflammatory reaction in the joints, which may sometimes lead to improvement of the chronic process.

BORIC ACID AND SODIUM BORATE (BORAX)

These are fairly antiseptic, but not potently germicidal, and it is questionable whether they check bacteria under clinical conditions. They are not deleterious locally or systemically in the amounts ordinarily used on small areas, but larger doses are fatal. Boric acid is a mild astringent, through its acidity. Sodium borate is a mild alkali and dissolves mucus. Its alkalinity makes it incompatible with alkaloids, local anesthetics, salts of metals and with acacia. Boric acid is employed in surgery as dusting powder, as saturated (4 per cent) aqueous solution, as boroglycerite and in collyria (2 per cent of boric acid, which may be buffered with 0.5 per cent of sodium borate). A 25 per cent paste of borax in glycerol or honey is painted on ulcers of the mouth or gum, as in thrush, four times daily. Dusting with boric acid powder, 10 per cent in talcum, is among the most effective measures for the prevention and treatment of ringworm of the foot (Weidman *et al.*, 1945). The borate ion has no other therapeutic uses. Boric acid and borax have been employed as food preservatives. Small single doses are generally innocuous; their continued use produces slight but cumulative effects, so that their employment is not advisable. Directly harmful effects follow doses of 2 to 5 Gm. of boric acid or borax, and 15 to 30 Gm. may be fatal (Schwyzer; C. Potter, 1921).

Occurrence.—Minute traces of boron occur in all animals, most abundantly in the oceanic (Bertrand and Agulhon, 1912). *Plants* also take it up readily from the soil (Cook, 1916), and it appears to be necessary for several growth functions, especially cell division, in addition to making iron more available (W. L. Powers, 1939). Small quantities produce marked increase of growth (of beans, Fagundes, 1934; flax in nutritive media, optional concentration = 0.5 mg. per liter, Skolnick, 1933). Somewhat higher concentrations (but still dilute) cause spotting of the leaves (Haselhoff, 1913).

Seedlings of a variety of plants, when grown in nutrient solutions, soon die unless the solution contains 0.3 to 3 mg. of boron per liter, varying with the species (Skolnik, 1935). *Animals* do not appear to require it; at least, addition of boron to a boron-poor diet does not improve the growth of rats (Hove *et al.*, 1939). However, boron lengthens the survival time of rats on potassium-deficient diet (J. T. Skinner and McHargue, 1945).

Antiseptic Efficiency.—Boric acid is not a disinfectant. Even saturated solutions do not kill bacteria. Solutions of 0.3 per cent check putrefaction and decomposition, but not the growth of pathogenic organisms (Bernstein, 1910). The antiseptic efficiency varies for different bacterial cultures. It begins with about $\frac{1}{10}$ saturated; and for most is complete with about $\frac{1}{4}$ saturated (Tanner and Funk, 1919). Borax is somewhat less efficient. Their popularity as food preservatives is attributable to the absence of distinctive odor and taste. The acid is used in meats in the concentration of 0.5 per cent; in milk, of 0.2 per cent. Borax and the insoluble calcium borate kill *house fly larvae* in manure (Cook and Wilson, 1917), but it may render this toxic to plants. As a general *insecticide*, sodium borate is considerably less effective than fluoride (G. D. Shafer, 1915).

Borate Buffered Eyewaters.—The *p*H of eyewaters should be adjusted to their constituents. Zinc sulfate and epinephrine may be dispensed in boric acid, 1.24 per cent, NaCl 0.29 per cent, approximately *p*H 5.3. Neutrality (*p*H 7.1) is obtained with boric acid, 1.24, sodium borate, 0.13 per cent; alkalinity (*p*H 8.3) with boric acid, 0.8, sodium borate, 0.6 per cent.

Acute boric poisoning has occured rather frequently by intravenous injection of boric acid solution in mistake for saline; by similar mistakes in infant feeding (C. G. Barnum, 1945); by flushing serous cavities; by enemas, and by the application of powdered boric acid or boric ointment to extensive burns and eczemas (E. H. Watson, 1945; review, C. C. Pfeiffer *et al.*, 1945).

The symptoms develop rather slowly, beginning about eight hours after ingestion, with vomiting, diarrhea, rapidly progressing prostration; then convulsive tremors, meningismus, convulsions, exfoliative dermatitis ("boiled lobster" erythema), ending in a progressive shock syndrome. Death may occur in about thirty-six hours, from 2 to 5 Gm. of boric acid or 15 to 30 Gm. of borax. *Pathologic changes* consist in focal hemorrhages, vascular engorgement and leukocytic infiltration of the skin; degeneration of the renal tubules; rather insignificant fatty parenchymatous degeneration of the liver. The most characteristic changes are neurophagia and hypochromatosis in the brain and spinal cord, produced by a third of the MFD, and by the application of the 10 per cent boric acid ointment to burns of 4 per cent of the body surface. Boron can be demonstrated in both white and gray matter of all parts of the central nervous system and in the peripheral nerves. It is not combined with phospholipids or cholesterol. It accumulates also in the liver and body fat. *Treatment* of boric poisoning is by evacuation, and large intravenous injection of Ringer's solution or plasma (Pfeiffer *et al.*, 1945).

Boric Acid Hemolysis.—Blood corpuscles suspended in 1 per cent boric acid do not undergo any visible change; but their osmotic properties are altered, so that they become laked if transferred to isotonic salt solutions. This alteration is due to the presence of boric acid within the cells, for laking does not occur if the corpuscles are washed in hypertonic salt solutions (Kosakai, 1919).

The **effects of small doses** of boric acid and borax, such as are used in preserving foods, would not be serious, even if the consumption were continued for a long time. However, the results are somewhat deleterious in normal individuals, and they would probably be more so in patients with digestive or renal disturbance. A man living largely on preserved food may ingest as much as 0.5 Gm. of boric acid (or its equivalent in borax) per day; the consumption would generally fall below this figure, but could rise to several grams. All investigators agree that quantities to 0.5 Gm. have no immediate action of any kind in healthy individuals. When the consumption is continued for a long time, boric acid seems to have a *cumulative action* on digestion and absorption, metabolism and the kidneys (Forster, 1883; Rost, 1905; Wiley, 1904). The digestion becomes somewhat deranged; the body weight decreases; the feces become more watery. If a slight albuminuria was present, this is increased (Wiley). The cumulative effect may be explained by the observation that the *excretion* of boric acid is slow, requiring several days, although it begins within ten minutes, and reaches its maximum in the second hour. With continued daily hypodermic injections of 200 mg. per Kg., fourteen to eighteen days are required to reach a urinary plateau (Pfeiffer *et al.*). On the average, 15 per cent is retained, the other 85 per cent being excreted mainly by the urine, to a slight extent by sweat and milk, and practically none by the feces (Wiley). The excretion is not hastened by diuresis (Rost, 1905). A trace occurs normally in milk and eggs (Bertrand and Agulhon, 1913); it is increased materially by the addition of boron to the food. It also passes through the placenta to the fetus (Hove, Elvehjem and Hart, 1939).

Somewhat larger doses, 1 to 3 Gm. per day, produce the described effects more rapidly and more severely Headaches appear. With 5 Gm., the subject soon becomes unable to do any work. Quantities above 2 Gm. per day should be condemned as distinctly harmful. The growth of immature rats is retarded by 0.25 per cent of boric acid in their drinking water, but not by 0.1 per cent (Pfeiffer *et al.*). Harrington, 1904, observed that the continued administration of borax to cats leads to severe kidney lesions. The internal use of boric acid (against *obesity*) sometimes produces *skin disorders* resembling pityriasis (Memmesheimer, 1935). Kahlenberg and Barwaser, 1928, reported that boric acid is promptly *absorbed from the skin*, but others have been unable to confirm this (Pfeiffer *et al.*, 1945). The actions on the *uterus*, which are not very marked, were investigated by J. W. C. Gunn, 1920.

PREPARATIONS.—***Boric Acid**, U.S.P. (Boracic Acid), H_3BO_3; translucent colorless scales, or light, fine, bulky powder, unctuous to the touch; odorless; of slightly saline taste. Slowly sol. in water (1:18); sol. in alc. (1:18); freely sol. in glyc. (1:4). Dose, 0.3 to 1 Gm., 5 to 15 grains, as urinary antiseptic. Locally, in lotions, injections, gargles, and the like, 2 to 4 per cent (1½ to 3 teaspoons per pint). A saturated watery solution contains about 5 per cent, or 25 grains per ounce. *Glycerite of Boroglycerin*, U.S.P., contains about 50 per cent of boroglycerin, $C_3H_5BO_3$, prepared by heating boric acid and glycerin. It is used externally, diluted with ten parts of water. *Boric Acid Ointment* contains 10 per cent. *Liquor Antisepticus*, N.F., contains 2.5 per cent of boric acid, and aromatic oils. A number of proprietary mixtures, *e. g.*, "listerine," have a similar composition. Their antiseptic efficiency is slight (Verhoeff and Ellis, 1907).

* **Sodium Borate,** U.S.P. (Borax), $Na_2B_4C_7.10H_2O$. Colorless, transparent crystals, or white powder, odorless, of sweetish, alkaline taste. Sol. in water (1:16), with alkaline reaction; very sol. in glyc. (1:1); practically insol. in alc. *Incompatible* with alkaloids, acids, mucilage of acacia. (Free boric acid is not incompatible with most alkaloids.) Dose, 0.3 to 1 Gm., 5 to 15 grains.

◆

THEORIES OF NARCOSIS

The neutral aliphatic hydrocarbons resemble each other in their main actions. Their most conspicuous effect on the higher animals consists in stupefaction, passing with larger doses into insensibility and motor paralysis; *i. e.*, into profound narcosis or anesthesia of central origin. Analogous narcotic or depressant effects are produced on all forms of protoplasm and on unorganized ferments. Hemolysis is also a marked effect.

The term "narcosis" is applied in biology to reversible decrease or abolition of the normal cell activities by agencies that are not highly selective. It may be produced by a variety of physical and chemical conditions: by cold, fatigue, electric inhibition (anelectrotonus), oxygen deficiency, certain ions and strikingly by the neutral aliphatic derivatives used clinically as general anesthetics, hypnotics and sedatives. Various attempts have been made to explain the fundamental nature of narcosis, and particularly to correlate it with the composition and with the other chemical and physical properties of the narcotics. The results indicate that there are striking quantitative relations between the narcotic strength of the hydrocarbon series and their lipoid and surface affinity. The efficiency increases with their solubility-partition coefficient (Meyer-Overton Law), which is an index of the lipoid affinity; and with their depressive effect on the surface tension of water, which is an inverse index of surface affinity (I. Traube). The lipoid and surface affinity are generally parallel; when they conflict, the narcotic efficiency appears sometimes to follow the one, sometimes the other. Both properties tend to condense the narcotic agent on the surface of the cell; their relative share in this is determined largely by the amount of lipoid in the cell membrane. The condensation of the agent on the cell surface has at least three effects: (1) it increases its potency by increasing its concentration; (2) the reduction of surface tension alters the distribution of solutes and the electric potential in the cell; and (3) this, together with the adsorption of the lipolytic substance into the lipoids of the cell membrane, alters its *permeability*. This is decreased at first, interfering with the increase of permeability involved in stimulation. This appears to be the essential cause of the narcotic action. If the action progresses too far, the cell may be disorganized, injured or killed, in which case the permeability increases. Other narcotic agents produce analogous changes in permeability, possibly through different mechanisms. At all events, the action of the aliphatic narcotics is on the cell surface and not on the cytoplasm; for they do not produce narcosis if they are injected into the interior of amebae (Marsland, 1934). Quantitatively similar actions are produced on enzymes, suggesting that the chief factor of aliphatic narcosis is the "blanketing" of the reacting surface (Warburg). Other theories of narcosis will be discussed in the small type.

Influence of Chemical Structure.—The earlier studies indicated that the actions of this series appear to be influenced by the chemical structure, and much labor was expended on determining the share of various side chains (Binz, 1881; Baumann and Kast, 1890). The results seemed to show certain relations, but the generalizations did not stand the test of wider experience (Meyer, 1899; Kionka, 1900). The chemical structure affects the narcotic action only indirectly, by modifying the partition coefficient and the surface affinity, which vary in a definite manner with changes in composition. Special side chains may be responsible for side actions; chlorine compounds are peculiarly toxic to the heart.

The *empiric relations* are practically interesting and important, although they have lost theoretical significance. The following conclusions appear justified: other things being equal, the strength of action increases with the length of the chain. A limit is soon reached, however, for the drugs become less volatile, less soluble and less absorbable the higher they stand in the series; so that the higher paraffins are entirely insoluble and inactive. With normal alcohols the narcotic potency for *tadpoles* increases to C_{12} and decreases beyond C_{14} (K. Meyer and Hemmi, 1935). *Hemolysis* by straight-chain alcohols increases linearly with the log of the number of carbon atoms (Ponder and Hyman, 1939). *Inhibition of phagocytosis* increases with the molecular weight of primary alcohols, but decreases with amyl, hexyl and heptyl alcohols (H. Welch and Slocum, 1943).

The ethyl radical, C_2H_5, seems best adapted to therapeutic purposes. The action may be modified by replacing the H of the group by other elements or groups. The compounds so formed all possess the typical action of the hydrocarbon group; but this may be so overshadowed by other actions as to be scarcely appreciable. A good example of this is the introduction of the group NO_2. This acts much more strongly than the hydrocarbon part of the molecule, and consequently the nitrite action is obtained before there can be any hydrocarbon action. The same is true if we substitute an aromatic radical. The introduction of certain other radicals weakens the hydrocarbon action to a great extent, especially the acid-forming radical CO_2H. The introduction of hydrocarbon radicals into an amine molecule destroys their action entirely. The introduction of more than one OH group also weakens or destroys the action. Aldehydes and ketones are more active than the corresponding alcohols. The introduction of the halogens, and especially of Cl, often enhances the action, but this is not proportional to the number of Cl molecules introduced. The introduction of O (ethers) also increases the action. The introduction of acids (esters) weakens it.

Lipoid Affinity of Narcotics.—Bibra and Harless, 1847, shortly after the discovery of anesthesia, drew attention to the fact that practically all fat solvents are narcotics, and suggested that they dissolve the fats out of the nerve cells. The difficulty of explaining the rapid recovery proves that this theory cannot be correct, and it was accordingly abandoned; but later workers continued to point out more or less quantitative relations. Hermann, 1866, *f. i.*, showed that all the aliphatic narcotics dissolve red blood corpuscles, connected this with their lipoid solubility, and first suggested the modern lipoid theory. Conversely, Richet, 1895, argued that the narcotic efficiency is inversely proportional to the solubility in water. The relations observed by Hermann and by Richet were striking but not conclusive. It was only by their combination that an exact quantitative relation could be demonstrated. This was done, independently and practically simultaneously, by H. Meyer and by Overton, 1899 and 1901. They showed a close parallelism between narcotic efficiency and the "partition coefficient": $\frac{\text{Solubility in fat } (S_F)}{\text{Solubility in water } (S_W)}$ usually determined on olive oil. The higher this coefficient, the more powerful the narcotic action ("*Meyer-Overton Law*"). The parallelism occurs so frequently that it must be assumed that the lipoid affinity as expressed by this coefficient is concerned in some way in the narcosis. There are, however, exceptions which indicate that it is not the only factor.

Objection has been made to the olive oil coefficient (Moore and Roaf, 1906), since the cell lipoids, especially in the nerve tissues, include lipoids of quite different solubility characters, such as cholesterol and the phosphatides, lecithin, cephalin, cerebrin, cerebrosides, and the like (W. Koch, 1911). This would affect the degree rather than the direction of the relation. Closer approximations are obtained with olein-alcohol, $C_{18}H_{35}OH$, whose solvent properties closely resemble those of the spinal cord lipoids (K. H. Meyer, 1935).

Evidence for the Meyer-Overton Law.—The narcotic concentrations have been determined mainly on tadpoles; but the law has also been tested on other animals, plants and tissues, with general agreement, but with some differences (review, M. Kochmann, 1936). Fuehner, 1909, investigated the influence of *mixed narcotics*, and found that the coefficient and narcosis were always modified in the same direction. The serial relation of aliphatic alcohols and other aliphatic derivatives was studied on the *frog heart* by A. J. Clark, 1930; on the *ciliary movements* of the gills of oysters, by S. Nomura, 1928. The relation applies also to other properties than narcotic action; for instance, to *local irritation* (A. Rikl, 1928). *Exceptions to the Meyer-Overton law* may occur from complicating factors. The influence of *temperature* on narcotic efficiency is not always parallel to the partition coefficient or to the surface tension. Hoeber, 1919, found that the relation between temperature on narcosis and partition coefficient does not hold for muscle and nerve. In tadpoles, the susceptibility to the narcotics undergoes interesting changes with the *development of the animals* (Vernon, 1913). The critical concentrations also vary for different tissues; indeed, for different functions of the same tissue, so that it is unsafe to generalize widely. It is also sometimes difficult to differentiate between narcosis and other forms of injury. *The Meyer-Overton law applies only to the aliphatic narcotics.* Morphine and other basic and saline narcotics do not obey the law, and must act by entirely different mechanisms.

Influence of Extraneous Fats on Narcosis.—It might be expected that narcosis would be affected by fatty tissues, deflecting a certain amount of the anesthetic; but this does not seem to be the case to a notable degree; presumably the cell walls of adipose tissue are not easily permeable to lipoids.

Mansfeld, 1905, suggested that the low resistance of starved animals is due to this. The theory is not convincing, for in starvation the resistance is lowered in many other directions. Cloetta, 1907, tried the converse experiment, the influence of increasing the fatty tissue. His results do not justify general conclusions, but previous injection of *cholesterol* materially increases the depth of anesthesia by ether or barbiturates (Starkenstein and Walden). *Lecithin* does not have this effect, although it has about the same solvent-affinity for ether (Foldes and Beecher, 1943).

Quantitative Distribution of Narcotics in Brain.—The total amount absorbed into the brain substance depends largely on the mass of myeline sheath, neuroglia, and so forth, which are not involved in narcosis. For this reason, the relative amount of narcotic found in different parts of the brain does not furnish a clew to the site of action (Meyer and Gottlieb, 1936).

Surface Affinity.—The close parallelism of narcotic concentration and the depressive action on the surface tension to water was pointed out especially by J. Traube, 1904–1928, and Czapek, 1911, There is a similar parallelism between the surface tension effect and the partition coefficient, so that it is difficult to generalize as to which property is the determining factor in the narcosis. There appear to be more exceptions to Traube's rule than to Overton's (Lillie, 1916), but attempts to distinguish between them are not conclusive (review, M. Kochmann, 1936). Presumably both properties participate, to a varying extent in different tissues. Diminution of the surface tension of the plasma during ether anesthesia can be demonstrated on intact mammals (Trabucchi, 1928)

Fuehner, 1912, found that for *hemolysis*, and for animals devoid of a nervous system, the efficiency of homologous alcohols is parallel to the surface tension; but in proportion as the nervous system develops, the activity of the higher alcohols becomes relatively greater, and agrees better with the partition coefficient. With chlorine derivatives, the hemolytic action increases with the chlorine content and with the molecular weight, without relation to the surface tension (Plotz, 1920). The depression of *frog heart* by serial homologous alcohols follows a biphasic curve which parallels closely their effect on surface tension (A. J. Clark, 1930).

The **permeability of cell membranes** is diminished by narcotic concentrations, and increased by toxic concentrations.

In nerve fibers and in muscle, Hoeber, 1915, found that low concentrations of anesthetics decrease permeability, preventing the swelling which normally occurs in solutions of potassium salts. High concentrations increase the permeability; this would correspond to a toxic effect. Both phenomena have been confirmed on fish eggs by McClendon, 1915. Osterhout, 1912, 1918, showed that anesthetics decrease the electric conductivity, and therefore the permeability, of plants. Fatal concentrations again increase the permeability. Hemolysis also is an instance of increased permeability by toxic concentrations (Hoeber, 1915; Joel, 1915) The *relation of depression and stimulation to permeability* was illustrated by R. S. Lillie, 1912, on Arenicola larvae. Similar phenomena are observed in the effects of anesthetics on the sensitive plant.

Relation of Cell Permeability to Stimulation.—The decrease of permeability by narcotic concentrations interferes with the changes of permeability which are necessary for stimulation; according to the views of Nernst (1899), stimulation depends on a change in the electric polarization of the cell, due to a change in the concentration of the ions at the surface, brought about by a sudden increase of the permeability of this membrane at the moment of stimulation. This change is hindered when the permeability is decreased by the narcotics (review, R. S. Lillie, 1915). Changes in the plasma membrane could also be effected by other means, and the narcotic effects of salts can be explained in this manner. A plausible explanation of the actions of morphine and most of the local anesthetics is still lacking.

Anesthetics on Artificial Osmotic Membranes.—Lipolytic agents increase the electrical resistance of artificial membranes impregnated with lecithin; *i. e.*, they diminish the permeability to ions (S. Loewe, 1913). They also decrease, reversibly, the permeability of copper ferrocyanide and of collodion membranes, the lower homologues being more effective for ferrocyanide, the higher for collodion (Anselmino, 1928). Analogous phenomena are observable in artificial systems of phosphatide and salt solutions (J. Loeb and Beutner, 1913).

Pilocarpine Adsorption by Serum.—Serum adsorbs pilocarpine hydrochloride so that it does not diffuse through parchment. Addition of alcohol and other lipolytic agents displaces it so that diffusion occurs. However, the maximal efficiency in homologous series does not coincide with the maximal narcotic potency, indicating that such adsorption is not the fundamental cause of narcosis (Beutner and Hyden, 1929).

Excitability and Conductivity of Nerve.—Narcosis of a nerve, however produced, always lowers both these functions in strict parallel (Verworn, Erregung and Laehmung, p. 121). While a normal nerve conducts without loss of stimulus, a narcotized nerve shows a decrement during conduction (*ibid.*, p. 127). The narcosis of nerve structures, unlike that of skeletal muscle, follows an "*all or none*" *law*, so that any concentration that is effective at all produces complete inexcitability, if it is sufficiently continued. This holds not only for lipolytic agents, but also for heat and for curare (Mansfeld; Somlo; v. Szirmay; 1923). *Narcotized skeletal muscle* fails to respond first to electrical, then to thermal, and finally to chemical stimulation (Tissot, 1894); but this is conditioned on the strength of the stimulus (H. T. Graham, 1929).

Phagocytosis is stimulated by minute doses of lipolytic agents, parallel to their partition coefficient, probably explained by lowering of surface tension. Narcotic concentrations paralyze the movements of leukocytes (Hamburger and de Haan; Bubanovic, 1911).

Coagulation, Precipitation and Flocculation Theories.—Aliphatic narcotics generally tend to coagulate and precipitate proteins and other hydrophilic colloids, but this requires considerably higher concentrations than are attained in ordinary anesthesia. Claude Bernard in 1853 and 1875 suggested that narcosis might be due to some kind of reversible semicoagulation, perhaps analogous to the muscle rigor produced by chloroform. He did not furnish experimental evidence for the suggestion. Others have recurred to it time and again (Binz, 1891), and W. D. Bancroft and associates, 1931, shifted the ground to flocculation, but their evidence is also unconvincing (V. E. Henderson and Lucas, 1932). Indeed, the known effects of flocculation, as witnessed, for instance, in anaphylaxis, are quite the opposite of narcosis.

Bernard, 1875, based his suggestion on the observation that muscle exposed to chloroform or ether until it is paralyzed, but not in rigor, loses its transparency under the microscope. Binz (Lectures, 1891) reported that the cells of fresh brain sections are "coagulated" by solutions of chloroform or morphine, but this required concentrations never present in the living brain (for instance, 1 per cent of morphine); and even with these, his results have not been reproduced by others. Marinesco claimed that chloroform causes flocculation in cells, confined to the nucleus; but he also used fatal concentrations. Meantime data accumulated on the *effects of lipolytic narcotics in vitro*. Handovsky and Wagner, 1911, and A. Thomas, 1915, observed that they increase the *viscosity of lecithin suspensions, and the precipitability* of these by electrolytes. It is not safe, however, to generalize from this, for Hoeber and Gordon, 1914, reported that the anesthetics hinder the precipitation of lipoid suspensions by calcium; and W. Koch, 1910, showed that the various lipolytic anesthetics differ in their effects on the aggregation of the phosphatides. The anesthetics affect *lipoid emulsions* so as to promote the continuity of the fatty phase, and this shows a general parallelism with the narcotic phenomena (Clowes; M. Fischer and Hoskin, 1916). I. Traube and Klein, 1921, showed that the lipolytic anesthetics exist in watery solutions largely as colloids (as do also other difficultly soluble substances), and as such they tend to accumulate at the interface, and to produce *flocculation and precipitation of other colloids*. The adsorption of the anesthetics on colloids also explains the observation of Moore and Roaf, 1905, that the *solubility of chloroform in serum and tissue extracts* does not obey the ordinary laws of solution. The adsorption is not very firm, however, for Cushny, 1910, found that the *exhalation* of the volatile members of the alkyl series is exactly analogous to their evaporation from watery solutions.

Bancroft and Richter, 1931, reopened the subject with more delicate physical methods and reported *ultramicroscopic flocculation in vitro* with dilutions more nearly comparable to those occurring in life, and claimed to have observed changes of viscosity in the living. Changes of viscosity and even opacity in *living cells* as the result of chloroform, ether, and the like, have also been described by Frederikse, 1933, and Koehring, 1933, but they generally involved fatal concentrations; nor are changes in the viscosity or transparency characteristic of narcosis, for they occur with changes of *p*H (Rosenfeld and Weinberg, 1932, tissue cultures), in muscular contraction, and in the process of dying. Bancroft and his associates, however, asserted dogmatically that irritability is increased by imperfect and depressed by further flocculation; that decreased viscosity causes reversible, and increased viscosity irreversible, narcosis; that all narcotic effects are due to flocculation while solvent ions act as stimulants; and that mental disease, drug addiction, sciatica, old age and chicken cholera are also due to this flocculation, which they claimed to resolve with thiocyanate (Bancroft and Russler, 1932). V. E. Henderson and Lucas, 1932, pointed out the weakness of the deductions, and Birkholder, 1932, the errors in the experimental evidence.

Dubois, 1894, observed exudation of water in narcotized plant cells, and suggested that narcosis consists in *dehydration*. Overton, however, showed that the phenomenon is a manifestation of irreparable injury, and not of narcosis.

Verworn's Theory of Oxygen Deprivation.—Verworn, 1909 (Harvey Lectures, 1911), pointed out that narcosis is generally accompanied by diminished oxidation, and that deficiency of oxygen produces anesthetic phenomena. He therefore suggested that narcosis is due to interference with oxygenation, to incapacity of the cell substance to undergo oxidation, even in the presence of oxygen, while nonoxidative destruction proceeds unchecked. Verworn's facts do not prove the theory, for since narcosis suppresses irritability, it would naturally depress oxidation; this would be the effect instead of the cause of the narcosis. Conversely, the suppression of irritability by oxygen deprivation does not prove that every narcosis must be due to oxygen deprivation. This could be accepted only if interference with oxidation and narcosis were always strictly parallel. This is not the case.

Anesthetic Effects of Oxygen Deprivation.—The anesthetic effects of asphyxia have long been familiar. Frogs perfused with saline solution become inexcitable, but the excitability is preserved or reappears if the solution is oxygenated (Verworn, 1900). Similarly, excised nerve loses its excitability in an atmosphere free from oxygen (Froelich, 1904). Mansfeld, 1909, showed that the results are additive; the paraldehyde narcosis in tadpoles is increased by degrees of oxygen deficiency which are in themselves harmless. On the other hand, there are instances (nerve trunks, vorticella, cilia) in which oxygen deprivation acts slowly, while anesthetics act promptly. HCN, which is a strong asphyxiant, is a weak anesthetic. Anaerobic organisms are also subject to narcosis, showing that this has nothing to do with free oxygen or its penetration into the cells.

Respiration of Excised Nervous Tissue.—Anesthetic concentrations of ether and other anesthetics have no effect on the oxidation of dextrose by slices of cerebral cortex (Jowett, 1938; F. N. Craig, 1943); but higher concentrations inhibit the oxidation of glucose, lactate, pyruvate, and somewhat of glutamic acid; not of succinate or p-phenylene diamine. Oxidation by yeast is not inhibited by these concentrations (Quastel and Wheatley, 1934). Herter found that the oxidizing capacity of tissues for methylene blue is greatly diminished in anesthesia. Vernon, 1909, claimed a quantitative relation between the hemolytic effect of alcohols and their influence on the respiration of excised kidneys. Tashiro, 1913, found that anesthetics greatly diminish the CO_2 output of nerves. Warburg, 1910, and Loeb and Wasteneys, 1913, found the oxygen consumption normal in narcotized sea urchin eggs.

Indole furnishes a strong argument against the explanation of narcosis by oxygen deprivation. It is a potent inhibitor of brain respiration in rats, but its administration leads to convulsions, not to narcosis, although the blood contains enough of the poison to lower brain respiration *in vitro* by a third to a half. Narcotic concentration of barbiturates does not decrease brain respiration significantly, *in vivo* or *in vitro* (M. C. Hutchinson and Stotz, 1941).

Reduction of flavoprotein and cytochrome into inactive complexes has been suggested as a possible basis of the cerebral narcotic action (M. E. Greig, 1946).

Blood Catalase.—Burge, Weill and Ashman, 1918, claimed that narcosis is accompanied by a decrease of the catalase content of the blood, roughly parallel to the depth and rapidity of the anesthesia; but with a more reliable method, Becht, 1919, found practically no change of catalase during anesthesia; if anything, there was a slight increase. There is no evidence that the catalases have anything to do with the ordinary processes of the body. More probably, they serve to destroy peroxides that might become harmful (Loew).

Unorganized Ferments.—The lipolytic narcotics retard the action of ferments in general, by being adsorbed on the active surface of the enzymes (Warburg, 1927); for instance, zymase (Warburg and Wiesel, 1912); yeast invertase (Meyerhof, 1914); oxidase (Vernon, 1912); of pepsin, rennin, trypsin, and so on; of colloidal platinum (Meyerhof); activated blood charcoal and other inorganic catalysts. The relative activity is similar to that for protoplasm; but the concentrations required for the unorganized ferments are considerably greater than the concentrations that suffice for the narcosis of living protoplasm, so that they cannot be transferred directly. The *luminescent* reaction of purified luciferin and luciferase is retarded *in vitro* by urethane, sulfonamides and p-aminobenzoic acid, without affecting the total luminescence produced (F. H. Johnson and Chase, 1942).

Cerebral Anemia.—The analogies of narcosis in the higher animals with the phenomena of natural sleep suggested a common origin to the earlier investigators. Since sleep was then explained by cerebral anemia (Durham, 1860), the same explanation was adopted for narcosis (Bedford-Brown, 1860). It was subsequently found, however, that changes in the cerebral circulation are small and variable (Cl. Bernard, 1875).

All the theories of *deficient nutrition of the brain*—whether through anemia or otherwise—are disproved by the fact that narcosis can be induced in frogs in which all the blood has been displaced by saline solution, or in which the cerebral circulation has been arrested; in excised nerve-muscle preparations; in animals which do not possess blood; in plants; and even in unicellular organisms.

Morphologic Changes.—Diminution and fusion of the *Nissl granules* have been described by good observers after deep anesthesia; other observations have not been able to confirm this, and the changes may be only artifacts. Kocher, 1916, emphasized the numerous sources of error and the inconstant results of such observations. It is also stated that the dendrites of many pyramidal cells show moniliform enlargements; the alterations disappear completely within forty-eight hours, even when caused by chloroform anesthesia of nine hours' duration. Lépine and Duval attributed anesthesia to retraction of the dendritic processes.

Temperature Narcosis.—Claude Bernard pointed out that reversible narcosis can be produced in frogs by careful warming; and G. H. Parker, 1939, found that surgical anesthesia of cold-blooded animals can be secured by packing them in cracked ice for ten to fifteen minutes, with quick recovery on warming.

◆

ALCOHOL

Ethyl alcohol is a local irritant. After absorption, it depresses the central nervous system, especially the "higher functions." It simulates stimulation, chiefly by lowering the normal restraining functions; but there may be some direct facilitation of motor processes and respiration. The psychical symptoms show individual differences according to temperaments and circumstances, but they tend to run an ascending course with increasing doses, through euphoria, comfort and enjoyment, to elation and vivacity; then downward through loquacity, garrulity, emotionalism either affectionate or quarrelsome or both, to violence, then hebetude, stupor and finally coma. Motor symptoms run through a similar but not necessarily parallel course.

"Stimulant" Effects of Alcohol.—These, as observed in most individuals after taking "moderate" doses of alcohol, appear at first view typical of stimulation. There is an increase in the rate of the *respiration* and of the *heart;* the *blood pressure* rises. The *skin* is reddened, with a grateful sensation of warmth and comfort. There is an increased *vivacity* of motion, action and speech, which later may acquire a stamp of brilliancy, perhaps of inspiration. The *subjective condition* generally veers toward self-appreciation. Shyness, if it ordinarily exists, is replaced by self-confidence. The person under the influence of alcohol feels an unlimited confidence in his own powers and accomplishments, both intellectual and physical. He attempts difficult and impossible tasks, and feels that he accomplishes them. He may similarly overestimate the performance of others.

No better description of these effects has been given than that of Horace: "What wonders does not wine! It discloses secrets; ratifies and confirms our hopes;

thrusts the coward forth to battle; eases the anxious mind of its burthen; instructs in arts. Whom has not a cheerful glass made eloquent! Whom not quite free and easy from pinching poverty!"

These manifestations are so conspicuous and apparent that alcohol in proper doses has been considered a typical stimulant. However, the critical study of its actions tends to the conclusion that *most of these actions do not depend upon true direct stimulation* of the nerve centers, but that they are the indirect result of incoordination, of accessory factors of environment, and of reflex stimulations.

Of the physical phenomena, the *flushing of the cutaneous vessels*, and its attendant sensation of warmth, are due to central vasomotor depression. The *quickened pulse* results partly from reflexes caused by swallowing and by irritation of the mucous membranes, partly from the emotional excitement and increased movements; not at all from a direct action on the cardiac nervous or muscular mechanism—for it is absent in animals, and very brief in man if the factor of excitement be eliminated. The *quickening of the respiration* is largely due to similar causes.

The *psychic phenomena* are explained chiefly by dulling of certain mental faculties while others are still practically unaffected, resulting in disturbance of the "normal balance of the brain." The first functions to be lost are the finer grades of judgment, reflection, observation and attention—the faculties largely acquired through education, which constitute the elements of the restraint and prudence that man usually imposes on his actions. The orator no longer considers that he may be called to account for his utterances; he allows himself to be carried by the impulse of the moment, without reflecting on ultimate consequences, and, as his expressions become freer, they acquire an appearance of warmth, of feeling, of inspiration. Not a little of this inspiration is contributed by the audience if they are in a similar condition of increased appreciation.

The view that alcohol increases the intellectual and physical powers of the individual is shown by actual experiments to be erroneous, and based almost entirely upon the subjective condition of the individual, his weakened faculty of judgment and precipitate but faulty or misdirected reactions. The failure of alcohol to produce real stimulation is also attested by common experience. Persons who have to undergo severe exertion, either physical or intellectual, rarely take alcohol before or during their labor, but only when this is finished, and then not for any stimulating, but really for its depressing, effect, for the feeling of comfort and general relaxation which it induces. The continued use of large doses of alcohol diminishes the activity of the individual, and even moderate doses tend to have the same effect.

Another characteristic feature, evidently resulting from this paralysis of the higher functions, is the *loss of the power to control moods*. There may be causeless merriment or sadness, friendliness or the opposite. It is proverbial how this abolishes self-control: "There is truth in wine." On the other hand, habits of self-control, where they have been cultivated, persist to some extent even in intoxication.

Efficiency Tests.—Independent investigations on typewriting, target pricking and rifle practice have shown uniformly that effective doses of alcohol lower efficiency by decreasing accuracy. This becomes especially conspicuous when the work is rapid, and when it requires close and continuous attention. Speed may not be reduced. The deleterious effects are least marked in tasks that are so familiar, or so easy and simple, so "semi-mechanical," that they do not require much attention. The details differ, especially in degree, for different tests and the conditions under which they are made, as well as for different individuals, and whether or not they are accustomed to alcohol and have learned to know their reactions and to allow for them. Most observers conclude that 30 Gm. of alcohol or even less have definite effects on performance and behavior.

After 10 Gm. of alcohol, no change could be demonstrated in the "higher mental abilities" in fifty subjects; 20 Gm. gave doubtful results (B. B. Cattell, 1930). Doses of 20 to 40 Gm. of alcohol practically double the errors in close work, and the effect with this dose lasts about two hours. With some individuals, 10 Gm. may produce the result; habitual drinkers are more resistant. The concentration in which the alcohol is given does not materially influence the response; but the effect is less if the alcohol is taken with or just after meals, for then it would be more slowly absorbed (Vernon and Greenwold, 1919; W. R. Miles, 1924). Heise, 1934, reported that 30 cc. of whisky, equivalent to 15 cc. of alcohol, increases speed but with carelessness, want of self-control and poor judgment.

The University of Chicago investigation of beer (1934) illustrates the difference in individuals. It included thirty-six subjects of various antecedents, tested for equilibrium (Romberg test), pricking, response to signals, and red and green light. The unit of dosage was the customary 350 cc. "bottle" of 3.2 per cent beer, equivalent to 13.65 cc. of alcohol. Two bottles consumed in fifteen minutes had no apparent effect; with four bottles in thirty minutes five tests in sixty-nine showed definite impairment of motor control; eight to fourteen bottles (109 to 190 cc. of alcohol) in three and a half hours showed consistently poor performance, except for visual reaction time. Of twelve subjects, eleven showed definite changes in behavior, and eight vomited.

Experimental Analysis of the Psychic Effects of Alcohol.—Jellinek and McFarland, 1940, analyzed 170 published papers on psychologic experiments with alcohol and concluded that the effects are purely depressant. Dodge and Benedict, 1915, who aimed to use the simplest methods of a given kind, found that moderate doses depress all kinds of neural processes, motor as well as sensory. The diminished efficiency is most conspicuous in the simpler and unconscious reflex processes, *i. e.*, those that are most independent of the will; for a normal individual even when somewhat alcoholized attempts automatically to compensate for diminished efficiency by greater effort. This in turn is likely to lead to more errors; for the extra effort is often ill directed, since alcohol diminishes caution and inhibitions.

Dosage, Time and Subjects.—Dodge and Benedict employed doses of 30 and 45 cc. of alcohol, diluted to 20 per cent. The depression reached its maximum in one to two hours; recovery started within three hours. The responses were essentially similar for abstainers and reformed drinkers.

Quantitative Response.—The results may be arranged in progressive order from those showing the greatest, to those of the least effects. *Reflexes:* knee jerk and lid reflex: latent period increased by 10 and 7 per cent. Muscle shortening diminished by 46 and 19 per cent. *Sensory Thresholds to Electric Stimulation:* raised by 14 per cent. *Motor Coordinations:* speed of eye movements and of reciprocal finger movements: diminished by 14 and 9 per cent *Elaborated Reactions:* reaction time of eye and speech organs; latent period increased by 5 and 3 per cent. *Memory:* no change.

Kraepelin, 1892, also concluded that alcohol is purely depressant to sensory or intellectual processes; but he believed that the generation of motor impulses is first stimulated, and only later depressed. In the light of more recent work, this "stimulation" of motor processes is apparently an erroneous interpretation; but this does not destroy the value of the actual data of the extensive studies of Kraepelin; namely, that the "stimulant" stage of alcohol favors mechanical performances—the "simpler reactions" of memorizing, mechanical reading, repetition, at the expense of the more intellectual processes—association, arithmetical and so forth. It favors motor impulsiveness, but produces intellectual dulness and silliness, lowers thought, judgment, resistance to temptation, and thus leads to further abuse. The euphoria probably depends on the deceptive feeling of facilitation and capability.

Psychic Depression.—With doses of 30 to 45 Gm. of alcohol, this lasts thirty to forty-five minutes; with 60 Gm., one to two hours. The phenomena are somewhat analogous to those of fatigue. In both, mechanical associations predominate. However, the lighter grades of alcohol "fatigue" disappear with exercise, while genuine fatigue is relieved only by rest.

Electroencephalogram changes of alcoholic intoxication are reported by G. L. Engel and Rosenbaum, 1945.

Motor Processes.—The facilitation begins at once and lasts at most twenty to thirty minutes; less with larger doses. It is followed by depression even with the small doses of 7.5 Gm. With 45 to 60 Gm., the initial facilitation is seen only exceptionally. The results depend somewhat on circumstances; in excitement, even large doses produce facilitation; and in fatigue, small doses may depress. The more mechanical the function, the more conspicuous is the facilitation. The force measured by the dynamometer is not increased, so that the rate rather than the force of motor impulses is favored. There is evidence that the muscular contraction proper is not quickened, but that the motor impulses are started more easily.

Perception of sensory impressions is impaired for hours, even by 7.5 cc. of alcohol (Kraepelin, 1916).

The *reflexes* from the frog's skin are depressed, even with the smallest effective doses (Hyde and pupils, 1913), before there are any gross symptoms.

Color Vision.—H. Schuly, 1916, found that small doses of alcohol increase the acuteness of vision, both for red and green. Large doses diminish it.

Alcohol on Muscular Work.—Ergographic experiments of Lombard, 1892, on man showed that the muscular force in voluntary contractions is not increased; but the appreciation of fatigue is lessened (Joteyko, 1904; Foerster, 1912), so that the total work may be increased. When a finger is tetanized, by electric stimulation, the total work is rather decreased (Lombard); the favorable effect must therefore be at least partly central (facilitation of cerebral motor processes). The voluntary response is modified by the previous state of the muscles as well as by the dosage of alcohol. Myers, 1912, reports no effects from 5 to 20 cc.; 30 to 40 cc. gave irregular results, most commonly a primary increase and secondary decrease of the work. The increase is seen only when the muscle is not too much exhausted, but it is favored by moderate fatigue. The depression of the larger dose is purely central. On *frog's muscle*, minute quantities have no effect; moderate doses were said to exert a favorable action on all the features of muscular activity; larger quantities are unfavorable (Lee and Salant, 1902). Crider and Robinson, 1916, attributed the reported favorable effect to experimental error. The *effects on invertebrates and lower vertebrates* were studied by Fuehner, 1912.

Alcohol and Automobile Accidents.—Various studies show marked increase of frequency and seriousness of automobile accidents with slight degrees of alcoholism, increasing with the amount. Effects of alcohol which are not considered as drunkenness in the ordinary sense, and which may not be apparent to the casual observer and even to some efficiency tests, are dangerous in driving automobiles. Diminished acuity of peripheral vision (R. Pickard), poor muscular control, slowed reaction time, impaired self-control and poor judgment when confronted with unexpected situations; and especially self-complacency, so that the driver does not compensate for his impairments; and above all, mania for speed and recklessness in taking chances, constitute a vicious circle that leads to disaster. This is shown by tests in the laboratory and on the road (H. A. Heise, 1934), and especially by the investigation of automobile accidents. It appears that practically any amount of alcohol increases the liability to automobile accidents, incidentally also on the part of pedestrians; and that the increase becomes alarming above 0.5 per thousand blood concentration, equivalent to 50 cc. of alcohol, or 4 ounces of whisky, or two to four bottles of beer.

Holcomb, 1938, who studied 270 drivers involved in motor accidents, and 1760 drivers picked at random near Chicago, found alcohol present in four times higher ratio in the accident group (47 per cent) than in the random group (12 per cent). Up to 0.5 to 0.6 per thousand concentration of alcohol in the blood (the maximum allowed to drivers in Norway), the percentage of accidents was about the same as without alcohol; but above this concentration, the ratio of accidents rose rapidly, so that with 1 per thousand it was four to six times that without alcohol; with 1.3 per thousand it was ten times, and with 1.5 per thousand of alcohol (The National Safety Council's "conclusive evidence" of drunkenness) it was twenty-five times as frequent as in drivers without alcohol. (The doses that give these concentrations are discussed below.) Confirmation of these conclusions by another approach is furnished in the data of Sachsenberg, 1938, from Germany, who found the percentage of "unsafe" drivers, incapacitated so as to be more reckless than 90 per cent of nonalcoholic drivers, to increase from 20 per cent at 0.2 per thousand blood concentration, to 40 per cent at 0.4; 49 per cent at 0.5; 66 per cent at 0.7; 75 per cent at 0.8; 87.5 per cent at 1.0; 90 per cent at 1.1; and 100 per cent at 1.4 per thousand. Heise, 1934, found decrease of efficiency even after an ounce (30 cc.) of whisky, with blood concentration not above 0.2 per thousand, although the ordinary psychomotor tests of alcohol were not positive till 150 cc. of whisky had been taken.

Use of Alcohol as Stimulant.—Although the "stimulant" doses do not increase intellectual efficiency, they could be employed for facilitating motor functions of short duration; not so much to increase their force, but for overcoming inhibition of hesitancy; to promote decision or resolution, *f. i.*, in speaking, in psychic dreads, and so forth. It would be unfavorable to attention, watchfulness or accurate judgment. The stimulant dose should generally not be more than 15 to 20 Gm. of alcohol; or if a longer effect is needed, 5 to 8 Gm. in twenty-minute intervals.

The *use of alcohol in convalescence and debility as an "analeptic," "restorative"* or *"stimulant"* is supported by long experience. The feeling of well-being caused by it, the sense of capability, the removal of worry, the enjoyment in the act of taking it, the rest and sleep induced by its narcotic action, its food value and its beneficial effects upon digestion, concur in its action. To this may be added its slight effects upon the vascular system—the altered distribution of blood, the diminished resistance to the heart—which may be of benefit in some cases. For these purposes, the alcohol should be taken well diluted, as light wines or beers.

The contraindications to alcohol may be resummarized as: danger of habit; states of excitement; sthenic stage of fevers; irritation of the alimentary or genito-urinary tract.

Use of Alcohol in Depressed Psychical States.—In hypochondria, melancholia, neuralgia and other obscure nervous diseases, alcohol relieves the patient by its mild narcotic and euphoristic action, but the temporary relief is generally obtained at the expense of a permanent alcohol habit, and is therefore not to be advised. *In catatonic syndromes,* alcohol may interrupt the catatonic stupor, producing temporary and sometimes lasting cessation of the mutism, torpor and negativism (Kantorovich and Constantinovich, 1935).

Use of Alcohol as a Hypnotic.—Alcohol, especially in the form of beer, taken at night and in the absence of excitement, is a fairly efficient hypnotic; but its usefulness is limited by the danger of chronic alcoholism. The hypnotic dosage corresponds to 45 to 60 Gm. of alcohol.

Alcohol analgesia has been used since antiquity to confer "Dutch courage." The heat-pain method shows that it produces indifference to perceived pain. The maximal analgesia, amounting to 45 per cent increase of threshold, is produced by 30 cc. of alcohol in about fifteen minutes, and lasts about two and a half hours; longer with larger doses (H. G. Wolff *et al.*, 1942).

Mullin and Luckhardt, 1934, confirmed with the Frey bristle technic that 60 to 75 cc. of alcohol, administered by mouth as 20 per cent dilution, distinctly decrease pain sensitivity for two or three hours. Sensations other than pain are not affected by ordinary doses (Wikler *et al.*, 1945).

General anesthesia by intravenous injection of alcohol is described by E. V. Verkovskaya, 1945: 2 to 2.5 cc. of alcohol per Kg. of body weight, diluted with twice its volume of 5 per cent dextrose solution, is administered by drip injection in ten to fifteen minutes (the fatal dose ies about 7.7 cc. per Kg.). Sleep sets in with about 1 cc. of alcohol, and lasts two to five hours. The patient awakens irrational and requires watching. Vomiting occurs in 6 per cent. Intravenous alcohol anesthesia for animals is described by Nitzescu, 1930.

Spinal reflexes are first augmented, then depressed, in spinal cats and in fish. Other alcohols and ether act similarly; the stimulation is doubtful with chloroform (Fuehner, 1926).

Respiration.—"Stimulant" doses of alcohol may increase the rate and depth of the respirations, by reflex and central stimulation. The response, however, is variable and generally small. With narcotic doses, the respiratory center is depressed. The *hypodermic injection* of 50 per cent alcohol (or of whisky or brandy) produces considerable temporary increase of respiration, by reflex irritation. This occurs also under morphine (Hanzlik, 1913).

In Higgins' experiments (1917) on *man*, 30 to 44 cc. of alcohol taken diluted produced little change in the rate or type of respiration (unless there was excitement). The threshold to CO_2 was sometimes lowered. The minute volume was generally diminished, by decreased CO_2 production. The bronchioles were generally unaffected; rarely dilated. The respiratory stimulation is especially large in fatigue. Wendelstadt, 1899, obtained similar results in man. The increased respiration is partly due to the general excitement and partly to reflexes from the local irritation (Jacquet, 1895). Some increase occurs even in sleep, so that the factors of environment are not essential. Nor can it be affirmed that it is due solely to reflex irritation, for other irritants do not produce an equivalent effect (Binz, 1903). Moreover, an immediate increase of respiration occurs if alcohol is injected into the brain through the carotid artery (Wilmanns, 1897). With *unanesthetized animals*, slow intravenous injection produced only slight respiratory stimulation, even when the injections were repeated beyond the excitement stage (Hyatt and Jensen, 1918). With a more perfect separate *perfusion* of the brain and medulla, Hooker, 1917, also found that the addition of 0.025 to 0.1 per cent of alcohol (corresponding to clinical concentrations) produces pure stimulation of the respiration. With 0.2 per cent, the stimulation was transitory, and was followed by prolonged inhibition. This would correspond to coma. It is therefore certain that the respiratory center is stimulated directly. In *cats*, Pilcher, 1912, found the rate usually increased by all except fatal doses. In *decerebrated cats*, doses of 0.5 to 5 cc. per Kg., dilute or concentrated, caused no change in the respiration (Lieb, 1915). With *decerebrate* and *vagotomized rabbits*, alcohol (10 cc. of 5 per cent per Kg.), heptyl alcohol and ether stimulate the respiratory center; chloroform does not (Blume, 1928).

The **effects on the circulation** are rather minor and inconstant, largely secondary to other actions, varying not only with the dose and concentration and mode of administration, but also with the condition of the individual. *Small therapeutic doses* (in man, to perhaps 5 to 25 cc. of absolute alcohol, diluted to at least 25 per cent) produce generally (but not always) an insignificant quickening of the pulse rate, due mainly to excitement. There is no evidence of direct cardiac stimulation (A. Grollman, 1942). The cutaneous vessels are dilated, and the splanchnic vessels are somewhat constricted, leading to a rise of the systolic blood pressure and a fall of the diastolic pressure. The mean aortic pressure rises slightly in most cases, but not always. The actions, taken together, alter the distribution of the blood, so that more is contained in the surface vessels and in the arteries, and less in the splanchnic veins. The amplitude and force of the pulse, the "mass movement" of the blood, the output of the heart, and the efficiency of the circulation in general are improved. Cardiac dilatation may be decreased. The actions reach their maximum in about half an hour, and disappear in an hour or two.

In men not accustomed to alcohol, even 10 cc. provoke a psychic response with transient rise of pulse rate, blood pressure, cardiac output and rise in the oxygen of the venous blood. *In moderate drinkers*, 30 cc. does not produce any demonstrable effects, in the absence of excitement. With 35 cc. or more, there are slight changes of pulse rate and appreciable increase of blood pressure and cardiac output (Grollman, 1930).

Somewhat larger doses (45 to 90 cc. of alcohol for man, diluted) produce at first the same effects, followed in an hour or less by decreased amplitude and force of the pulse, with progressive fall of the systolic pressure, and unaltered or rising diastolic pressure. If the alcohol is taken in more concentrated form on an empty stomach, this stage may occur at once, without the preliminary improvement of the pulse. The fall of the pressure is attributable to splanchnic dilatation, replacing the constriction of the first stage. The action is therefore comparable to that of the nitrites. The effects reach their maximum in one to one and one-half hours, and last one-half to one hour.

Toxic doses depress the vasomotor center, so that the blood pressure falls severely. The heart rate may be slowed through central vagus stimulation, or through the depressant action of the coma; or it may be quickened by the fall of blood pressure. It fails finally from anoxia, consequent on respiratory depression; the alcohol concentration of the blood is not sufficient to produce serious direct cardiac injury (H. W. Haggard *et al.*, 1941).

The hypodermic injection of whisky, like that of other volatile irritants, often produces a slight and transient rise of blood pressure (Lieb and Herrick, 1917).

Heart Rate.—The effect is greatly modified by the condition of the individual. In man, the rate is generally increased, mainly by the psychic and reflex actions (Dixon, 1907); the increase is often absent, especially if the patient keeps quiet (Zimmermann, 1896; Jacquet, 1891; Dixon). With larger doses quickening is the rule (John, 1918; Higgins, 1917), presumably to offset the falling blood pressure. Animals give similar inconstant results (Pilcher, 1912). The intravenous injection into nonanesthetized animals generally causes some slowing (Brooks, 1910).

General Blood Pressure.—*In man*, Lieb, 1915, observed practically no effect from diluted whisky (usually 5 to 10 cc.). When given concentrated, this dosage usually produced a slight reflex rise (about   mm.) of the systolic and diastolic pressure, returning to normal in less than one-half hour. The return of the diastolic pressure is somewhat slower, so that the pulse pressure is decreased. These effects are entirely reflex, and are most pronounced when the reflexes are hyperactive; least in apathetic patients and toxemias. Moderate users are more susceptible to them than are drinkers. With larger doses John, 1908, found a progressive fall of systolic pressure, with unchanged or rising diastolic pressure. In *unanesthetized animals* the oral administration produces a slight rise, lasting five to ten minutes; administration through a gastric fistula had no effect. Rapid intravenous injection causes the sharp drop, common to many drugs, followed by rapid recovery. Slow intravenous injection produces no marked change with doses of 0.5 to 5 cc. per Kg. (Brooks, 1910; Lieb, 1915; Hyatt, 1920).

Blood Flow.—Alcoholic beverages of the strength of wine, administered to normal men in moderate doses, produce a brief preliminary decrease, followed by a more lasting increase, of the blood flow in the hand. Both effects are vascular. Alcohol also favors vasodilator reflexes; *f. i.*, the contralateral heat reflex (G. N. Stewart, 1915). Hanzlik and Collins, 1913, found the circulation time in intestinal vessels distinctly slowed by relatively small doses of alcohol, intravenously, even when the carotid pressure was unchanged.

Vasomotor Changes.—Moderate doses of alcohol dilate the *skin capillaries* and lower the *vein pressure*, without change in the arterial pressure (McDowall, 1925). (Large doses increase the vein pressure; Capps and Matthews, 1913.) Since the blood pressure does not fall in the early stages, it is evident that this dilatation of the surface vessels is compensated, either by the constriction of other vascular areas or by increased output of the heart. Both factors appear to contribute to the result, according to circumstances. A brief turgor of the *posterior urethra* seems to follow the swallowing of a moderate quantity of alcohol. *Splanchnic vasoconstriction* in the early stage was demonstrated by Dixon, 1907, who found that the volume of the intestine decreases while the blood pressure rises.

General vasodilatation in the more advanced stages of the action is shown by the fact that the blood pressure is practically not increased, notwithstanding considerable increase of the output of the heart, as measured by the stromuhr (Hemmeter, 1889; Wood and Hoyt, 1905) or by the cardiometer (Dixon). If the vasomotor center is excluded by section, the injection of alcohol causes a more marked rise of pressure (Kochmann; Wood and Hoyt), showing that the vasodilator action of alcohol must be central. Porter and Turner, 1915, found that alcohol may suspend *vasomotor reflexes* even when the general level of the blood pressure is not altered. *Direct actions on vessels* appear to be insignificant. On perfusion, Dixon found in mammals slight dilatation with 0.1 to 0.2 per cent; higher concentrations gave constriction. Perfusion of the frog showed moderate constriction. In surviving arterial rings, Cow, 1911, found slight response: transient constriction followed by dilatation. Plumier, 1905, believed that alcohol has a peripheral constrictor effect.

Improved Nutrition of the Heart.—The *increased output of the heart in situ* is attested by the stromuhr, cardiometer, rise of pressure after destruction of the vasomotor center, and so forth. Since this improvement is not usually noted in excised hearts, it cannot be due to a direct action of alcohol on the cardiac muscle. Kochmann, 1905, attributed it to improvement of the coronary circulation by the general vascular changes. Peters, Rea and Grossman, 1936, found with Starling heart-lung preparation of dogs that alcohol in the concentration of drunkenness decreased the oxygen consumption, with decreased external efficiency.

Isolated Mammalian Heart.—Concentrations below 0.05 per cent generally have no effect. Occasionally there are indications either of depression or of stimulation; the latter especially if the heart has been exhausted (Dixon, 1907). Between 0.05 and 0.5 per cent, some depression becomes evident. This is first seen as increased volume, in systole and diastole, which progresses with the dosage, and develops into diminished output, rise of venous and pulmonary pressure, slight slowing and some tendency to arrhythmia. With 2 per cent, the heart is severely damaged, especially the auricles. Four to 5 per cent arrests the heart in diastole; the auricles stop before the ventricle. If the alcohol is removed, the heart recovers rapidly, even from severe depression (Sulzer, 1924; Kochmann, 1904; O. Loeb, 1905; Barry, 1915; Burridge, 1917; Lieb, 1917). The *coronary vessels* are said to be constricted, and the coronary flow diminished, by 0.1 to 0.2 per cent of alcohol (Sulzer, 1924).

The concentration of alcohol in the blood of living animals is 0.12 per cent in "slight confusion," and 0.7 per cent in deep narcosis. It is therefore improbable that the direct cardiac effects of alcohol play more than a minor part in either the therapeutic or toxic phenomena.

The *frog's heart* is stimulated by small, and depressed by higher, concentrations (Wood and Hoyt, 1905); according to others, even the smaller doses are depressant (Dreser, 1887; Toyoshima, 1928).

Turtle Heart.—The concentration required to reduce the height of contraction to one-half was studied for various alcohols by Vernon, 1910.

Pressure in Pulmonary Artery.—Dixon, 1907, and Wood, 1911, found this slightly increased, even when the carotid pressure is unchanged. Cloetta and Anderes, 1914, found the effect on the pulmonary vessels inconstant; generally dilatation, rarely constriction.

Cerebral Circulation.—Hirschfelder, 1915, described dilatation of the vessels of the pia mater and retina. Berezin, 1916, also observed dilatation.

Hemolytic Action—Alcohol added in sufficient concentration directly to blood causes hemolysis (C. H. Schulz, 1841). This concentration is not reached in living animals, but the resistance to laking agents is noticeably lowered (Fillinger, 1912). Continued administration increases the resistance of the corpuscles (Orban, 1913). If the relative hemolytic effect of different alcohols is compared, it is found to be proportional to their effect on surface tension, rather than to their lipoid solvent action (Fuehner, 1912). J. N. Schultz, 1912, investigated the influence of various substances (including sera in different diseases) on the alcohol hemolysis.

Blood viscosity is somewhat increased by the administration or inhalation of alcohol or methyl alcohol (Burton-Opitz, 1904, 1914).

Cerebrospinal fluid formation is increased by alcohol (Tajitsu, 1929). The *pressure* of the cerebrospinal fluid is not changed by alcohol unless it is lowered consequent on fall of systemic blood pressure (Bedford, 1946).

Use of Alcohol in Collapse.—Alcohol is used as a quickly acting ("diffusible") stimulant in sudden circulatory collapse, syncope, exhaustion, hemorrhage, traumatic shock, snake venom, strychnine, aconite, veratrum poisoning, and so on. The main element in this action is the reflex stimulation, increasing the pulse rate, the blood pressure and the respiration. The stimulation is prone to fail in the severer grades of hemorrhage and shock (Lieb and Herrick, 1917). The narcotic action may be useful. The subsequent vasodilatation is not sufficiently pronounced to have practical significance. The reflex action being brief, alcohol acts mainly as a temporary emergency remedy, to tide the patient over the immediate dangers. To secure these reflex effects, 25 cc. of whisky or brandy should be given undiluted, preferably hot, repeated every ten to fifteen minutes, according to effect. Similar reflex stimulation may be secured by *other diffusible stimulants:* ether, aromatic oils, camphor or ammonia. These may be administered by mouth (Spiritus Aetheris; Spiritus Camphorae; Spiritus Ammoniae Aromatics), or by smelling (aromatic ammonia, smelling salts).

Cardiac Disease.—Alcohol may be useful for temporary conditions, such as acute *myocardial insufficiency.* In *chronic lesions,* small doses may be valuable to lessen the worries of the patient, especially if he has been accustomed to its use. The vasodilator effect may be useful in *angina pectoris,* but it is inferior to the nitrites. Alcohol does not influence *pulmonary hemorrhage* (E. Frey, 1909).

Use in Exhausting Fevers (Typhoid, Pneumonia, and the like).—The discriminating employment of alcohol may be useful in these conditions; its indiscriminate use would do more harm than good.

The beneficial effects are probably mainly nutrient, owing to the *food value of the alcohol* and to the stimulation of the digestion and absorption of other foods. This not only conserves the general nutrition of the patient, but *increases the output of the exhausted heart.* The pulse becomes stronger and more regular. The altered distribution of the blood by the mildest degrees of alcohol action would also be beneficial: The *dilatation of the cutaneous vessels* removes the blood from the atonic and therefore congested internal organs, and lessens the venous distention of the heart. It would tend to lower the temperature, although the antipyretic effect is but small. The narcotic action of alcohol is useful by quieting the febrile excitement, thus reducing the demands on the strength of the patient. On the other hand, if the action of the alcohol proceeds to the point of inducing splanchnic dilatation and lowering blood pressure, it will exaggerate the serious circulatory abnormalities of fever. Again, in the acute, stimulant stages of the "sthenic" fevers, alcohol is likely to increase the circulatory excitement, and should be avoided. The individual observations on each patient can alone guide its employment: The dose may be increased or maintained so long as it improves the prominent symptoms, quiets the patient, regulates and strengthens the pulse, and lowers the temperature. When it ceases to have these effects—particularly when the pulse becomes "excited," or when the odor of alcohol remains on the breath—it should be diminished or stopped. The amount should be governed by the previous habits of the patient; but astonishingly large quantities can often be given to fever patients without producing inebriation even if they are unaccustomed to its use; the febrile organism probably oxidizes the alcohol more rapidly. Ordinarily, one may begin with ½ to 2 tablespoonfuls of brandy in half a glass of milk, every three hours, increasing the frequency as needed.

Temperature.—The ingestion of alcohol causes a sensation of warmth, due to the increased blood flow to the temperature nerves of the stomach and skin. This sensation is deceptive, for increased blood flow to the surface and the *diaphoresis* increase the heat loss, so that the internal temperature tends to fall. With small doses this tendency may be overcome by the increased movements of the patient; but with larger doses the heat loss becomes pronounced (Pilcher, 1912), and is exaggerated by the depressant action on the temperature-regulating centers, impairing the compensatory heat production. The fall of temperature is especially great if the surrounding atmosphere is cold, and also if the heat dissipation was previously low, as in fevers.

Use of Alcohol in Chills and Exposures.—It is evident that this would be detrimental *during* exposure to cold; the temporary relief and feeling of warmth is obtained at the expense of an increased loss of heat, and consequently diminished power of resistance. But if taken *after* the exposure, the dilatation of the cutaneous vessels favors the absorption of external heat, and also prevents the tendency to congestion of internal organs, and thereby the tendency to "catch cold." Another effect may be important: Constriction of the cutaneous vessels, such as is produced by chilling, leads to reflex constriction of the vessels of certain internal surfaces and organs, especially the respiratory tract and perhaps the kidneys, so that these are rendered less resistant to infection and injury. Cutaneous vasodilatation by alcohol, the nitrites or by counterirritation may prevent or arrest the damage.

The diuretic action of alcohol is parallel to its concentration in the blood (M. G. Eggleton, 1922), aided by the ingestion of fluid when the drink is beer; the other ingredients of alcoholic beverages are not important in this respect (H. W. Haggard *et al.*, 1941), with the exception of the juniper oil of gin.

John, 1908, found the average quantity of urine in four to six hours after taking 1½ liters of water to be 1500 cc.; with 1½ liters of 3 per cent alcohol, he averaged 1800 cc.; with the same quantity of 6 per cent alcohol he averaged 2000 cc. of urine. Alcohol irritates the urinary passages or perhaps rather causes a reflex turgor of the posterior urethra (and is therefore *contraindicated in cystitis and urethritis*); this may increase the desire to micturate, and may make the diuretic effect appear greater than it really is. Dogs fail to show more than the water diuresis, with oral administration of any dosage of alcohol (Januskiewicz, 1911). (Intravenous injection would arrest the urine flow, as do other hypotonic solutions.)

Local Actions of Alcohol.—Concentrated alcohol "hardens" tissues by abstracting their water and precipitating the proteins. It is therefore irritant and astringent. The effect is proportional to the concentration.

Applied to the skin, it causes some redness and smarting, followed by slight anesthesia. It is employed as a *mild rubefacient* and counterirritant in sprains and other minor pains. It may be applied in 10 to 70 per cent concentration, by friction or embrocation. It is often combined with other mild irritants, as in Soap Liniment, Camphor Spirit, "Witch-hazel Water" and Arnica Tincture. If the alcohol is sponged on the skin and permitted to evaporate, it produces a *cooling effect.* This is utilized in *fever,* and in excessive perspiration ("night sweats" of phthisis). The cleansing and hardening of the skin are also useful in this connection to prevent the development of *bed sores.* The astringent and stimulant action promotes the healing of *ulcers* (25 to 50 per cent).

On *mucous membranes,* the local action produces hyperemia or inflammation according to the concentration. The diuretic action of alcohol indicates that it irritates the renal cells.

Cell Division of Epithelium of Frog Skin.—Weak solutions produce marked increase of mitosis; a stronger (0.8 M) concentration causes irregular and incomplete metaphase; 1.2 to 1.5 M result in gelatinization of the cells. Methyl and propyl alcohol produce qualitatively similar effects (Aisenberg, 1936).

Subcutaneous injections of alcohol in concentrations above 50 per cent are painful and may cause ulceration; especial care should be used not to inject it near a nerve.

Intraneural injections of alcohol were introduced by Schoesser for the relief of neuralgia and spasms. They are generally effective, but are frequently followed by toxic degeneration of the nerve. They should therefore be avoided for motor or mixed nerves (sciatica), and find their best field in trigeminal neuralgia, as a substitute for the extirpation of the gasserian ganglion (Fischler, 1907), which they have largely superseded. Their effect is not permanent, nor are they entirely free from risk; but they have a field of usefulness. Cadwallader, 1915, studied the results of various concentrations: 80 per cent alcohol produces immediate and complete paralysis followed by absolute histologic degeneration. The paral, ysis may persist for one to three years, or until regeneration is complete; in scar formation there may be no regeneration. Fifty per cent causes less severe paralysis and degeneration; 25 per cent has but little effect in either respect.

Bactericidal Action of Alcohol.—Nonsporing bacteria on dry surfaces are killed by short exposure to alcohol of 50 to 90 per cent; 95 per cent is less effective, 100 per cent notably less. The normal moisture of the skin dilutes the concentrated alcohol so that it is generally effective (G. T. L. Archer, 1945), but 70 per cent (by weight) is preferred for skin sterilization. Friction increases the effectiveness by insuring better contact (A. Beyer, 1911; P. B. Price, 1939).

When tested by dropping bits of a rat's tail into the solution, 70 per cent ethyl alcohol sterilized in five minutes, 50 per cent propyl alcohol in one minute. The propyl alcohol is therefore more effective. The following failed to disinfect in five minutes: phenol, 2 per cent; mercuric chloride, 0.1 per cent; formaldehyde, 4 per cent; Dakin's solution; ether; acetone (Christiansen, 1918).

The **influence of alcohol on digestion** varies with the quantity and concentration, with the state of the digestive functions, with the habits of the individual, and probably also with the flavor and extractives of the beverage. In general, moderate doses act as "condiment" or stimulant to digestion. In this the flavor and the hyperemia cooperate to increase the appetite, the flow of digestive juices, the movements of the stomach, and absorption. The action of ferments is also accelerated. *Small quantities* of alcohol, taken with meals, therefore tend to have a favorable action on digestion. If digestion is perfectly normal, these effects are superfluous; the utilization of food and the total time of digestion are scarcely influenced. In pathological conditions, in depressive emotional states, and perhaps in overeating, the effects may be beneficial. With oral administration, in man as well as in animals, the favorable effect obtains with concentrations up to 10 per cent; with 10 to 20 per cent, the mucus is increased, as well as the juice. Above 20 per cent, the mucus is further increased, but the secretion is decreased. *Large quantities* of alcohol, especially when in concentrated form or in the empty stomach, produce irritation which surpasses the physiologic limit and interferes with the functions. This is seen most markedly in the habitual use, when the inflammatory changes become chronic.

Use of Alcohol in Indigestion.—Alcohol, in the form of wine or diluted spirits, taken with meals, is clinically of value in some forms, and harmful in others. It would be useful as a "counterirritant" in functional colic and gastralgia, and harmful in acute gastritis. The euphoristic and calmative actions tend to prevent and remove the unfavorable inhibitory effects of depressed or harassed and irritable mental conditions; so that alcohol may be valuable in the course of or convalescence from fevers or exhausting illness, phthisis, and so forth, and it may be a useful adjustant in nervous dyspepsia. Sometimes it is harmful by increasing the hyperchlorhydria. Champagne is also used as an *antemetic*. Its action depends perhaps more on the carbon dioxide and cold and on the psychical effect, than on direct actions of the alcohol.

Normal Human Gastric Functions.—These were studied by Beams and Barlow, 1936, in a number of normal men, by analysis of gastric contents and roentgenoscopy. Fifty cc. of alcohol (500 cc. of 10 per cent) produced marked increase in gastric tonus and peristalsis, but with lengthened emptying time. With the therapeutic dose of 15 cc. (as 500 cc. of 3 per cent), the effects were slight, but in the same direction. With the same dose, as 50 cc. of 30 per cent, there was marked increase of mucus and acid secretion, the free acid more than the total. With 3.5 cc. (50 cc. of 7 per cent), the acid was increased similarly, but the mucus was not. Concentrations of 5 to 10 per cent in man slightly increase the gastric peristalsis and tonus, and somewhat prolong the time of emptying (von Friedrich and Bokor, 1934). *Hunger contractions* are inhibited by alcohol, as by many other chemical and mechanical stimuli—food, smoking, chewing, dilute acids or alkalis (Carlson, 1913). Alcohol may, however, render the sensation of hunger more intense (W. W. Scott *et al.*, 1938).

Excised Intestine of Rabbit.—The movements are mainly depressed by monovalent alcohols; very dilute solutions produce a primary stimulation (Kuno, 1914).

Secretion of Saliva.—The presence of alcohol, strong or dilute, in the mouth increases reflexly the amount and the solids of the saliva, as do many other substances (acetic acid, ether, and so on). This increased secretion does not take place if the alcohol is introduced directly into the stomach through a fistula or if it is given subcutaneously.

Secretion of Gastric Juice.—The oral administration of 50 cc. of 7 per cent alcohol is used as a clinical *test of gastric secretion* (Bloomfield and Keefer, 1928). The secretogogue action is ordinarily due to peripheral parasympathetic stimulation, for it persists after section of the vagi, but is abolished by atropine. Some increase occurs, however, if the local action of the alcohol on the stomach is excluded, as in the "Pavlov stomach" (Zitowitsch, 1905; Bickel and Elkeles, 1926), or if the alcohol is placed into the intestine (Chittenden) or rectum (Kast, 1906). Dragstedt, Gray *et al.*, 1940, consider the phenomena similar to those evoked by histamine, and suggested that they are produced by the liberation of this substance

Pancreatic Juice.—Gizelt, 1906, claimed that the secretion is stimulated when alcohol is administered by mouth, intestine or subcutaneously, but only if the vagi are intact.

Bile.—Salant, 1906, found that alcohol by mouth (but not intravenously) increases the flow by 50 to 350 per cent; the solids are also increased. Increased bile secretion was confirmed for large doses by Okada, 1915.

Action on Ferments.—Since alcohol is readily absorbed, and no great amount of it reaches the intestine, it can influence only the ferments of the stomach. *In vitro,* 1 to 2 per cent of alcohol increases the rapidity of peptic digestion. Up to 15 per cent causes no perceptible retardation. With 15 to 18 per cent, the digestion is reduced by one-fourth to one-third. With 20 per cent, the digestion is strongly inhibited (Chittenden, Mendel and Jackson, 1898). Beers and wines have a slightly more unfavorable effect on account of the extractive matter contained in them.

Effects on Absorption.—Alcohol increases the absorption of other substances under certain conditions (Riemschneider, 1900, strychnine; Edkins, 1928, dextrose), but not under some other conditions (Ryan, strychnine, 1912). D M. Tennent, 1941, found absorption of dextrose delayed by increasing doses of alcohol. Brequet, 1912, found only a slight effect on the gastric absorption of strychnine, salicylate or iodide. Tschekounow, 1914, observed no increase for saccharose, iodine or NaCl. Hanzlik found the absorption of phenol and iodide diminished by strong alcohol. Alcohol intended as antidote may therefore even increase the toxicity of poisons, if both are taken by the stomach, and this is not evacuated.

The **absorption of alcohol** occurs rapidly, mainly from the small intestine. The unabsorbed alcohol averages about 50 per cent in fifteen minutes after oral ingestion, 1 per cent after three hours (Harger *et al.*, 1937). The rate is practically independent of the quantity.

Nemser, 1907, found that the amount absorbed at each level of the digestive tract depends mainly upon the time during which the fluid naturally sojourns at this level; little of the alcohol is therefore absorbed from the mouth; about a fifth from the stomach; little from the duodenum; the greatest quantity from the jejunum, and the remaining fifth from the ileum. Hanzlik and Collins 1913, studied the *absorption from intestinal loops* in living animals. It was rather better from the colon than from the stomach or small intestines; the length of the loop had little influence. The intestinal wall retains a certain amount of alcohol firmly, thus apparently arresting its absorption. Voeltz, Baudrexel and Dietrich, 1912, found similar phenomena in the absorption of alcohol by the *urinary bladder*, which is fairly extensive (Nicloux and Nowicka, 1913). Absorption from the *skin* is negligible (R. V. Bowers *et al.*, 1942).

Excretion of Alcohol.—Only a small proportion of the ingested alcohol is excreted, by the kidneys and lungs; generally less than 2 per cent, and probably never more than 10 per cent. The remainder is completely oxidized in the tissues. The proportion excreted depends upon the dose and other conditions. It is greater if the respiration is increased as by muscular work, or if the absorption is more rapid, as when the alcohol is taken on an empty stomach (Voeltz *et al.*, 1912).

Channels of Excretion.—This occurs mainly by the kidneys and lungs; a small amount is excreted and reabsorbed from the urinary bladder. Administering 30 to 50 cc. of alcohol in 250 cc. of water, Carpenter and Lee, 1938, found the total excretion in urine and air to be only 0.8 to 1.6 per cent of the ingested amount, with the subject at rest, and 1.1 to 2.1 per cent during muscular work. The pulmonary excretion is fairly constant, between 2 and 4 per cent; that by urine varies between 1½ and 13 per cent, depending largely on the sojourn and reabsorption in the bladder (Nicloux and Nowicka, 1913). Haggard and Greenberg, 1934, found 2.1 to 4.3 per cent excreted by the *kidneys*, depending on the urine output, and about 8 per cent, with rather wide variations, in the *expired air* A negligibly small quantity is excreted by the *stomach* when alcohol is administered by rectum (Lukas, 1930). The *milk* may contain a small amount if large quantities are ingested, but not with ordinary doses (Klingemann; Koldewijn, 1910; Schottmueller and Schumm, 1912). The maximum amount would be too small to affect sucklings (Voeltz, Paechtner, 1913). Lenoble and Daniel, 1917, found that after ordinary alcoholic intoxication, it appears promptly in the *cerebrospinal fluid*, and persists there for an average of ten days. The excretion curve is similar to that of the urine. It is *not* excreted in the sweat or feces (slight traces by intestinal loops, Hanzlik and Collins, 1913). The excretions do not contain an appreciable amount of acetone or other intermediate decomposition products (Masing, 1854).

The Fate of Alcohol in the Tissues; Effect on Metabolism.—Over 90 to 98 per cent of the ingested alcohol disappears in the body, being completely oxidized to carbon dioxide and water (Atwater and Benedict, 1902), probably with acetic acid as an intermediate stage. The quantity oxidized is proportional to its concentration in the blood (Haggard and Greenberg, 1934). When it is taken in fractional doses, a man of 70 Kg. can burn 240 cc. of alcohol in twenty-four hours (British Royal Commission, 1934). By the chemical energy thus liberated (about 7 calories for 1 Gm. of alcohol, or 4 calories for 1 cc. of whisky) alcohol can replace carbohydrates and fats in the diet. Although it is not used directly in muscular work, since this does not increase the rate of its oxidation (Carpenter, Lee and Burdett, 1933; Carpenter and Lee, 1938; Canzanelli, Guild and Rapport 1934; Nyman and Palmlov, 1934), its combustion conserves other energy material. and it is therefore used indirectly. Its utilization is complete and economical, for it does not increase the basal heat production (Le Breton and Schaffer, 1935; Grubbs and Hitchcock, 1938). By its poisonous side action, however, it may at first cause an increased nitrogen excretion in individuals not accustomed to its use; but this action disappears in a few days, and it then *saves nitrogen* like any other food.

When added to an ordinary diet, the CO_2 excretion, the oxygen consumption and the output of heat are not materially changed (Higgins, 1917). The alcohol therefore saves the other constituents of the diet from decomposition, and the body shows a corresponding gain in weight. If it is added to a diet deficient in carbohydrates or fats, the metabolism is the same as if an isodynamic quantity of these foods were added. When alcohol is added to a complete basal diet of rats, these grow more rapidly than the controls, with greater retention of nitrogen and decomposition of fat. In these respects it is about three-fourths as effective as equivalent quantities of sucrose (H. H. Mitchell, 1935). It spares carbohydrates in man even when large amounts of sugar are supplied (Toegel and co-workers, 1913). Alcohol can also be utilized in the form of rectal injections. Carpenter, 1917, found the respiratory quotient (in man) generally lowered in two to three hours after the injection of 25 cc. of alcohol diluted to 5 or 10 per cent (reviews, T. M. Carpenter, 1940; H. H. Mitchell and Curzon, 1940).

Food Value of Alcohol.—While alcohol is a food, in the sense of being a source of energy, other factors must be taken into consideration. The increased nutrition may itself be detrimental to the body, either by preventing the complete combustion of metabolites or by leading to an abnormal deposition of fat; for it decreases markedly the metabolism of fats, and somewhat that of carbohydrates (Carpenter and Lee, 1937). A more potent objection to considering alcohol as a generally useful food lies in its toxic action, especially its psychical effects. Alcohol should therefore be employed as a food only when a sufficient supply of energy cannot be obtained from an ordinary diet; as, for instance, in *digestive disturbances*, or when the demands on the organism are unusually large, as in *fever*. (The food value of alcohol was reviewed by H. H. Mitchell and Curzon, 1940.)

The proverbial *obesity* of persons addicted to the overuse of weak alcoholic liquids (in which the nutrient effect is less obscured by the toxic actions) is a striking illustration that too liberal a nutrition is not necessarily beneficial. That alcohol lessens the oxidation of metabolites is shown by an *increased excretion of uric acid and ammonia* nitrogen at the expense of urea (Paton and Eason, 1901; Mendel and Hilditch, 1910). This points to a modification of the functions of the liver. *Excessive doses* of alcohol are always detrimental to nutrition, lessening both assimilation and disassimilation. The effects resemble those of the anesthetics.

Rate of Oxidation.—Man can oxidize alcohol at the rate of about 10 cc. per hour; dogs about 0.185 cc. per Kg. per hour (Mellanby, 1919); mice about 0.65 mg. per Gm. per hour, about five times the human rate (Nicloux, Le Breton and Doutcheff, 1934). The rate of oxidation in rats increases with the concentration of alcohol in the blood, about 30 per cent for 100 mg. per 100 cc. (M. G. Eggleton, 1940). The oxidation of the alcohol is completed rather slowly; with 2 cc. per Kg., it requires about eighteen hours (Voeltz and Dietrich, 1915). In man, the combustion of 30 cc. requires about eight hours; of 45 cc., twelve hours (Higgins, 1917). The *rate at which alcohol is oxidized is fairly constant for a given individual* (for instance, the amount which must be injected intravenously to maintain a constant concentration level in the blood; Newman and Cutting, 1935). It is not significantly increased by *habituation* (dogs, 6.8 cc. per Kg. daily for thirteen months; Newman and Cutting, 1936); and small doses of alcohol give the same concentration in the blood, brain, liver and kidneys of habituated as of normal rats (Levy, 1938), so that tolerance is not due to increased destruction. The oxidation of alcohol by minced brain through acetaldehyde and acetic acid is effected by a nicotinic acid and riboflavin (J. G. Dewars, 1943).

The *liver* is apparently the chief site of the initial oxidation of alcohol, and insulin is necessary for this function. Excised diabetic liver does not oxidize significant quantities of alcohol, and this ability is restored by insulin injection (B. B. Clark *et al.*, 1939, 1941). The rate, however of alcohol oxidation, as judged by the blood level and urine excretion, is the same in diabetic as in normal subjects (A. E. Koehler *et al.*, 1944). The data as to the influence of *dextrose* and other carbohydrates with and without *insulin* on alcohol oxidation are confusing. Some investigators report that insulin increases the rate of oxidation of alcohol, especially if dextrose is also injected (B. B. Clark *et al.*, 1941), but others find no effect (R. Gregory *et al.*, 1943). The reasons for the contradiction are obscure. Lang and von Schlick, 1936, did not find any material change of the blood alcohol curve after insulin, caffeine or *thyroxin*. Preusse, 1933, and Widmark, 1935, also found that thyroxin treatment had no bearing on the effects or utilization of alcohol, contrary to Riesser and Hadrossek, and to Vollmer, who had claimed that thyroxin, lactate, glucose and methylene blue render mice less susceptible to alcohol. Large doses of *acetanilid* inhibit alcohol oxidation (N. Rakieten, 1942). *Dinitrophenol* increases the oxidation of alcohol by excised tissues. Safe doses do not do so in living animals (Newman and Cutting, 1935), or only slightly (P. L. Ewing, 1940), but the alcohol is more rapidly eliminated by the increase of pulmonary ventilation (Newman and Tainter, 1936). Similarly, increase of *external temperature* is said to lessen its oxidation, and to promote its excretion (thus 96 per cent oxidized at 16° C.; 92 per cent at 26°; Voeltz and Baudrexel, 1913). Hyperpyrexia by shortwave radiothermy does not materially increase its oxidation rate in dogs (P. L. Ewing, 1940). *Pituitrin* and epinephrine had no effect on the utilization (Widmark, 1935).

Acidosis, with decreased CO_2 capacity of the blood by 4 to 5 volumes per cent, results from large doses of alcohol (5 Gm. per Kg.) in dogs. The lactic acid of the blood is increased by 50 per cent, and after twenty-four hours is still 20 per cent above normal (B. B. Clark and Morrissey, 1938).

Effect on Nitrogen Metabolism.—In man, large quantities, corresponding to 96 cc. of 95 per cent alcohol (500 calories), divided into six doses per day, with constant diet, caused no pronounced disturbance in the alimentary utilization of food. These doses spared protein; the partition of the urinary nitrogen was unchanged, except that the *purine excretion*, both endogenous and exogenous, was increased. Larger doses caused a loss of nitrogen and a relative increase of urinary ammonia. Mendel and Hilditch, 1910, investigated the effects of moderate quantities on man and dogs. With smaller doses (40 cc. of rum, three times daily) and in individuals accustomed to its use, Hammett, 1916, found no increase of uric acid. Stehle, 1915, found no increase in the excretion of endogenous uric acid. Winterstein, 1914, claimed that alcohol increases the gas metabolism of the spinal cord of pigs.

The blood sugar level is somewhat raised by therapeutic doses of alcohol (12 to 17 Gm.) in normal individuals, but is lowered in diabetic patients. The effect appears in half an hour and lasts about five hours (Labbe *et al.*, 1927) It is probably not important. In well fed rats, intoxicant doses (3 Gm. per Kg.; but not 1 Gm. per Kg.) produce a marked increase of blood concentration and decrease of liver glycogen; this effect is absent if the liver glycogen has been depleted by fasting (D. M. Tennent, 1941).

Alcohol in Diabetes Mellitus.—Benedict and Förök, 1906, found that the replacement of 50 to 80 Gm. of food fat by isodynamic quantities of alcohol lessened the excretion of sugar, acetone and nitrogen. O. Neubauer, 1906, also reported it as useful. Higgins, Peabody and Fitz, 1916, found that alcohol (100 to 180 cc. of whisky per day) did not prevent acidosis in normal persons on carbohydrate-free diet. Mosenthal and Harrop, 1918, also found that alcohol was unable to replace isodynamic quantities of protein or even fat in conserving a nitrogen balance. Excessive quantities, however, cannot be expected to exert a favorable action, since the toxic effects will predominate.

Distribution of the Ingested Alcohol in the Tissues.—Since alcohol diffuses readily, it is quickly distributed through the fluids and tissues, so that its concentration is soon practically parallel to their water content (Nicloux, 1933), and inverse to their content of solids or lipoids; the oil: water *partition coefficient* of alcohol is 0.03:1 (Lindenberg, 1933). The concentration is therefore about a third lower in the tissues than in the blood, and a seventh higher in the urine than in the blood (Haggard and Greenberg, 1934). It is notably low in bone and in lipoid tissue. With these two exceptions, the concentration in all the tissues, including the brain, is fairly equal, after equilibrium has been established (Harger, Hulpieu and Lamb, 1937). One to one and one-quarter hours after ingestion, the alcohol concentration of most tissues is 70 to 80 per cent of the plasma concentration; that of fat is 10 to 20 per cent (M. G. Eggleton, 1940). The concentration of the alveolar air is also in equilibrium with that of the blood.

Because of the uniform distribution, *the concentration of alcohol in the tissues* may be deduced fairly closely by dividing the total quantity in the body by the body weight, with some deduction for bone and fat (Mellanby, 1919); the quantity in the body corresponds to the total amount absorbed, less that which has been destroyed or eliminated. The relation of absorption to destruction is determined chiefly by the dose and the time.

Vollmering, 1912, found that soon after absorption the ratio was blood > liver > muscle > brain. Later, the brain contained the most. Adipose tissue was slow to take it up, but retained it longer. Voeltz and Dietrich, 1912, found 3 to 12 per cent still present in the body fifteen hours after doses of 2 cc. per Kg.; 2 to 4 per cent had been excreted by the respiration, 0.4 to 4 per cent by the urine, and 90 per cent had been oxidized. *Quantitative tests* for alcohol in tissues are described by Gettler and Siegel, 1937, Am. J. Clin. Path., *7:* 85; a simplification of Widmark's (1930) test for blood, and so forth, by Abels, 1936, J.A.M.A., *109:* 294. The method of Nicloux, 1931, determines 0.1 mg. with a limit of error of 5 per cent. The specificity of these tests is discussed by Heise, 1934, and Tiffeneau, 1933. They depend on the reduction of bichromate and could therefore be vitiated by other reducing substances, but none such are likely to be present unless they were administered or added intentionally.

Concentration of Alcohol in the Blood.—With oral administration of a single dose, this ascends as a parabolic curve, with the maximum in one-half to two hours, in most cases between thirty and sixty minutes (Carlson *et al.*, 1934, give a succinct bibliography). It remains at this highest level for some time (the "Grehant plateau") and then descends gradually. The ascent is determined chiefly by the rate of absorption.

If adequate time elapses, the concentrations are practically identical in samples of blood from the arteries, veins and capillaries, and from different areas (Liljestrand and Linde, 1930), including the fetal blood (Kostitch, 1922), and also in the cerebrospinal fluid and the fluids of the eye; but it may take more than one hour to secure equilibrium, largely because of differences in the local circulation. For instance, when rats were killed by intraperitoneal injection of alcohol, 20 mg. per Gm., the concentrations (per cubic centimeter) found in the blood at the moment of death were: right heart, 16.0 mg.; arterial blood, 15.8, jugular vein, 9.4; femoral vein, 6.3 (Haggard and Greenberg, 1937).

Influence of Conditions.—The blood concentration course is not constant even for the same individual under like conditions; but *changed conditions* do influence it in definite directions (Tuovinen, 1930):

Fasting or with Food.—The blood concentration rises somewhat higher if the alcohol is consumed fasting (as the preprandial cocktail) than with food (Widmark, 1915; Southgate and Carter, 1926; Tuovinen, 1930), owing to the more rapid passage into the duodenum. The difference, however. is not great.

Concentration in Which the Alcohol is Taken.—The results are so contradictory that the effect may be considered negligible: It has been reported that the concentration in the blood rises with the concentration in which the alcohol is taken (Simonin, 1930); that it is higher between 5 and 20 per cent than between 40 and 60 per cent (Tuovinen, 1930); and that it makes no material difference (Widmark, 1915).

Muscular exercise tends to lower the concentration somewhat (Cassinis and Bracaloni, 1930), by the increased pulmonary ventilation; but the difference is scarcely appreciable (Carpenter and Lee, 1938). Increased *altitude* above sea level (Biehler) and presumably also *fever* would similarly tend to lower the concentration; but the concentration is reported to rise more rapidly at high altitude, and (temporarily) to a higher level (R. A. McFarland and Forbes, 1936). The administration of *dextrose* (25 Gm.) with insulin (15 units) to acutely intoxicated individuals doubled the rate of fall of alcohol concentration in their blood (W. Goldfarb *et al.*, 1939). *Insulin* alone has no effect on the alcohol concentration or symptoms even in diabetic patients. Injection of *posterior pituitary* extract lowers the alcohol concentration, in normal individuals and in diabetes insipidus. *Diuresis by increased water intake* does not alter the concentration materially (Blotner, 1939).

Habituation.—The blood concentration generally rises and falls more rapidly in those accustomed to alcohol; the peak concentration may be higher or lower than in abstainers, but it is not maintained as long (Fleming and Stotz, 1935; Bogen, 1927). The chief cause of the tolerance, however, is psychic adaptation to the effects.

The *actual concentration with different doses* averages close to a peak blood concentration of 0.001 per cent of alcohol per 1 cc. of alcohol ingested (about two-thirds of the concentration which would obtain had all been absorbed and none destroyed). Conversely, the peak concentration of 0.01 per cent would be attained by 10 cc. of alcohol, 25 cc. (nearly an ounce) of whisky, or 300 cc. (nearly a bottle) of 3.2 per cent beer.

The *urine concentration* ranges from one-half to twice the concentration of the blood, but one and one-third may be taken as a fair average; or conversely, the blood concentration may be taken as three-fourths of the urine concentration (Carlson *et al.*, 1934; Bornstein and Budelmann, 1930). The error probably falls well within the range of variation of physiological response, so that the urine determination may be substituted when blood is not practicable, especially if the bladder is emptied in half-hour intervals. Absorption of alcohol from the bladder is insignificant with concentrations that occur after alcohol is drunk (H. W. Haggard *et al.*, 1940). Diuresis by forced water intake does not alter the alcohol concentration of the urine (Blotner, 1939). Glucose administration also has little effect (Carpenter and Lee, 1937).

Cerebrospinal Fluid Concentration.—Alcohol is excreted freely into this fluid (as are also acetone and chloroform, Hald, 1911), and this has long been used for the diagnosis of alcoholic psychosis (Selig, 1913), as demonstrable quantities may persist for ten days (Lenoble and Daniel, 1917). Its concentration curve is similar to that of the urine and blood (Bogen, 1927); but there is a distinct lag in the ascent, especially with the lumbar fluid, even after intravenous injection. With oral administration, when the peak concentration is reached in twenty minutes for the blood, the cisternal fluid does not reach this level till after fifty minutes, and the lumbar fluid not till after three hours; so the intoxication symptoms are at their height when the lumbar fluid concentration is still low. This is therefore useless for the chemical diagnosis of alcoholic intoxication unless an hour or, better, three and a half hours have elapsed (Newman and Mehrtens, 1933). It is not clear why it should be used even then, since the urine and expired air are at least equally reliable, and the blood is more so.

Gettler, 1931, reported that the *brain* shows somewhat lower alcohol concentrations than the cerebrospinal fluid, probably because of its lower water content. *Epinephrine* potentiates the depressant action of alcohol. U. Friedemann ascribed this to increased permeability of the brain capillaries, "auxoneurotropic" action. Hulpieu and Cole, 1946, attribute it to alteration in the circulation.

The *saliva concentration* agrees closely with the blood and may be used as index of intoxication (Abels, 1936).

Ocular Fluids and Lens.—Nicloux and Redslob, 1931, found the concentration in the vitreous humor the same as in the blood; that of the lens was about one-half.

The *expired air* gives a fairly uniform relation to the alcohol concentration of the blood (Liljestrand and Linde, 1930), especially when the dilution with tidal air is discounted by determining the ratio of alcohol to CO_2: the weight of alcohol per 190 mg. of CO_2 (about 4 liters of expired air) equals the weight of alcohol per cubic centimeter of blood (Harger, Lamb and Hulpieu, 1938; details of method). The concentration in the air is highest inthe first fifteen minutes after ingestion, and is low in three hours (Carpenter and Lee, 1938).

Relation of the Alcohol Concentration (in the Blood or Urine) to Inebriation.—These correlate closely in a given individual so that they may be used as a *chemical* test of drunkenness; but different individuals do not react equally. The following compilation gives the usual range of responses, to increasing venous blood concentrations, which is the most reliable criterion (Ellerbrook and Van Gaasbeek, 1943); for the urine these would average a third higher. In translating these back to dosage, it may be accepted that the alcohol concentration of the blood is practically in simple proportion to the quantity taken, and that between half an hour and five hours after taking it, 0.01 per cent of alcohol in the blood corresponds to a dosage of 10 cc. of alcohol, or 1 ounce of whisky, or a 12-ounce (300 cc.) bottle of beer. The compilation indicates little if any change below 0.01 per cent; somewhat decreased competence with 0.015 per cent, and definitely decreased competence with 0.06 per cent; with 0.1 per cent a third of the subjects are diagnosed clinically as inebriated; at 0.15 per cent half are so diagnosed. This is generally accepted as the "critical concentration" for the *chemical diagnosis of drunkenness, i. e.,* 0.15 per cent in the blood, or 0.2 per cent in the urine or 1 mg. per liter of expired air; corresponding to 150 cc. of alcohol, or about a pint of whisky or about ten bottles of beer. This may be justifiable as a basis for legal action, but it should be remembered that a third of the subjects reach this stage with two-thirds of the concentration and that a tenth of this quantity impairs judgment.

Various "raw" liquors, "moonshine," and the like, all give the same concentrations for the same degree of intoxication (Bogen, 1927).

The compilation is chiefly from Bogen (B); from Carlson and associates (C), 1934, on beer; from Tuovinen (T), 1930; from Miles (M), 1933; and from Widmark (W), 1932 and 1934. Widmark's series covers the official reports on automobile accidents in Sweden, some 560 cases by 1932, including the clinical diagnosis by the physicians (150 in this series), and the chemical determination in the blood by Widmark's micro-method (Biochem. Ztschr., *131:* 473, 1922), which includes acetone, acetaldehyde, glycerol and organic acids; but their variation is negligible in comparison with alcohol.

Correlation of Alcohol Content of the Blood (Per Cent) with Clinical Symptoms.—*Effects doubtful:* 0.006 to 0.01: Initial stimulation phase begins (T); behavior tests practically normal (B and others).

Effects slight (0.01 to 0.05 per cent):

0.015: Decreased accuracy in typing tests and increased seriousness of automobile accidents (Heise, 1934),

0.02: Subjective effects: Slight dizziness, warmth, comfort; pleasant, sociable (M); although

0.027: Showed no change in other types of performance tests, or in visible behavior (C).

0.03: Mild euphoria, feeling of "good fellowship" (M); visible behavior and behavior tests, practically normal for most.

0.05: "On top of the world"; normal inhibitions greatly weakened, boastful, clumsy.

Effects definite, but not marked (0.06 to 0.1 per cent):

0.06: Notable decrease of motor control (Romberg test) in C's series. One subject in fourteen showed incoordination and loss of control.

0.07: Feeling of remoteness; upsets chair on rising (M). In the W series, none under 0.08 were diagnosed clinically as inebriated, but between

0.08 to 0.1: A third were diagnosed as conspicuously "under the influence"; at

0.1: Staggers perceptibly; talks to himself; speech slurred and confused; fumbles long with keys (M).

0.15: Definitely drunk, but not helpless. Half were diagnosed as under the influence in the W series. In C's series with beer, the performance tests were distinctly poorer, eleven subjects in twelve showed gross changes in behavior, and two out of three vomited.

Helpless and fatal (0.2 per cent upward):

0.2: Emotional and cross; needs help to walk or undress; one in five unable to speak; nauseated; poor control of urination (M).

0.225: Practically all were diagnosed as inebriated (W).

0.265: All were so diagnosed (W).

0.3: Stuporous, sleeping and vomiting by turns; combative when aroused.

0.4: Comatose in most cases.

0.5: Always fatal clinically, generally several hours or even days after onset of coma. Death sometimes occurs with considerably less than 0.5 per cent (W. W. Jetter, 1943).

For dogs, Turner 1932, found definite intoxication with 0.25 per cent; pronounced with 0.3, stupor with 0.4 per cent. Death did not occur with 0.55 per cent.

A "*critical concentration*" of *drunkenness,* widely accepted for legal purposes, is 0.15 per cent in the blood, 0.2 in the urine, generally equivalent to 150 cc. of alcohol, about a pint of whisky, or about ten bottles of beer; but it should be remembered that one in three may reach this state with two-thirds of the quantity; and that a tenth of this quantity impairs judgment. On the other hand, at 0.15 per cent, half were diagnosed as not drunk, and even at 0.18, one in five escaped this diagnosis, in the (W) series. Other studies (S. Smith and Stewart, 1932) have confirmed the variability of the borderline concentrations in different individuals as to psychological and police tests. The A.M.A. Committee of 1939 recommended that persons with less than 0.05 per cent by weight of alcohol in the blood (or corresponding amounts in other fluids) should not be prosecuted for driving "while under the influence of alcohol"; those with 0.05 to 0.15 per cent only if physical examination gives definite confirmation of being "under the influence"; and that 0.15 per cent or more should be considered sufficient evidence of such detrimental "influence." The National Safety Council, 1944, made analogous recommendations.

Epinephrine, if administered before the alcohol, increases the narcosis beyond what would correspond to the blood level (the *auxoneurotropic* action of Friedemann). This is attributed to the diversion of a greater quantity of alcohol to the brain, by the epinephrine contraction of the blood vessels in other areas (H. R. Hulpieu and Cole, 1946).

Blood Sugar Level and Fatal Dose.—Haggard and Greenberg, 1937, reported for fasting rats that the alcohol concentration in the jugular vein blood at the moment of death varies directly with the blood sugar level, so that death occurs at 0.8 per cent of alcohol with 0.07 per cent sugar; at 0.95 per cent with 0.1 per cent of sugar; and at 1.2 per cent alcohol with 0.2 per cent of sugar. The blood sugar therefore appears to protect against alcohol fatality. The explanation is not clear.

Habituation on the Response to Concentration.—Bogen, 1927, reported that at any given concentration level, habitual drunkards show the same symptoms as those not accustomed to alcohol, but this lacks confirmation. In rats, habituated animals require a higher concentration of alcohol in the brain for intoxication than do normal animals (Jeanne Lévy, 1934).

Castration lowers the resistance of female rabbits to the acute narcotic action of alcohol, and their resistance is increased by administering estrone, so that intoxication requires higher blood levels. The general metabolism of alcohol is not affected; thus the mechanism appears to be central (L. Goldberg and Störtebecker, 1943).

Existence of Alcohol in Normal Tissues.—A trifling quantity of alcohol appears to be produced in the tissues in the course of normal metabolism. Its presence was claimed by W. H. Ford, 1872, confirmed by Landsberg, 1904, and identified through transformation into ethyl iodide by Gettler, Niederl *et al.*, 1932; but the quantity is extremely small. In human material, Hargen and Goss, 1935, found none to 0.027 mg. per 100 Gm. in the blood; 0.05 to 0.12 in the brain; 0.085 to 0.227 in the liver; 0.044 to 0.142 in the kidneys; and 0.060 to 0.185 in the urine. Hog brain contained 0.47; dog's, 3.0. McNally, Embree and Rust, 1937, found 1.1 to 5.2 in human placenta. The highest figure for urine is only a twentieth of the lowest concentration that gives recognizable effects. Reach, 1907, reported that fresh rabbit's muscle contains to 0.0017 per cent of alcohol; the liver may contain 0.02 to 0.14 per cent. Voeltz and Dietrich, 1915, recovered a total of about 0.1 cc. from normal dogs. Dakin believed that this "normal" alcohol is not formed in the tissues, but by intestinal fermentation; but Taylor, 1913, found it even after the removal of the entire digestive tract.

Acute Alcohol Poisoning.—The *narcotic stage* is characterized by a combination of most or all of the following symptoms (British Association Committee): odor of breath or vomitus; dry furred tongue, or excessive salivation; irregularity of behavior—insolence, abusive language, loquacity, excitement, sullenness, disorder of dress; suffusion of conjunctiva; abnormality of pupils, which may take various forms; convergent strabismus (esophoria), but with undiminished visual acuity (Colson, 1940); hiccup; loss or confusion of memory, especially of recent events, and of appreciation of time; speech hesitant, thicker; impaired articulation; tremors; errors of coordination and orientation: Romberg sign, manner of walking, of turning sharply, of sitting down and rising, of picking up coin or pencil from the floor.

The *anesthetic stage* sets in as consciousness, sensation and muscular tonus are gradually lost. The plasma volume is increased by withdrawal of tissue fluid to dilute the Na and Cl retained by temporary renal impairment (W. B. Nicholson and Taylor, 1940).

In the *paralytic stage* proper, the symptoms are those of beginning medullary paralysis: the respiration is slow and stertorous; the pulse, scarcely discernible; the skin, cold and cyanotic; the pupils are generally dilated; the reflexes, abolished. The temperature falls severely. The odor of the breath is diagnostic. If large doses have been taken on an empty stomach, the paralytic symptoms may set in at once.

Recovery.—The coma—if the intoxication has progressed so far—passes into natural sleep, often with sweating. On awakening there follows a series of symptoms, the "hangover," pointing mainly to *acute gastric catarrh*, and perhaps to cerebral edema and to functional neuritis, and grouped by the Germans under the name of "Katzenjammer": headache, coated tongue, loss of appetite, irritable stomach, diarrhea, muscular pains, and so forth, The *skin*, after severe alcoholic poisoning, may show effects resembling those of contusions or burns: edema, blisters, extravasation of blood, and gangrene. Bedsores are common. A few cases of total functional blindness of both eyes have been reported, with normal pupillary reactions and normal fundi. They improve rapidly (F. D. Carroll and Goodhart, 1938).

Death is relatively rare. It may occur within half an hour, or the coma may grow deeper and terminate in paralysis of the respiration or the heart, or in pulmonary edema, generally within twenty-four hours. If the coma lasts beyond thirteen hours, recovery is exceptional. Death may also occur later, either from prolonged coma, or after a protracted debauch, as the result of gastric irritation and exhaustion. The *acute fatal dose* is probably variable. In analogy with animals, it would require about a quart of whisky; cases of death from a pint are recorded (Lewin). With children, 100 to 200 cc. of 50 per cent alcohol is fatal.

Treatment of Acute Alcohol Poisoning.—*Ordinary drunkenness* treats itself adequately with time and sleep. Strong coffee or aromatic spirits of ammonia may serve as temporary stimulants, and paraldehyde as sedative. With *severe intoxication*, the stomach should be evacuated by lavage or perhaps preferably by apomorphine, which acts also as hypnotic. With *coma*, dextrose may be injected intravenously. Dangerous depression of respiration and cyanosis indicate oxygen inhalation, especially as alcohol intoxication increases the susceptibility to oxygen deficiency (Barach, 1934); but practically the benefit is not great (Butler, 1936).

The addition of 5 or 10 per cent of carbon dioxide has been advocated to promote pulmonary ventilation, but this effect is insignificant and does not modify either the symptoms or the toxicity (Newman and Card, 1936; Fleming and Reynolds, 1935). However, H. W. Haggard *et al.*, 1940, reported that CO_2 inhalation by stimulation of the respiratory center definitely increases the blood concentration which must be attained to stop respiration (normally, 0.89 to 1 per cent). The following did not alter the fatal level: caffeine, dinitrophenol, strychnine, amphetamine, sodium bromide, acetanilid and related antipyretics. Morphine lowered the fatal level markedly. Pilcher, 1912, had shown that the administration of caffeine is useless in serious poisoning and may be detrimental. Amphetamine, metrazol, picrotoxin and coramine have a limited mutual antagonism with alcohol in rabbits (H. W. Werner, 1939), but it is doubtful whether they should be used clinically. Amphetamine, for instance, lightens the narcosis of moderate doses of alcohol, but increases the toxicity of near-fatal doses (Reifenstein, 1940). The *"morning after"* may be treated with coffee, analgetics, bromide, magnesia, bicarbonate or citrate (against the acidosis; B. B. Clark and Morrissey, 1938), and, if severe, by gastric lavage.

Poisoning by Denatured ("Industrial") Alcohols.—Alcohol for industrial use is mixed with nauseant, irritant and toxic substances to render it unfit for drinking and so secure exemption from the internal revenue tax. The Journal of the American Medical Association, 1920 (*74*:343), describes the usual formulas. The "*Industrial Methylated Spirit*" of the B.P. is a mixture of 19 volumes of alc. (95 per cent) with 1 volume of wood naphtha, chiefly methyl alcohol. Such spirits produce the effects of the added poison along with those of the alcohol, and are much more dangerous than ethyl alcohol. The use of wood alcohol for denaturing industrial alcohol is especially unfortunate, since prolonged exposure to vapors from alcohol containing only 4 per cent of methyl alcohol has given toxic eye symptoms (J. M. Robinson, 1918). The drinking of spirits containing only 1 per cent of wood alcohol is said to result in visual disorders, generally after three or four months, or with large doses (Eleonskaia, 1916).

Peculiarities of Alcoholic Beverages and their "Impurities."—Whisky, brandy and other distilled spirits that contain 40 to 50 per cent alcohol are termed *"potable" spirits*, since higher concentrations cannot be conveniently swallowed until they are diluted, because of the choking reflexes from the local irritation. The fresh or "raw" distillates, including "moonshine" and other illegitimate liquors, contain other higher alcohols and ethers and esters formed from these, called collectively "fusel oil," sufficient to give a strong and disagreeable flavor. These may be removed almost completely by fractional distillation (completely so for synthetic alcohol), yielding the nearly unflavored "neutral spirits"; or they may be diminished and modified by "aging" in wooden barrels, especially charred, for two years or longer. This gets rid of the disagreeable substances, by adsorption and oxidation, and develops the desired bouquet, through formation of the so-called "oenanthic" ethers. This process, which furnishes the "straight" liquors, entails considerable loss by evaporation, as well as the storage costs (storage in glass does not age distilled liquors). Various shortcuts have been devised, especially dilution of unaged or partly aged liquors with neutral spirits, resulting in "blended liquors"; but this term may also be applied to mixtures of naturally aged spirits. "Factitious liquors" are made by adding flavoring substances to neutral spirits.

The impression prevails that the "impurities" add materially to the harmfulness of the liquors, but practically all scientific investigations have confirmed the conclusion that there is practically no objectively discoverable difference in action between any of the potable spirits, ranging from the rawest to the most delicate. They are all about equally and insignificantly more irritant and more toxic than pure ethyl alcohol. The differences are purely in the flavor and its psychic suggestions. This could be deduced from the nature and quantity of the impurities. The "*fusel oil*" of raw grain alcohol, which is popularly considered the chief offender, amounts to only 0.2 per cent of the alcohol, corresponding to 0.08 cc. per 100 cc. of whisky; and about 95 per cent of this small quantity consists of amyl, butyl and propyl alcohols (Bell, ref. report of Select Committee, British Parliament, 1891), which are but little more toxic than ethyl alcohol; the unidentified remainder, amounting to only 4 mg. in the 100 cc. of whisky, is no more toxic. Acetaldehyde in raw whiskies may amount to 0.1 per cent (Doran and Beyer, 1923), and this might add slightly to the local irritation, but evidently not enough to be appreciable. *Furfurol*, (about 0.005 per cent in "pot still" liquors) formerly believed to modify the intoxication, does not appear to do so. (Larger doses are convulsant, Laborde, 1888; McGuigan, 1923. It is used as a paint and varnish remover; Gardner, 1923.)

Various Royal British Commissions which have investigated the subject scientifically have all come to the conclusion that the fusel oil is distasteful but not harmful even in the worst specimens examined by them; but the cheaper liquors are likely to be consumed in larger quantities and in debauches, which probably accounts for their sinister reputation. In animals and patients, Chopra, 1927, found the toxicity essentially identical for aged, immature and "factitious" spirits. Bogen, 1927, found that various "raw" liquors give the same degree of intoxication for the same blood concentration of alcohol, as does alcohol itself or aged spirits. Barlow, 1936, in an extensive experimental investigation on animals and men, comparing the purest synthetic ethyl alcohol, pure grain alcohol, blended whisky and straight whisky, found no difference in any respect qualitatively and practically none quantitatively, although the toxicity and local irritation did increase slightly in the order given. Perhaps the only investigation that suggests a difference is that of MacNider, 1924, who reported a greater tendency to albuminuria in dogs, for "moonshine" liquors; but this is not a common feature in clinical intoxication.

As to other liquors, most of the traditional differences probably depend upon the circumstances under which they are ordinarily consumed. *Brandy* does not differ from whisky except in flavor. With *gin*, the juniper iol, adds to the diuretic action. *Beer* is diuretic by the volume of its water, and its somnifacient action is probably enhanced by the lupulin of the hops. *Absinthe* gradually niduces mental hallucinations.

The annual per capita consumption of alcoholic beverages in the United States in 1936 was estimated as 11 gallons of beer, 1 gallon of distilled liquors, and 0.44 gallon of wine (J. A. Waddell and Haag, 1938).

***Alcohol**, U.S.P. (Ethanol, Spiritus Vini Rectificatus), contains not less than 92.3 per cent by weight, 94.9 per cent by volume, of C_2H_5OH. Colorless, volatile liquid, of characteristic odor and burning taste. Freely miscible with water, ether, chloroform, and so forth. Since condensation occurs on mixing alcohol and water, the percentage of the resulting product cannot be deduced by a simple ratio. Tables for making the commonly needed percentages by the dilution from the official alcohols are given in the U.S.P. and B.P. *Dehydrated Alcohol*, U.S.P. (Absolute Alcohol or Ethanol), is not less than 99 per cent by weight of C_2H_5OH. Very hygroscopic. *Diluted Alcohol*, U.S.P., a mixture of equal volumes of official alcohol and water, contains 41 to 42 per cent by weight or from 48.4 to 49.5 per cent by volume of C_2H_5OH.

Whisky, N.F. (*Spiritus Frumenti*), is an alcoholic liquid obtained by the distillation of the fermented mash of malted cereal grains, and contains between 47 and 53 volume per cent of alcohol. It must be aged in wood at least two years. *Brandy*, N.F. (*Spiritus Vini Vitis; Spir. Vini Gallici, Cognac*), is distilled from grape wine and contains 48 to 54 volume per cent of alcohol, aged in wood for at least two years. Other distilled spirits have about the same alcohol concentration: *Holland Gin*, distilled over juniper berries; *Rum*, from molasses; *Arrack*, from rice, and so on.

Wines are made by fermenting the expressed juice (must) of the grape. If this contains the skins of dark grapes, the wine will be red; if made from light grapes, or from the juice of dark grapes without skins, it is "white," *i. e.*, an amber color. A wine which contains much alcohol (15 to 20 per cent) is "generous"; one poor in alcohol, "light"; one containing much sugar, "sweet"; poor in sugar, "dry." If it contains CO_2 it is "sparkling"; if tannin, "rough" or "astringent"; if acid tartrates, "acidulous."

Malt liquors contain alcohol, CO_2, sugar and usually hops. The color varies from pale amber to dark brown, the difference being due mainly to charring of the malt. Lager beer is made by slow fermentation at a low temperature; porter, ale and stout, by rapid fermentation at a higher heat.

The alcohol percentage of the principal alcoholic beverages is (by volume): 18 to 23 per cent: Sherry (Vinum Xericum), Port (Vinum Portense), Madeira, Marsala, Tokay, Malaga. 10 to 17 per cent: Champagne, Claret, Rhine Hock), Catawba. 6 to 13 per cent: Cider (from apples) (Perry (from pears) and other fermented fruit juices

3.5 to 7 per cent: Ale, Porter, Stout and Export Beers.
2.5 to 3.5 per cent: Lager Beers, Fermented Milks (Kumiss, Yogurt).

THE HABITUAL MODERATE USE OF ALCOHOL

A certain amount of alcohol, varying for individuals, may be taken occasionally or daily without demonstrable permanently injurious effects. The relaxation, the easing of strain, of maladjustments, of excessive self-consciousness, of excessive inhibitions, indeed the euphoria, may sometimes be beneficial; but they may also lead to diminished efficiency, especially in accuracy; impaired judgment; increased liability to automobile accidents; loss of self-reliance; perhaps diminished resistance to disease; danger of excesses, periodic or continuous; higher incidence of venereal diseases; and general disrespect for law and order. On the other hand, the moderate use of alcohol is often blamed for shortened duration of life and for various physical injuries, without adequate data, or on the basis of effects produced only by large quantities.

The Research Council on Problems of Alcohol, 1946, claims that fifty million persons in the United States take alcohol, that 6 per cent of these become excessive drinkers, and that 1½ per cent become chronic alcohol addicts. The amount spent annually in the United States on alcoholic drink is given as seven billion dollars.

Duration of Life.—It has been claimed, on the basis of life insurance statistics, that the average duration of life is distinctly less for those who habitually drink alcohol, even in moderate quantity, than for total abstainers. Raymond Pearl, 1938, considers that this deduction is mistaken, and that there happens to be rather an increase. Heavy drinking definitely shortens longevity. Rats receiving 5 per cent of ethyl alcohol in their drinking water, and averaging for nine months a daily consumption equivalent to 2.1 cc. of absolute alcohol per Kg. of body weight, are somewhat sluggish and stupid, but their mortality rate was not significantly different (L. L. Boughton, 1944). On the other hand, Arlitt, 1919, claimed that the duration of life is shortened.

Diminished Resistance to Pneumonia and Other Infections.—Capps and Coleman, 1923, found that the mortality rate in 3500 pneumonia patients at Cook County Hospital rose from 22.5 per cent for total abstainers and occasional drinkers, to 34.4 per cent for "moderate" drinkers, and 49.9 per cent for heavy drinkers. The "moderate," however, extended over a heterogeneous group, from the daily consumption of a glass of beer to heavy drinkers and occasional drunkenness. Increased susceptibility to *other infections* has been demonstrated experimentally on animals acutely intoxicated by alcohol. This may be explained by the observation of Pickrell, 1938, that alcoholic stupor breaks down the resistance of rabbits previously immunized to pneumococci, by changes in the capillary endothelium which prevent the dilatation and increased permeability with which it normally reacts to infection, in this way hindering the emigration of protective leukocytes. Polynuclear leukocytes also fail to gather about bacterial injections into the skin of alcoholized rabbits (R. H. Rigdon, 1943). Mueller, 1904, Wirgin, 1905, and others found that the *formation of antibodies is lessened* if rabbits are kept mildly intoxicated for several days after the injection of an antigen. Laitinen, 1907, reported that small doses (0.1 cc. per Kg., daily) suffice to render the erythrocytes less resistant to hemolysis, and also lessen the resistance to infectious diseases. He asserted that this lessened vitality is transmitted to the offspring. For human subjects, Reich, 1915, claimed diminished resistance of erythrocytes to hypotonic solutions, and slight decrease of the bactericidal action of serum against typhoid bacilli. The effects, however, varied greatly, so that it is difficult to estimate their importance. Phagocytosis was not affected.

Diminished Resistance to Poisons.—Hunt, 1907, found that the long-continued administration of small quantities of alcohol to mice or guinea pigs increases their susceptibility to the fatal action of *acetonitrile.* This is attributed to a derangement of metabolism which hastens the decomposition of the nontoxic nitrile into the cyanide. It is not produced by methyl alcohol, chloral, and so forth.

CHRONIC ALCOHOLISM

The excessive use of alcohol, the habitual consumption of large quantities for long periods, leads to functional and organic changes, the latter compounded of local irritation, capillary injury, fibroses, neuritis, and others less definite. The most frequent lesions are mild inflammation and possibly atrophy of the gastric mucosa; edema and congestion of the brain and meninges; possibly minor alterations in the kidneys; occasionally hepatic cirrhosis (A. W. Wright, 1941). The effects are partly direct, partly the result of malnutrition and vitamin deficiency, which are difficult to disentangle.

Gastro-Intestinal Irritation.—The first results are local, and depend largely on the concentration of the spirits; but vitamin deficiencies and nervous irritability play a part. Catarrh of the alimentary canal progresses from the pharynx downward, with the usual symptoms of catarrhal gastro-enteritis: loss of appetite, gastric distress, irregularity of stools, craving for spices, and so on. In excessive beer drinking the habitual overdistention of the stomach leads to chronic dilatation.

Seventy per cent of the patients with chronic alcoholism are said to have gastric disorders; 50 per cent, achylia; 40 per cent, morning nausea. However, W. B. Seymour Spies and Payne, 1939, found their group of chronic alcohol addicted patients singularly free from gastric complaints. L. H. Berry, 1941, observing a hundred persons with chronic alcoholism of long standing, found definite gastritis in about a third, mild gastritis in another third, and no gastritis in the remaining third. An extensive *review* of the effects of alcohol on the digestive tract is given by Beazell and Ivy, 1940.

Malnutrition and emaciation result from the gastro-intestinal irritation, nervous disturbances, vitamin deficiencies and generally inadequate food, owing to anorexia and often to economic distress. The malnutrition in turn is partly responsible for the neuritis, the central nervous disturbances and the skin changes.

Growth.—Daily consumption of alcohol by young rats, in doses of 2.5 to 10 cc. per Kg. for twenty weeks, produced prompt and marked retardation of growth. The effect was about as marked with the lower dosage as with the higher, and with dilutions of 2½ per cent as with 10 per cent (Sollmann, 1920).

Degenerative Changes in Internal Organs.—The continued presence of alcohol in the body sets up a series of low grade irritant and degenerative phenomena in various other organs with which it comes in contact. These changes consist in fatty infiltrations, cellular degeneration, and hypertrophy of connective tissue. They involve chiefly the liver (cirrhosis) and the kidneys. The dilatation of the skin vessels (bibulous nose, acne rosacea) may be diagnostic. Statistical studies indicate, however, that alcohol is not concerned in arteriosclerosis (Cabot, 1904, autopsies) or angina pectoris. The incidence ratio of heavy, light and nondrinkers is practically the same for patients with angina as for those with normal hearts (White and Sharber, 1934).

The necrotic changes in the tissue cells may be attributed to the continued irritation from the constant presence of the alcohol; to this must be added the interference with circulation due to the changes alcohol causes in the blood vessels. Both concur in the production of the degenerations. Of these, the fatty are the most common, since alcohol, by its combustion, prevents the normal consumption of fat. Repeated administration of alcohol to dogs, for several days, uniformly increased the *total fat of the liver*, sometimes to 300 per cent. The *cholesterol content* was also somewhat increased (Ducceschi, 1918). Connective-tissue formation results as a consequence of necrosis of the parenchyma.

Hepatic cirrhosis has a definite connection with chronic alcoholism, which probably acts as a predisposing cause, by interference with proper nutrition, producing successively fatty infiltration, perilobular fibrosis and eventually portal cirrhosis (C. L. Connor, 1938; C. H. Greene, 1943). *Pancreatitis* has also been reported (E. Clark).

In America, half to two-thirds of the patients with Laënnec's cirrhosis have a history of excessive alcohol consumption (Ratnoff and Patek, 1942); the frequency of cirrhosis was notably less during the prohibition years (N. Evans and Gray, 1938). Cirrhosis, however, develops in only a minority of alcoholic subjects, variously estimated as 1 to 30 per cent (Ratnoff and Patek); and about two-thirds of the deaths from cirrhosis are of noninebriates (Jolliffe and Jellinek, 1942). There is no satisfactory evidence that alcohol produces cirrhosis directly; nearly all investigators agree that it does not do so in animals, nor do contaminants of alcoholic beverages give clear-cut results (review, P. György, 1944).

Dietary hepatic cirrhosis is produced in rats by diets deficient in protein, specifically of methionine, and vitamin-B-complex factor (György and Goldblatt, 1942). The chief factor is a high ratio of cystine : methionine, and improvement follows if methionine is increased (P. György, 1944). Addition of alcohol to the deficient diet increases the cirrhosis (J. V. Lowry *et al.*, 1942).

Defective diet is a common occurrence in chronic alcoholism, and furnishes the presumptive explanation. Patek and Post, 1941, claimed amelioration of clinical cirrhosis by diet rich in the B complex.

The degenerative changes in the *kidneys* lead to nephritis, with cirrhosis, albuminuria, diminished secretion of urine, secondary weakening of the heart, and so forth; but there is no conclusive evidence that alcohol is a causative factor in Bright's disease or arteriosclerosis (review, M. Bruger, 1940). The *heart* itself, however, in common with skeletal muscle, shows primary fatty degeneration. This, together with the atheroma, and so on, leads to hypertrophy and dilatation of the viscus, and later to dropsies, and like results. The heart rate is generally rapid. The fatty changes in *voluntary muscle* lead to muscular debility, especially in beer drinkers, in whom there is more material for fat formation. *Gout* is a common sequence of moderate alcoholism. The *respiratory organs* show chronic catarrhal inflammation of the passages, and a disposition to fatal pneumonia. *Changes in the skin*—vascular ecchymoses, acne rosacea, disposition to furuncles and carbuncles—may be counted among the earlier actions.

These various anatomic lesions of important organs result in a pronounced *lowering of resistance*, and a high mortality with infectious diseases and operations. It appears that the amount of antitoxic complement is lessened.

Experimental chronic alcoholism, in rabbits, produced fatty changes in the heart, liver and kidneys, and cellular infiltration of the pia (Lissauer, 1913). Hepatic changes occur also on intravenous injection (Schafir, 1913). In the heart, Otto, 1914, found degenerations of ganglion cells, atrophy of muscle, and scar tissue. Large single doses (4 cc. per Kg.) may also cause changes. Single small doses do not leave any lesions (v. Otto, 1914).

Nephrotoxic Effects in Dogs.—MacNider, 1925, reported that whisky produces much more damage than pure alcohol. He described albuminuria, polyuria, fatty infiltration of the glomerular vessels, more severe in dogs which were already nephropathic.

Nervous phenomena may be central and peripheral, organic and functional. Tremor of the hands and tongue sets in early; *periph-*

eral neuritis comes later, chiefly from vitamin deficiency. Optic neuritis occasionally results in blindness.

Vitamin deficiency as the causative factor in alcoholic polyneuritis was suggested by G. C. Shattuck, 1928, and G. R. Minot, 1929. It was established by Blankenhorn and Spies, 1935, who found that polyneuritis is curable by vitamin rich diet, even though the patients continued to consume whisky at the rate of a pint to a quart daily. Jolliffe, Colbert and Joffe, 1936, confirmed that the incidence (or absence) of polyneuritis in alcoholic addicts corresponds closely to *thiamine deficiency* in their diet and that marked improvement occurred with the administration of this substance (Jolliffe and Colbert, 1936). However, M. R. Brown, 1940, found that a series of patients with alcoholic polyneuritis improved quite as well on the ordinary hospital diet as when intensive thiamine and parenteral liver therapy were added. Ethyl alcohol mobilizes *vitamin A* from its tissue stores, increasing its concentration in the blood (S. W. Clausen *et al.*, 1940), and causing temporary improvement in twilight vision (Pett, 1940).

Mental Manifestations.—Lassitude and diminished activity and changes of temperament (confirmed on mice; Nice, 1912) occur early, followed considerably later by mental deterioration, habituation, stultification, and sometimes hallucinations, delirium tremens, paranoia, Korsakow's psychosis; also organic brain changes and neuritis (review, Seliger and Cranford, 1945). A good part of the mental phenomena are only indirectly related to alcohol, and in many instances they are the cause rather than the result of alcoholism.

Ten to 30 per cent of the cases of *insanity* have been attributed directly to alcoholism; but Heron, 1912, found the proportion of mental defects as high in the recent as in old cases of alcoholism. *Epilepsy*, which is a hereditary nervous disease, is seventy times as frequent in alcoholics as in the general population. These facts illustrate how frequently alcoholism is the result rather than the cause of mental degeneration.

Alcoholic mental disease may result from either regular or periodic drinking. It generally comes only after many years of heavy drinking, averaging twenty-two years for men, fifteen years for women. About a fourth of these patients give a history of delirium tremens (H. M. Pollock, 1940). *Anatomic changes* are reported as chronic meningitis with thickening; serous effusions into ventricles; softening; tendency to hemorrhages and apoplexy. Histologically, shrinkage and alterations in the staining properties of the cells and changes in the dendritic processes have been averred. They may be ascribed principally to the vitamin deficiencies (L. Alexander, 1941; Scheinker and Aring, 1943).

Delirium Tremens.—This peculiar manifestation, chiefly an acute and temporary mania, with hallucinations and delusions of persecution, may occur in drunkards continuously consuming large quantities of alcohol, but generally at the end of a prolonged alcoholic debauch, especially when joined with inanition and exhaustion, exposure, overexertion, trauma, hemorrhage, operations, psychic shock or any serious illness, especially pneumonia. It is not likely to occur in "Saturday-night drinkers," or in a periodic drinker unless a high concentration of alcohol is maintained for many days (Doane, 1939). It was formerly thought that sudden withdrawal of the alcohol could bring on an "abstinence delirium," but this is doubtful (Holitscher, 1908). Inanition plays a definite part in provoking the attack, through vitamin deficiency which is especially detrimental to the carbohydrate metabolism of the central nervous system. Administration of thiamine shortens the attack even though the alcohol consumption is continued (H. E. Kiene *et al.*, 1940), and nicotinic acid (0.6 Gm.) is reported to be even more effective (Mainzer and Krause, 1939).

The *symptoms* begin with a day or two of premonitory restlessness, tremor, insomnia and anorexia. They pass into excessive tremor, persistent insomnia, violent and talkative delirium and terrifying hallucinations of sight, touch and sometimes hearing. The attack runs its course in a few days, ending in prolonged sleep. Acute amblyopia has been reported (Kaiser, 1912). The mortality, from various causes, is about 10 to 15 per cent in uncomplicated cases, but may be as high as 37 per cent (Piker and Cohn, 1937), or 50 per cent with trauma. The phenomena are not due to direct narcotic or excitant actions of alcohol, but to encephalopathy, probably chiefly acute cerebral edema (Holitscher, 1908); the cerebrospinal fluid pressure is increased in most cases (Steinbach, 1915). The events are perhaps based on deterioration of the capillaries; petechial hemorrhages are common in the gastric mucosa (E. F. Hirsch, 1916). The other tissues are dehydrated.

Treatment of Delirium Tremens.—Lowering of cerebrospinal pressure by withdrawing 50 to 75 cc. of spinal fluid through a lumbar puncture is reported to be promptly effective, but others advise it only for diagnosis. It may be followed by intravenous injection of 50 to 100 cc. of 50 per cent dextrose solution. Dextrose in orange juice may be given liberally by mouth; also sodium chloride, 2 Gm. every four hours, with liberal water, to combat the general dehydration. High caloric and high vitamin food should be given. Nicotinic acid (0.6 Gm.), and thiamine are reported highly effective. If a direct sedative is needed, paraldehyde (4 to 12 cc., 1 to 3 drachms by mouth or rectum) is generally preferred. Barbiturates are effective in large, but not in ordinary, doses. Active delirium may be allayed by pentobarbital intramuscularly or, if necessary, intravenously. Bromide (1 Gm. every one to four hours) or chloral (not over 1 Gm., at night) may be used against the preliminary restlessness and for continued sedation. Alcohol should never be allowed, nor should morphine be given (K. M. Bowman *et al.*, 1939; Cline and Coleman, 1936; Piker and Cohn, 1937). The attack is likely to continue three to five days even with the best treatment.

Fertility and Fecundity.—These are diminished by high degrees of alcoholism, such as may be entertained experimentally in animals; but unfortunately this is not apparent in human experience, even with advanced habitual drunkards.

In an extensive series on mice, Agnes Bloom employed what she defines as "moderate" doses, but these averaged 1.5 cc. of alcohol per kilogram of body weight, corresponding to nearly half a pint of whisky for man, daily through several generations. With such so-called moderate doses she found some decrease of fecundity and fertility, and some interference of growth, the effects being greater if the alcohol was given to the fathers than for the mothers. The toxicity of alcohol for fetal rats is about the same as for adults; newborn rats are somewhat more resistant (Chesler *et al.*, 1942). Stockard, 1912, found that chronic alcoholism, induced in guinea pigs, either parent, diminishes fertility and causes most of the embryos to die before or shortly after birth. The offspring are often defective, sometimes with gross deformities. This degeneration is transmitted for at least three generations; in fact, it rather increases (1914). Stockard also found (1909) that alcohol and other anesthetics cause various morphologic defects in fish embryos, but this is a different matter.

Bertholet, 1909, reported that the testicles of chronic alcoholics generally show atrophy of the parenchyma, and increase of interstitial tissue, with corresponding decrease and abnormalities of the *spermatozoa*. This would lead to more or less impotence. Ivanow, 1913, reported that the addition of 2 per cent alcohol *in vitro* has practically no effect on the motility of spermatozoa; 12 per cent has little effect; with 15 per cent there is marked impairment. Contact for thirty minutes with 10 per cent alcohol does not hinder their fertilizing action, and the fetus is normal. Arlitt and Wells, 1917, claimed that in white rats the spermatic tissue reacts before any other to the daily administration of alcohol. Arlitt, 1919, also reported that chronic alcoholism induced in rats results in partial or complete sterility in both sexes and in a high mortality of the offspring, and that these defects are transmitted for several generations. With female pigeons, the daily inhalation for one to two hours of nearly paralytic doses of alcohol, for two to four months, reduced the size of the egg yolk materially (Riddle and Bassett, 1916).

Exposure of the ova or spermatozoa of the fish fundulus to alcohol before fertilization produces impaired and abnormal development (Gee, 1917). The concentrations and other conditions of such experiments are so peculiar that they have little meaning for the human problem.

Children of Alcoholic Parents.—The influence of alcoholism of the parents on their offspring is questionable, the data as well as opinions being so contradictory that no definite conclusions may be drawn.

Miss Elderton and Karl Pearson, 1910, in a statistical study covering 3600 school children, could find no real evidence of either physical or mental deterioration (death rate, mean weight and height, general health, mental and visual defects). They concluded that the danger of alcoholic parents lies in the transmission of the hereditary defects which caused the parental alcoholism. O. L. Mohr, 1933, reviewing the more important animal experiments, concluded that most of these have been insufficiently controlled, and that there is no sound evidence of the production of inheritable variations following paternal or maternal alcoholism, even when this exceeds anything that occurs in man. McDowell, 1919, observed lowered efficiency in the solving of maze and similar problems by the nonalcoholic offspring of heavily alcoholized *rats*. Pearl, 1916, found the progeny of *fowl* treated with ethyl or methyl alcohol or ether rather stronger than the controls, although fewer eggs were hatched.

While it is not proved that ordinary alcoholism has a direct influence on the germ plasm, the embryo is exposed to the influence of the alcohol, since this passes readily through the placenta, and exists in the same concentration in the fetal blood as in that of the mother (Nicloux, 1905). Moreover, the children inherit the degeneracy which induces alcoholism in the parents. The statistics of prisons and asylums indicate a tendency to psychic and moral degeneracy among the descendants—epilepsy, idiocy, insanity, disposition to crime and to alcoholism; but it is not decided whether the defective inheritance concerns a degeneration induced in the parent by alcohol, or the degeneration underlying the abuse of alcohol. The latter is more probable (British Royal Commission, 1931).

The **treatment of chronic alcoholism** follows the same principles as with other drug habits. The first essential is the complete ithdrawal of the drug. This may be facilitated by scopolamine. Emetine may be used to establish an adverse conditioned reflex; it is successful in a considerable proportion of patients (F. Lemere, Voegtlin *et al.*, 1942). Suggestion may be useful. The local action of the alcohol may be replaced by capsicum or ginger, the stimulation by beef-tea. Amphetamine sulfate, 30 mg. before breakfast and lunch, helps to make the patient more cheerful and cooperative (M. M. Miller, 1942). Bloomberg, 1939, recommended 5 mg. two or three times daily for some months, to alleviate the craving and so enable the patient to become reestablished. The prospects of cure are better than with morphine or cocaine, but relapses are frequent.

METHYL ALCOHOL

The extensive use of this substance (*Wood Alcohol*, Columbian Spirit) in the arts (as a combustible, anti-freeze, solvent for shellac, and so forth) and as an adulterant of alcoholic beverages and medicines has given rise to numerous cases of poisoning. Over 200 deaths were said to have occurred in the United States in six months, in 1930, from this agent, obtained chiefly from gasoline stations (J.A.M.A., *97:* 1711). The acute symptoms resemble those of ordinary alcoholic intoxication. The main differences are in the stronger local irritation and in the more protracted and more serious after-effects, the coma lasting several days and often terminating in death. An important feature is the frequent occurrence of incurable blindness from retrobulbar neuritis and retinitis. This may occur after taking 10 cc., but the individual susceptibility varies greatly. The effects are produced by the purest samples, and are therefore due chiefly to the methyl alcohol itself, although they may be exaggerated by the impurities (acetone, and so on) which are usually present. Methyl alcohol should never be applied to the body, externally or internally. Its presence in foods and drugs is properly prohibited by law. Protection against the inhalation of its vapors should be enforced in the trades.

Etiology.—The practical seriousness of methyl alcohol poisoning is illustrated by the fact that Buller and Wood found 153 cases of blindness and 122 deaths recorded up to 1904, although the existence of the danger had only been recently recognized. A wholesale poisoning occurred among the inmates of a Berlin municipal lodging house (Stadelmann and Magnus Levy, 1912; Baskerville, 1913, abstracted the cases then in the literature.) Adulterated cologne and bay rum, and the like, have proved toxic when used externally. The "methylated industrial spirit" of the B.P. is ordinary ethyl alcohol mixed with 5 per cent of crude wood alcohol. It has been claimed that mixtures of the two alcohols are more toxic than corresponding doses of either (Pantaleoni, 1927), but this requires confirmation. The *vapor* of methyl alcohol (varnish) is dangerous if ventilation is insufficient (bibliography, J.A.M.A., 1913, *60:* 1237). The inhalation is also highly toxic to animals, the effects agreeing with those in man (Tyson and Schoenberg, 1914; McCord, 1931). Considerable absorption occurs when the air contains 0.2 per cent (A. Loewy and Heide, 1914).

The **general symptoms** begin with *gastro-intestinal* disturbance, excruciating abdominal pain (also after inhalation), general weakness, nausea, vomiting, vertigo, headache. Muscle twitching is common and may increase to convulsive spasms and tonic cramps, especially of the legs. The symptoms of ordinary *alcoholic intoxication* supervene, with delirium, restlessness, unconsciousness, collapse and coma. The pulse is good at first, but later becomes weak. Acidosis is responsible for part of the symptoms (O. Roe, 1943). The plasma CO_2 may fall 10 volumes per cent (W. B. Chew *et al.*, 1946). Dyspnea is agonizing with rapid or deep forced breathing and severe cyanosis. The temperature is subnormal, 35° to 36° C. *Death* is much more frequent than with ethyl alcohol. It occurs in coma, from respiratory paralysis, in a few hours to three days. The *fatal dose* is probably from 100 to 250 cc. *Postmortem examination* shows marked hyperemia and edema of the brain and retina; acute degenerative changes in the gray matter of the brain and spinal cord; and hemorrhages in the cerebral meninges, mucosae, heart and lungs and irritation of the stomach, duodenum, kidneys and bladder (Berner, 1936; Menne, 1938).

Late Symptoms.—Sometimes the symptoms are deferred for several days and then prove rapidly fatal. Delirium may set in after the acute symptoms have subsided. Cystitis is a frequent sequel. The most important sequel, however, is blindness. Deafness may occur.

Optic Injury.—The symptoms are bilateral and consist in scotoma, dimness or total blindness; the pupils are dilated and insensitive to light. The loss of vision may start in a few hours, or be delayed several days; it generally becomes complete; subsequently there is some improvement, which in most cases, however, finally relapses into total blindness or large central scotomas, which are generally permanent (Buller and Wood, 1904; other reports summarized are by Woods, 1913). The ophthalmoscopic findings are at first normal, but later show hyperemia and edema of the fundus and destructive inflammation of the optic nerve or retinal elements or both, followed by their atrophy (Tyson and Schoenberg, 1914). The effective dose varies greatly: 10 cc. has caused blindness in some cases, while 90 cc. has failed to do so in others. Permanent impairment of vision occurs in something like half of all cases of poisoning. The pathologic changes in rabbits are described by Kasava, 1913.

Habituation.—Continued administration to dogs induces tolerance to the normally fatal dosage. The excretion of formate by the urine diminishes with the habituation (Leo, 1927). Fatty degeneration of the liver has been reported.

Cause of the High Toxicity of Methyl Alcohol.—This is not due to impurities, for the purest methyl alcohol is quite as toxic as the impure. The *acute* toxicity of methyl alcohol in animals is about 10 per cent less than that of ethyl alcohol (also for rotifers; Whitney, 1912), but the *subacute* toxicity is markedly greater. This is due to the slower oxidation of methyl alcohol, so that it persists longer in the tissues. The elimination of a single large dose of methyl alcohol extends over a week. Accordingly, while the coma of ethyl alcohol rarely lasts twenty-four hours, that of methyl alcohol may last for three or four days.

This protracted action leads to cumulative effects (Pohl, 1893; Reid Hunt, 1902). Sollmann, 1921, found that *daily* repetition of sublethal doses is more fatal with methyl than with ethyl alcohol. Birch-Hirschfeld demonstrated a similar cumulative action on monkeys. "Tippling" has also been found especially dangerous in man.

Fate.—The protracted and cumulative action is connected with the slow excretion. Voeltz and Dietrich, 1912, found after 2 cc. per kilogram that during two days about 21 per cent was excreted unchanged by the lungs, 3 per cent by the urine, 39 per cent had been burned, and 37 per cent was still in the tissues. Haggard and Greenberg, 1939, found 70 per cent eliminated by the lungs. Nicloux and Placet, 1912, found it present in the blood and brain after five days. The *distribution in the tissues* follows the same principle as for ethyl alcohol; *i. e.*, it is proportional to their water content (Yant and Schrenk, 1937). The *concentration in the blood* is about the same as in the urine (Chabanier and Ibarra-Loring, 1916). The blood concentration in six fatal human cases ranged from 0.114 to 0.238 per cent (Harger, Johnson and Bidwell, 1938).

Formaldehyde and Formic Acid as Intermediate Oxidation Products.—Methanol is oxidized in large part to formaldehyde, and this to formic acid (Pohl, 1893; Keeser, 1931). This is rapidly excreted, but gives rise to some acidosis (O. Roe, 1943). It has been suggested that the formaldehyde or formic acid is responsible for the nerve injury (Keeser); but neutral formates are not especially irritant, and it is improbable that free formaldehyde can exist in irritant concentrations in the neutral or alkaline reaction of the body.

The **treatment of methyl alcohol poisoning** includes gastric lavage and the administration of alkali (Worth Hale, 1924) with dextrose and insulin (B. B. Clark and Gibson, 1933); morphine to allay suffering. W. B. Chew *et al.*, 1946, advocate prompt alkaline treatment by intravenous sodium lactate and oral bicarbonate. Good results are claimed for daily lumbar puncture, even against the blindness, but the prognosis is not good, either as to this or as to fatality. The pressure of the cerebrospinal fluid is not altered, except as it decreases with fall of blood pressure (T. H. B. Bedford, 1946).

Impurities.—The best commercial wood spirit contains about 95 per cent of methyl alcohol; the common varieties, 75 to 90 per cent; some samples, only 35 to 40 per cent. The impurities consist of acetone, methyl acetate, allyl alcohol, aldehyde, empyreumatic products, and the like (Baskerville, 1913). It has been suggested that these are responsible for the peculiar toxicity (Mueller, 1910). Most investigators, however, have found no essential difference between the ordinary and the purest obtainable articles (Hunt, 1902; Buller and Wood, 1904; Sollmann, 1921); nor do any of the impurities produce the characteristic effects (Baskerville, 1913).

Acetone (Dimethyl-Ketone), U.S.P., $CH_3.CO.CH_3$, is used as a solvent for fats, resin, rubber, and so forth. It occurs in wood alcohol and acts similarly to methanol (Morris and Graham, 1927), being somewhat more toxic for acute and less so for delayed fatality (Sklianskaya *et al.*, 1936). Acute poisoning has been reported from its use in synthetic plaster substitutes (R. B. Elliott, 1946).

Its inhalation produces bronchial irritation and stupor, but serious poisoning is rare. It is a rather feeble narcotic, causing considerable dyspnea (Albertoni, 1884) and progressive fall of temperature, respiration and heart rate, proportional to the concentration of the vapor. After inhaling 1 per cent vapor for forty-eight hours, or 5 per cent for five to eight hours, guinea pigs show congestion of the spleen, lungs and kidneys, and pulmonary edema (Specht *et al.*, 1939). Hypodermically (guinea pigs), it is more toxic than methyl alcohol (Rhamy, 1912). It is excreted mainly by the lungs.

Acetoin (methyl acetyl carbinol), $CH_3.CH(OH).COCH_3$, produces inebriation resembling that of alcohol. It is about a fourth more potent as regards respiratory failure (L. A. Greenberg, 1943).

Butanone (methyl ethyl ketone) was studied by Patty *et al.*, 1935, as regards the toxicity of its vapor.

Higher Alcohols.—In acute intoxication, the toxicity of the alcohols increases with the size of the molecule as illustrated by the acutely lethal dose for cats (Macht, 1920): Taking methyl alcohol as 1, ethyl as 1.2; propyl

2.95; butyl, 19.7; amyl, 39. This (*Richardson's law*, 1869) applies also to the individual tissues; sensory and motor nerves, ciliated epithelium, muscle, ova, heart (Kuno, 1913). The toxicity of the alcohols for rabbits was studied by Munch and Schwartze, 1922; for paramecium, by Bills, 1923. The toxicity of aliphatic alcohols in relation to their constitution and fate is reviewed by W. F. von Oettingen, 1943.

Iso-propyl alcohol, $CH_3.CHOH.CH_3$, is used as a solvent and substitute for ethyl alcohol. It resembles this closely in action, local and general. It is used, best in full strength, as *antiseptic* for metal instruments, with the advantages over 70 per cent ethyl alcohol that it is more effective, penetrates better, is more rust-resistant, and less irritant to the skin. Neither is effective against spores. It boils between 71° and 83° C. and mixes freely with water (N.N.R.).

The odor and taste are disagreeable, so that it is not suitable for internal use (H. C. Morris and Dragstedt, 1946).

Its *acute narcotic potency* is about twice that of ethyl alcohol (A. J. Lehman *et al.*, 1944). No instances of eye injury have been reported. It is oxidized and disappears from the blood stream at about the same rate as does ethyl alcohol (Bijlsma, 1928; Fuller and Hunter, 1927). Insulin and water diuresis, with or without dextrose, have no effect on the metabolism of iso-propyl alcohol (A. J. Lehman, 1946). When 0.1 to 20 Gm., as 40 per cent solution, are administered to man, it appears in the urine and alveolar air, partly as acetone (H. Kemal, 1927). *Continued administration* to rats, as 5 per cent in the drinking water over nine months, averaging 1.87 cc. per Kg. daily, rendered them somewhat sluggish and stupid, but the mortality rate was about that of the controls (L. L. Boughton, 1944); 2.5 per cent continued for two generations had no effect on reproduction or offspring. Dogs *developed some tolerance* with more rapid fall of the blood level, in contrast to ethyl alcohol (A. J. Lehmann *et al.*, 1945).

The actions of **propyl alcohol,** $CH_3.CH_2.CH_2OH$, were studied especially by Macht, 1921, and Grant, 1923. **N-butyl alcohol** (*butanol*), $CH_3(CH_2)_3OH$, is reported to produce corneal lesions in industrial workers, not in animals (Cogan and Grant, 1945).

Allyl alcohol, $CH_2{:}CH.CH_2OH$, occurs in commercial methyl alcohol to the extent of about 0.2 to 0.5 per cent. It produces gastro-intestinal irritation, convulsions and coma, but is apparently much less toxic than methyl alcohol (Atkinson, 1924). However, McComb, 1932, found it highly toxic to various animals.

Iso-amyl alcohol, $C_5H_{11}OH$, the main constituent of "fusel oil," is more violent than ethyl alcohol in its acute and subacute actions (Salant, 1909) and the after-effects are more pronounced, but its admixture up to 1 per cent produces little difference in acute alcoholic intoxication (Baer, 1898). The toxicity of the amyl alcohols, their ketones and metabolites, is reported by H. W. Haggard *et al.*, 1945. **Amyl acetate,** the so-called "banana oil" used as a solvent in cellulose lacquers, when inhaled irritates the nose and produces headache, confusion, throbbing, palpitation, nausea, gastric derangements, but workmen soon acquire considerable tolerance. Exposure of guinea pigs to 0.2 per cent vapor of secondary amyl acetate shows only conjunctival and nasal irritation; 1 per cent causes narcosis, coma and death in five hours of exposure. The brain, lungs, liver and kidneys are congested (Patty *et al.*, 1936). *Cyclohexanol acetate,* which is used similarly, causes the same effects.

Caprylic alcohol, octyl alcohol, $C_8H_{17}OH$, is used as anti-foaming agent in various industries. No poisonous effects on the workers have been reported. In animals, it acts as a mild local anesthetic. Intravenous injection lowers the blood pressure (Clerc, Stern and Paris, 1934). Its hemolytic potency is fifty times that of ethyl alcohol (P. L. McLain, 1939).

VOLATILE ANESTHETICS

Ether, chloroform and other volatile hydrocarbons are employed mainly for producing surgical anesthesia. General anesthesia is conceived clinically as reversible paralysis of the central nervous system; specifically, loss of consciousness, pain and voluntary movements, without serious impairment of respiration and circulation (M. Kochmann). These hydrocarbons depress successively the psychic centers, then probably the basal ganglia and cerebellum; then the spinal reflexes, first the sensory and then the motor functions of the cord, probably from below upward; and finally the medullary centers. The most highly evolved functions are affected first. Chloroform also has a direct depressant effect on the cardiac muscle and is generally more dangerous. Locally, they act as irritants. For surgical anesthesia it is aimed to produce unconsciousness, preferably with muscular relaxation, with the minimum of danger, unpleasantness and after-effects. Volatile anesthetics have advantages over dissolved anesthetics in that their rapid absorption and elimination by the lungs makes it possible to adjust their action more quickly and more accurately to the condition of the patient. They require skillful attention, however, and are apt to interfere more or less with the oxygen supply. These disadvantages may be diminished by the preliminary administration of sedatives. The relative advantages and disadvantages of general, local and spinal anesthesia involve other considerations which lie largely outside pharmacology.

Discovery of Surgical Anesthesia.—The use of narcotics for dulling the pain of operations dates back to antiquity: however, the discovery of the means to achieve complete and safe anesthesia is an accomplishment of the nineteenth century (1842 to 1847). The credit must be divided among several investigators: Humphry Davy for the definite suggestion; C. W. Long for the independent discovery, but inadequate publication of ether anesthesia; Horace Wells for the successful use and publication of nitrous oxide; Jackson and Morton for the successful public demonstration of etherization; Flourens and Simpson for the introduction of chloroform (Claude Bernard, Anésthesie).

The Egyptians probably employed narcotics. The Assyrians are said to have strangled children before circumcision, producing anesthesia by the aid of CO_2. This method was revived by Valverdi in Italy early in the seventeenth century. The Chinese used hashish. All kinds of narcotics were given during the middle ages, especially opium and drugs containing hyoscine (such as the legendary "mandrake," Mandragora officinalis). "Scopolamine-morphine-anesthesia" is an interesting reversion to this ancient method, which became obsolete when the vastly superior inhalation anesthesia was discovered. Sir Humphry Davy in 1799 announced the anesthetic properties of nitrous oxide (laughing gas) and suggested: "As nitrous oxide in its extensive operation appears capable of destroying physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place." The suggestion was not acted upon at the time. The production of insensibility by the inhalation of ether had also been observed repeatedly in accidents and experiments; Charles T. Jackson, a chemist of Boston, etherized himself into unconsciousness, in the winter of 1841 to 1842, and thereby conceived the idea of ether anesthesia. He did not apply it further, but discussed it with various persons, among others with Morton. Dr. Crawford W. Long, of Jefferson, Ga., who had witnessed the effects of ether inhalation in "ether parties," was the first, in 1842, to perform an actual surgical operation under ether anesthesia. Interesting accounts of this have been given by his daughters, Mrs. E. L. Harper (Wisconsin Medical Journal, Sept., 1934) and Frances Long Taylor (Marquette Medical Review, March, 1937). In 1845 he administered ether in delivering his own child, and this was also the first recorded use of anesthesia in childbirth (Boland, 1936). However, he neglected adequate publication of his discovery of anesthesia until after this had been discovered independently by others. Dr. Horace Wells, a dentist of Hartford, Conn., witnessed an exhibition of "laughing gas" in a public lecture by Colton in December, 1844. He noticed that one of the subjects was insensible to pain; acting on this hint, he had a tooth extracted under its influence on the next day. The operation was a complete success. He introduced the gas into general dental practice in Hartford, and gave the matter wide publicity, without reservation. The intoxicant action of ether being well known, he tried this with Dr. Marcy of New York, early in 1845, but thought it inferior to the gas. There can be no question that Wells discovered anesthesia independently, and that he introduced it successfully into practice; he seems to have been the first to realize fully the importance of the discovery. Unfortunately, an attempted public demonstration in Boston in January, 1845, partly failed and was met with ridicule. The successful demonstration of ether by Morton threw nitrous oxide completely in the shade for many years. Wells was greatly disappointed, became insane and committed suicide (Truman Smith, 1858, "An Examination of the Question of Anesthesia"). The use of the gas was revived about 1863 by Colton (whose demonstration had started Wells), and by 1868 it was extensively used in dentistry. It has since been reintroduced into major surgery, and has thus vindicated the claims of Wells. William T. G. Morton, a dentist of Boston, and a former friend of Wells and Jackson, probably received inspiration from both. It is said that after hearing about Wells' discovery, Morton consulted Jackson about the manufacture of nitrous oxide, and Jackson suggested ether as more convenient. Morton seems to have started successful experiments with ether anesthesia in September, 1846. In October, 1846, he gave a perfect demonstration at an operation by Dr. J. C. Warren at Massachusetts General Hospital. The complete success of this operation achieved the introduction of anesthesia into surgery. Morton obtained a patent in November, 1846. This step, and the methods he was said to have employed to obtain it, raised much opposition. His life was embittered by the controversies, and he died of apoplexy. Jackson, the third party to the unfortunate contention for priority, also became insane. The use of anesthetics spread rapidly, and related substances were tried: chloroform was used on animals by Flourens in 1847, and in the same year, on the independent suggestion of McWaldie and Duncan, by Simpson of Edinburgh, on man (Gilmour, 1934). Flourens in the same year also called attention to ethyl chloride. It was used surgically by Heyfelder in the next year, but was then neglected till 1895. The first fundamental scientific work on the action of anesthetics was published by Snow, 1858. Ether was discovered by Valerius Cordus, 1540; chloroform, independently by Liebig, Soubeiran and Guthrie, 1831. The clinical use of *hypothermia* ("*crymotherapy*") for producing amnesia and general anesthesia is reviewed by L. W. Smith, 1942. The structural alterations of the brain in *concussion* anesthesia were studied by Windle and Groat, 1944.

Stages of Anesthesia.—The main actions of alcohol, ether, chloroform, chloral and the numerous other hydrocarbon or lipolytic narcotics are very similar; but they show practically important differences in severity, rapidity, duration and sequels. The successive effects may be divided into "stages." Hewitt, *f. i.*, classifies these as (1) analgesia, (2) light anesthesia, (3) deep anesthesia, and (4) bulbar paralysis. Since the effects pass without abrupt transition from one stage to the other, all classifications are arbitrary. In the following, they will be divided merely into the preanesthetic, anesthetic and paralytic stages. In surgical practice, the normal course of anesthesia is generally "complicated" by asphyxial phenomena, traumatic reflexes, hemorrhage, and so forth.

Preanesthetic Stage.—This sets in with a comfortable *feeling of warmth*, spreading over the whole body, but soon associated with a distressing *sensation of suffocation*, if the access of air is limited, as in the "closed" methods. The *local effects* make themselves felt by prickling and smarting of the nose, throat and conjunctiva, with hypersecretion of mucus, tears and saliva. The suffocation, as well as the direct effects of the anesthetics, results in more or less *excitement and struggling*, sometimes convulsions, especially in hysterical patients. The *reflexes* are at first rather exaggerated, later somewhat depressed and less purposive. Tonic muscular *spasm*, general or of the jaws, glottis or respiration, may occur. Sensation becomes impaired after the first few inhalations, first with disturbance of the special senses, then poor localization and diminished acuity of touch and pain. Stimulation may evoke responses, although it is not felt. This "*primary analgesia*," while the patient is still conscious, may be used for short operations, especially under chloroform and nitrous oxide.

The mind becomes *confused*, with hallucinations (noises, and so on), sensation of stiffness and want of muscular control. The patient may lose self-control and indulge in loud incoherent talking, laughing, singing, and the like, passing gradually into unintelligible muttering. These initial excitement symptoms vary in duration and intensity in different patients. Alcoholics may exhibit violent delirium and even mania. *Vomiting* (probably central), retching and coughing may occur. The *face* is flushed; the *pupils* are at first dilated, then gradually constricted; the *pulse* is rapid; the blood pressure, increased; the *respiration*, somewhat quickened and at times irregular, sometimes suspended if the vapor is too strong.

Ether as Intoxicant.—The resemblance of the earlier effects of ether to those of alcohol led to its use as an intoxicant. This is said to have been common in Ireland toward the end of the last century. A teaspoon to a tablespoonful produces effects similar to those of whisky, but they are produced, and pass off, more promptly than with alcohol (discussion and literature, J.A.M.A., *64:* 168, 1915).

The *anesthetic stage*, which it is aimed to produce and maintain, is characterized by complete paralysis of the brain and of the motor reflex centers of the cord, and usually some depression of the medullary centers. *Consciousness, sensation and most reflexes are lost*—the *corneal reflex* being among the last. Consequently the *muscles are lax*. The smooth muscles are not usually affected, but there is sometimes a relaxation of the sphincters. The pulse is full and soft, the rate rather slow with chloroform, slightly faster than normal with ether; the *blood pressure* is lowered by chloroform, normal or rather raised by ether. The *respiration* is regular and deep, often softly snoring or stertorous; rather rapid with ether. The *temperature* falls in consequence of the diminished muscular activity and increased heat loss. The *pupils* are somewhat small and respond sluggishly to light. The *face* is pale with chloroform, often cyanotic with ether.

The medullary depression does not reach a dangerous degree if the administration is carefully done. But with *prolonged anesthesia* the pulse tends to become progressively weaker, the respiration more shallow, and the temperature lower—it may fall as much as 5° C., through paralysis of the function of temperature regulation.

The *paralytic stage* involves progressive paralysis of the medulla. This stage must be carefully guarded against. All *reflexes* disappear. The *respiration* becomes shallow, irregular, labored and then ceases. The *skin* is cold and pale, and covered with the clammy sweat of the "agony." The *pupils* are widely dilated. The *pulse* becomes slow and weak, and ceases normally after the respiration.

Recovery of Patient from Normal Anesthesia.—The rapidity of the recovery is inverse to the duration of the administration. The first change after the withdrawal is usually in the respiration, which becomes quieter and less stertorous. Then the lid reflex and deglutition movements reappear. The pupils generally grow smaller, but dilate easily. The breathing may be disturbed by swallowing, coughing, retching and actual vomiting, usually just before consciousness returns. This is commonly succeeded by sleep, lasting several hours. Thirst and gastritis persist for some time.

Individual Functions.—The proper administration of anesthetics requires a detailed knowledge of their effects on the important individual functions in the successive stages.

The **reflexes** are progressively suppressed; first those which require consciousness, then the spinal muscular reflexes, and last the medullary reflexes of the respiration and circulation. The gradual abolition of all spinal reflexes by ether and chloroform produces complete muscular relaxation in the anesthetic stage—an important surgical advantage over nitrous oxide or local anesthesia. The relaxation and reflexes are also valuable in judging the depth of the anesthesia, for the reflexes vary with remarkable uniformity according to the concentration of the anesthetic in the blood and even according to the concentration in the air. There are, however, rare exceptions. No initial stimulation of reflex excitability is noticeable (Mann, 1918). The reflexes disappear in a rather *definite order;* but this is not the same for chloroform and ether, indicating that their actions are not strictly alike (Storm van Leeuwen, 1916). In recovery, the reflexes tend to return in inverse order, but not absolutely so (Cetveriko, 1928). There is also some variation with individuals, so that judgment of the degree of anesthesia should be based on a composite of various reflexes. Those which are especially utilized practically are the laryngeal and pharyngeal (gagging), conjunctival, pupillary, and muscle tonus. Among the last to disappear are the rectal, vesical, peritoneal and genital. The patellar reflex persists late. The movements of paralysis agitans cease during anesthesia as they do in sleep.

Appraisal of Depth of Anesthesia in Animals.—The criteria were reviewed by Girndt, 1932. He favors the composite suggested by Magnus and Versteeg.

The Sensory Component Is Depressed before the Motor Component.—In the early stages sensation is blunted; motion is unimpaired or indeed increased. The psychical condition is similar to that from alcohol, but the facilitation of motor processes is early obscured by the sensory depression (Kraepelin, 1892). In decapitated cats, the spinal cord stimulation by moderate doses of aliphatic narcotics results in convulsive twitching (Blume, 1926). In the deeper stages, the sensory cells of the spinal cord are paralyzed before the motor cells: if chloroform is restricted to the upper half of the cord, so that this will not react to reflexes from the upper extremities, it will still respond to impulses from the unpoisoned sensory cells of the lower cord (Bernstein). The response to direct stimulation of the cord disappears first from the sensory posterior columns (Flourens, 1847). Eventually, the motor cells also become inexcitable.

The *cerebral motor cortex* is depressed, but loses its excitability only in deep anesthesia (Hitzig, 1873; ether, Dandy, 1927; chloroform, Chauchard and Chauchard, 1927).

Action Potentials of the Cerebral Cortex.—Ether, chloroform and alcohol first increase the spontaneous electrical fluctuations (alpha waves) as in sleep, but these become damped as the narcosis progresses. In anesthesia they are greatly weakened without much change of frequency. Finally they are abolished, first in the cerebrum, then in the cord and last in the medulla. The response to inhibitory stimuli, *f. i.*, of the sciatic, is abolished rather early, apparently by blocking the afferent approach. In waking, the waves reappear in the reverse order (H. Berger, 1934, human; Hasama, 1935, rabbit; Derbyshire *et al.*, 1936, cat; Bremer, 1935). The *p*H of the cerebral cortex falls and recovers closely parallel to the diminution of electrical activity (W. S. McCulloch and Dusser de Barenne, 1939). *Pre- and postanesthetic excitement* is due partly to stimulation of certain cerebral regions, partly to functional disharmony with synchronous excitation of some parts and depression of others. The wave frequency changes are more or less characteristic for each anesthetic agent, but these tend to fall into two groups (H. K. Beecher and McDonough, 1939): *Avertin narcosis* in human subjects decreases the rate and duration of the waves, but they remain clearly defined. *Barbiturate narcosis* (by pentobarbital, pernocton or evipal) produces the large regular waves characteristic of normal sleep, but if the dosage is increased to deep anesthesia, the waves are depressed as with ether. *Asphyxia* damps the waves, similar to deep avertin or pentobarbital narcosis.

Respiration.—This is influenced, not only by the direct action of the anesthetic, but also by the patency of the respiratory channels; local and distant reflexes; the state of the circulation, and so forth. *In the early stages*, if local irritation is avoided, the respiration is generally somewhat deeper and quicker from stimulation of the respiratory center. More commonly it is likely to be irregular, especially if the administration is started abruptly, on account of the struggling, choking sensation and local irritation. The latter may produce temporary expiratory stoppage by a trigeminal reflex (Kretschmer, 1870), but in man this reflex is not usually so strong or lasting. The "choking" is especially pronounced with ether. Reflex closure of the larynx may produce asphyxia under chloroform (Bernard). With chloroform, spasmodic arrest of respiration may also sometimes occur, especially in vigorous subjects, and is probably a common cause of the early deaths. This is less likely to occur if dilute vapors are employed.

As the patient passes into anesthesia, the breathing becomes regular and noisy; with ether, the depth and rate may at first be increased; with chloroform they are decreased, partly by the low blood pressure. The respiration is mainly diaphragmatic. The snorting and the louder "stertor" are generally produced by the vibration of the tongue against the pharyngeal wall. "Stridor" is laryngeal, due to paralysis or spasm of the vocal cords or obstruction of the glottis by mucus. As anesthesia deepens, increase of concentration usually makes the respiration temporarily deeper, quicker and more stertorous, and *vice versa.* Cheyne-Stokes respiration is not uncommon with chloroform, but it is exceptional with ether, because the CO_2 tension is high.

Reflex respiratory changes occur even during full anesthesia, but are most marked if the anesthesia is light. The respiration is usually stimulated by the operative procedures, which may provoke coughing, deglutition, retching, stertor or spasmodic inspiratory or expiratory arrest. Operations during partial anesthesia are therefore dangerous.

With the approach of the paralytic stage, the respiration becomes more stertorous (softly snoring with chloroform), irregular, dyspneic, gasping and finally stops, gradually or suddenly, often with some postmortem gasps. Paralysis of the respiratory center is the usual mode of death in deep anesthesia. Chloroform has a more pronounced paralytic action than ether; the paralysis may also be due to low blood pressure.

Reflex Inhibition of Respiration.—Deep etherization depresses or abolishes all augmentory reflexes, but intensifies those that produce inhibition. For instance, stimulation of the afferent vagus or superior laryngeal fibers causes only short arrest of the respiration in normal animals. As etherization deepens, the arrest becomes longer. With deep anesthesia, not much beyond the surgical limit, the arrest is so long that the resulting asphyxia kills the heart (F. C. Mann, 1918).

The *factors in the respiratory effects* are classified by Y. Henderson and Scarbrough, 1910, as follows:

1. *The Threshold of Excitability for Carbon Dioxide.*—This is *elevated* (*i. e.*, the excitability is depressed) by morphine, chloroform and deep etherization. It is *lowered* by light etherization, by the acidosis of deficient oxygenation, and by fear.

2. *The Carbon Dioxide Content of the Blood.*—This acts as a stimulant to respiration. It varies inversely as the respiratory ventilation.

3. *The Threshold of Excitability for Afferent Impulses.*—This is *raised* (*i. e.*, respiration is depressed) by deficiency of carbon dioxide (acapnia); and by morphine, chloroform and ether. It is *lowered* by fear.

4. *The intensity of afferent impulses,* especially pain and psychic impressions.

5. *Inhibitory cerebral impulses,* such as the fortitude of the patient.

The several anesthetics act differently on these factors: *morphine* raises the threshold for carbon dioxide, but has less effect on the threshold for afferent impulses. It quiets excitement. *Chloroform* raises the threshold more for afferent impulses than for carbon dioxide. *Ether* may lower the carbon dioxide threshold, while the afferent threshold may be elevated. Hence, ether tends to increase respiration (Fonteyne, 1906), so much so that in dogs it may cause fatal acapnia (Y. Henderson, 1925). Most ether fatalities occur in the preanesthetic stage, the respiration almost always failing before the heart (Cunningham and Anderson, 1908). This tendency may be neutralized by morphine. The *respiratory excitement* during the early stages of anesthesia has a similar tendency; it lowers the carbon dioxide content of the blood and thus tends to subsequent failure of respiration. Good surgical anesthesia obviates the development of acapnia by preventing pain hyperpnea.

Excessively deep anesthesia paralyzes respiration by raising the threshold of the respiratory center, and by diminishing the production of CO_2. The paralysis is essentially central, although a curare action on the phrenic nerves may play a minor part (Githens and Meltzer, 1914).

Anesthesia before pain prevents acapnia by lessening the afferent hyperpneic impulses. The induction of *anesthesia after pain* is more dangerous, because the lowered excitability during hyperpnea is liable to lead to acapnia (Henderson, 1910). The acapnia also damages the heart, so that it succumbs more easily to chloroform (Cathcart and Clark, 1913).

Stoppage of respiration is therefore most likely to occur with uneven anesthesia (Henderson, 1911).

Irritation of Respiratory Passages.—Ether and, to a less degree, chloroform produce irritation, with reflex phenomena, increased flow of saliva and mucus, and sometimes inflammatory after-effects. The hypersecretion is especially marked with ether; chloroform produces only a slight increase during induction, and practical arrest during full anesthesia. Emphysema, bronchitis and advanced tuberculosis are therefore special contraindications to ether. The increased flow of saliva and the anesthesia of the larynx may lead to *aspiration pneumonia* (Hoelscher, 1898). Pneumonia may also be due to direct irritation, to chilling, to lowered resistance, and to hemorrhagic emboli; it is not known which has the larger share. It is much more common with ether than with the other anesthetics. It has been attributed to *impurities,* especially aldehydes and peroxides (Bruns, 1895; Smith, 1913), but this has not been established. Excessive mucous secretion may also produce acute suffocation by "inundation." The *tongue* during anesthesia is liable to fall against and close the glottis. These accidents are largely obviated by proper position of the head.

Coughing, retching and vomiting sometimes occur immediately after starting the administration; or later, during imperfect full anesthesia, especially with ether, being partly due to the swallowing of mucus. Their occurrence indicates that the anesthesia should be deepened. The approach of vomiting is heralded by swallowing movements. If it cannot be averted, the head should be turned to the side and the opposite shoulder raised.

The *viscosity of mucus* (tracheal and frog's esophagus) is greatly increased by ether inhalation. Chloroform, ethylene and nitrous oxide do not have this effect (Lucas and Henderson, 1936).

Salivary Secretion.—The flow from Stensen's duct in dogs is increased two to five times during induction of and recovery from ether, chloroform and cyclopentane; not with ethylene, nitrous oxide or barbiturates. The salivation of ether induction is a reflex from the upper respiratory mucous membranes, for it does not occur if these are cocainized, or if the ether is administered by trachea or intravenously. During full anesthesia, the salivary secretion is arrested by all these agents, but pilocarpine provokes a copious flow (B. H. Robbins, 1935).

Ciliary Motion.—In the mammalian trachea and bronchioles this is depressed by ether, chloroform and ethyl chloride (Lucas, 1934; Sollmann and Gilbert, 1937; A. M. Ernst, 1938). Ethylene stimulates at first, then depresses (Lucas). With ether, the motion is further impaired by the increased viscosity of the mucus (Lucas and Henderson, 1936). In frog's esophagus, alcohol and ether, as well as ethylene, stimulate before they depress. Chloroform and chloral give pure depression (Lucas, 1934).

Bronchial Muscle.—Excised tracheal muscle is relaxed by ether, constricted by chloroform, in vapor concentrations such as occur in anesthesia (Trendelenburg, 1912). In intact animals, however, chloroform produces slight dilatation (Dixon and Brodie). In excised lung (guinea pig), temporary dilatation is produced by ether, chloroform and urethane (Baehr and Pick, 1913). Sollmann and Gilbert, 1937, found the effects rather slight with fresh microscopic sections. By the same method, Adriani and Rovenstine, 1941, observed some *dilatation* with chloroform, ether and divinyl ether; *constriction* (antagonized by atropine) with cyclopropane, amytal and other barbiturates; practically no effect with ethylene, nitrous oxide and paraldehyde. *Anaphylactic reactions* can occur during ether anesthesia, clinically and experimentally (L. M. Quill, 1937).

Pneumococcus Infection.—The resistance of highly immunized rabbits is inhibited during ether anesthesia (and alcohol stupor), the immigration of leukocytes being prevented by alteration of the capillaries. The phagocytic activity of the leukocytes is not inhibited (Pickrell, 1938). On the other hand, alcohol or ether narcosis of rabbits tends more or less to inhibit the inflammatory response, the hyperemia, edema and leukocytosis, to *bacterial and chemical irritants* (Cressman and Rigdon, 1939).

Circulation.—This reacts differently to the various anesthetics, directly and indirectly. Asphyxial rise of blood pressure tends to occur when the air exchange is impeded, as in rebreathing methods, including nitrous oxide and the "closed" ether administration, and if the percentage of oxygen in gases is too greatly restricted. Otherwise, the circulation is not greatly altered in anesthesia by ether, ethylene, cyclopropane and nitrous oxide with oxygen. Chloroform, however, causes marked and progressive fall of pressure, partly cardiac and partly vascular; and sensitization to ventricular fibrillation by the epinephrine. Cyclopropane also sensitizes to fibrillation, and may produce this directly if the concentration is too high (review, W. J. Meek, 1941). Chloroform death may occur through cardiac arrest, sometimes reflexly, but generally because the poisoned heart is unable to withstand the strain of the impaired respiration.

Electrocardiographic Phenomena in Surgical Anesthesia.—Four-fifths of 109 patients under the various anesthesias in current use developed some disturbance, usually of rhythm, especially sinus arrhythmia and extra systoles, also variations of amplitude, sometimes extreme ventricular irregularity, rarely complete heart block. Chloroform had the highest incidence, procaine the lowest. There was no constant relation between the arrhythmias and the depth of anesthesia (Kurtz, Bennett and Shapiro, 1936). In *dogs*, ether and cyclopropane tend to reverse the T wave and often cause transient arrhythmias. Amytal had no effect (Betlach, 1937). Cyclopropane is particularly liable to produce ventricular fibrillation.

Ether on Circulation.—*In the early stages*, the pulse rate and blood pressure are increased by the reflexes, excitement and incipient asphyxia. *During anesthesia*, the effects are similar to those of alcohol, stimulant rather than depressant: the cutaneous and cerebral vessels are dilated (also with chloroform, Berezin, 1916), the intestinal constricted (Derouaux, 1909), the pulse rate is increased to 80 to 110, and the blood pressure is practically unchanged, or somewhat above normal in man (Blauel, 1901). The face is reddened. The pressure in the pulmonary artery rises even if the carotid pressure remains unchanged (Wood, 1911). There is generally some venous congestion, especially with the "closed" methods (asphyxia). The threshold to vagus stimulation is raised (Jackson and Ewing, 1914), chiefly by an action on the vagus ganglia. The femoral blood flow in dogs anesthetized by ether is two or three times that under local anesthesia. The mechanism is not clear (J. F. Herrick *et al.*, 1932).

These indifferent or favorable actions on the circulation persist through the stage of surgical anesthesia, even if this is prolonged for hours. *In the paralytic stage*, the vasomotor center is gradually depressed: the pressure falls slowly, the face becomes pale, while the heart remains practically normal even when the respiration ceases. It can therefore usually be revived effectively by prompt artificial respiration. Fatty feeble hearts, however, may be affected more severely. The vascular effects are central; the cardiac changes are mainly the indirect results of the vascular disturbance, the heart muscle (Bock) remaining unchanged. Concentrations of ether which injure the heart directly can be reached only in perfusions.

Toxic Circulatory Effects and Concentration in Blood.—These were investigated on cats by Schram *et al.*, 1916. With normal cats, concentrations of 0.13 to 0.14 per cent of ether in the blood lower the blood pressure considerably by action on the vasomotor and vagus centers; but the heart muscle is not affected by this concentration. Even with the fatal concentration (0.17 per cent), the heart is scarcely damaged, although the circulation is depressed before death. If artificial respiration is performed, cardiac arrest occurs with 0.25 per cent of ether in the blood. This also is not essentially due to direct injury of the heart muscle; for by dividing the vagi, the minimal fatal concentration becomes 0.31 per cent. If low blood pressure is excluded (by the Starling arrangement), it becomes 0.44 per cent; if the nutrition of the heart is maintained (by Langendorff perfusion), the concentration rises to 0.553 per cent before the heart is arrested.

Asphyxial Effects on the Circulation.—Slight mechanical interference with the respiration rather improves the respiratory movements and the circulation by stimulating the medullary centers. Severer grades produce venous congestion and extensive bleeding from severed vessels. Profound asphyxia leads to extreme cardiac dilatation by paralysis of the vasomotor center and heart.

In light ether anesthesia, 12 to 16 per cent of CO_2 in the air raises the blood pressure, but slows and weakens the heart. These actions are much less pronounced in deep anesthesia (Cathcart and Clark, 1913). The secretion of *cerebrospinal fluid* is increased by the anesthetics and CO_2 (Dixon and Halliburton, 1913).

Heart Rate and Blood Pressure.—In light anesthesia, as in normal individuals (Marey, 1860), the heart rate tends to vary inversely to the blood pressure; *i. e.*, as the blood pressure falls, the heart rate quickens, a response involving the accelerator innervation. In deep ether anesthesia, however, and with anoxemia or profound anemia of the medulla, this coordination fails, so that the heart rate decreases with further fall of pressure.

Vasomotor Center.—Anesthetic doses of ether produce either no direct effect, or moderate stimulation. The stimulation is probably largely asphyxial, from respiratory depression (Pilcher and Sollmann, 1915). In decerebrate cats, ether, chloroform and similar anesthetics depressed the excitability of the vasomotor center to CO_2 (van Esveld, 1930).

Anesthetics on vasodepressor reflexes (from carotid sinus and aortic arch) are diminished or suppressed by ether, chloroform, chloral and barbiturates. Chloralose and urethane have little if any effect on any of the carotid sinus reflexes, cardiac and respiratory as well as vasomotor (Heymans *et al.*, 1931, 1933).

Narcotics on Circulation of Pia Mater.—In cats, ether dilates the pial arteries and veins, and *increases* the cerebrospinal fluid pressure and systemic blood pressure. Chloroform, barbital and amytal dilate the pial vessels and increase the cerebrospinal pressure, but lower the blood pressure. Avertin *diminishes* the pial pressure, and the cerebrospinal and the general blood pressure. Morphine (to 2.2 mg. per Kg.) leaves these pressures unchanged (Finesinger and Cobb, 1935). The vessels of the *cerebral cortex* are dilated by ether anesthesia more than in barbiturate narcosis; but the *hypothalamic vessels*, especially those of the nuclei, are less dilated with ether than with barbiturate (A. Laidlaw and Kennard, 1940; India ink injection of monkeys).

Anesthetics in "Shock."—In partial shock, ether anesthesia depresses the circulation more profoundly. The use of nitrous oxide-oxygen mixture (3:1) does not produce this depression. In any case, deep anesthesia, and rebreathing methods, should be avoided in shock (Cannon, 1919).

Plasma Volume.—Etherizing of dogs for one to two hours reduces their plasma volume by about 12 per cent; prolonging the inhalation does not result in farther fall unless the depth of the anesthesia is also increased. Restoration to normal or above occurs within two or three hours after discontinuing the inhalation (McAllister, 1938). The interstitial tissue fluid is also decreased by ether anesthesia, much less by nitrous oxide and cyclopropane. Barbiturates increase the plasma volume without much effect on interstitial fluid (D. D. Bonneycastle, 1942). The *water absorption by frogs* during anesthesia with various narcotics varies directly as the anesthetic potency (Mild and Serritella, 1934). The increase with alcohol is additive with that of pituitrin administration (F. Brunn, 1943).

Cardiac irregularities in ether anesthesia occur especially during the induction (I. G. W. Hill, 1932). Various electrocardiogram changes have been described, especially in the T wave, but have little if any significance. Blocks and ectopic beats are rare in light anesthesia, but may appear as this is deepened. They disappear rapidly on removing the ether. Ventricular tachycardia and fibrillation are rare with ether alone; and considerably larger doses of epinephrine are required to produce fibrillation with ether than with chloroform or cyclopropane. Ether-epinephrine syncope does not occur clinically (review, W. J. Meek, 1941). *Perfusion of excised frog heart* with 0.5 per cent of ether in Ringer solution causes marked depression at first; on continuing the perfusion, the activity returns to normal (Cattell, 1927).

Cardiac Nerves.—The excitability of the vagus trunk is not diminished in anesthesia (Berline and Chauchard, 1925), although the concentration of the anesthetic in the nerve is relatively high (Nicloux). The cat is peculiar in that the heart becomes nonresponsive to vagus stimulation under full ether anesthesia. The action appears to be on the ganglia, for acetylcholine still causes slowing, while nicotine does not. Accelerator stimulation is not affected (Kobacker and Rigler, 1929). In dogs, ether overcomes the morphine bradycardia, apparently by depression of the vagus system, not by sympathetic stimulation (B. H. Robbins *et al.*, 1939).

The effects of chloroform on the circulation are much more serious than those of ether. Even in smooth anesthesia the pressure falls markedly by central vasomotor depression. Slight faults, especially early in the administration, may produce sudden permanent arrest of the heart. "A.C.E. Mixture" and ethyl chloride act similarly.

In normal chloroform anesthesia, with carefully graduated administration, the pulse and blood pressure in the *preanesthetic stage* are somewhat irregular, but generally increased, and the face is flushed, similarly to ether. *As anesthesia* is reached, or shortly after, *the blood pressure declines progressively* (Lenz, 1853; English Chloroform Commission; Blauel in man); in an hour it may have fallen to one-half, in two and one-half hours to one-third, the normal level (Rosenfeld, 1896). This fall of pressure is primarily due to depression of the vasomotor center: The vessels are dilated, but constrict on stimulation of their nerves (Scheinesson, 1869). The depression of the center can be shown directly by the perfusion method (Sollmann and Pilcher, 1911). The dilatation involves mainly the splanchnic area (oncometer, Embley, 1902; increase of blood flow, Pick, 1899). The skin becomes pale and cold. The cerebral vessels constrict, the pulse is soft and slow but regular, the heart beating efficiently when the vasomotor paralysis is complete (no response to asphyxia, Knoll, 1878). The respiration also remains regular and efficient. The vasomotor depression is not necessarily harmful to the patient, unless it be excessive or prolonged.

With *prolonged anesthesia,* or with the approach of the paralytic stage, the heart is injured more or less by the direct action of the chloroform, as well as by the low blood pressure and asphyxia. It is also probable that degenerated heart muscle is more subject to these injuries. Ordinarily, however, the vasomotor paralysis dominates the circulatory phenomena until death, the heart beating after the respiration has stopped, although it may not be able to maintain a circulation.

With *faulty administration* the events are quite different. Excessive concentration of the chloroform vapor, particularly when the anesthesia is incomplete, stops the circulation before the respiration. This is the usual mode of chloroform death (Lancet Commission, 1893). If the heart is exposed, it may be contracting feebly, even after the respiration has stopped, so that literally the respiration stops first; but these feeble beats cannot propel the blood, so that, in fact, the circulation usually fails before the respiration.

The cardiac arrest may be due, in individual cases, to direct or reflex vagus stimulation, to asphyxia, to fibrillation or to direct paralysis of the cardiac muscle; or generally perhaps to a combination of these factors. Reflex circulatory disturbances are most dangerous in incomplete anesthesia where the reflex response is active; and in very deep anesthesia, when the low blood pressure may make even slight reflex changes fatal.

Cardiac Changes.—Early in chloroform anesthesia the heart is somewhat quickened, probably by muscular movements and sensory stimuli; or it may be inhibited by the trigeminal vagus reflex. After anesthesia is established, the rate is slowed progressively with increasing narcosis, to cardiac arrest by direct depression of the cardiac muscle or by circulatory collapse.

Circulatory Reflexes.—Chloroform tends to intensify depressive and to weaken augmentor reflexes. The cardioinhibitory response to the *carotid sinus reflex* is intensified (Hering, 1927); the vasopressor response is weakened (Moissejeff, 1926).

Trigeminal (Kretschmer) Reflex.—With rabbits, inhalation of chloroform (also of ammonia vapor) through the nostrils arrests the heart by reflex stimulation of the vagus, but it generally escapes from the inhibition within one or two minutes. The reflex is strongest if the vapor acts simultaneously on the nose and the larynx. There is little response from the pharynx and still less from the trachea (Traina, 1930). The trigeminal reflex is rarely effective in human subjects. Desoubry and Magne, 1914, confirmed that brusque chloroform inhalation produces complete arrest of heart and respiration in dogs and rabbits. However, if absorption of the chloroform is prevented, the arrest is temporary and is followed by rise of blood pressure from splanchnic constriction. In the usual fatal result, therefore, the toxic action of the absorbed chloroform plays an important part in preventing recovery from the reflex arrest.

Vasomotor Center.—The preliminary stimulation is partly due to a direct action of the chloroform, for it occurs when this is confined to the cerebral circulation (by perfusing this from the vessels of a second, chloroformed animal; Gaskell and Shore, 1893). In part, the rise of pressure is also reflex and asphyxial. The vasomotor center becomes depressed early; *f. i.*, the normal vascular compensation against the head-down position is destroyed (L. Hill, 1897). It does not become completely paralyzed until much later. Pilcher and Sollmann, 1915, confirmed that the vasomotor center is depressed directly during chloroform anesthesia. Indirect stimulation may, however, occur when asphyxia is induced by respiratory depression, or if the center becomes suddenly anemic by rapid fall of blood pressure or cardiac arrest. Under such conditions, the center may be violently stimulated, with or without preceding depression. In an intermediate stage of chloroform anesthesia, stimulation of the vasomotor center lowers blood pressure, since chloroform disturbs the reciprocity of antagonistic nerves so that afferent stimuli produce only inhibitory effects; chloroform causes the inverse effects to strychnine. The chloroform vasodilatation may therefore be due to the reversal of the normal pressor impulses of the center. Asphyxia, however, still causes vasoconstriction (Bayliss, 1908). When the vasomotor paralysis is complete, asphyxia does not raise the pressure.

Direct Action on Vessels.—Perfusion of excised organs with chloroform solutions produces a constriction in some organs, dilatation in others, especially the kidneys (Schaefer and Scharlieb, 1904; Filehne and Biberfeld, 1906). The required concentration, however (0.1 per cent), is almost twice as great as that which kills the heart and paralyzes respiration (0.06 per cent), so that this peripheral action can play no part in chloroform anesthesia (Sherrington and Sowton, 1904).

The pressure in the *pulmonary artery* falls, through the cardiac and respiratory depression (Wiggers, 1911).

Cardiac irregularities, ranging from isolated extrasystoles to sudden ventricular fibrillation, may occur at any stage, but especially early in the administration, tending to disappear when the anesthesia is either deepened or lightened. They disappear promptly when the patient wakens (review, W. J. Meek, 1941). *Multiple extrasystoles* are observed in the electrocardiograms of nearly half the patients under chloroform. They are analogous to those which in the *cat* are precursors of ventricular fibrillation under light chloroform anesthesia, which can be prevented or abolished by section of the cardiac sympathetic nerves, and provoked by the stimulation of these nerves or by injections of epinephrine (G. R. Brown *et al.*, 1930). *Dogs* react somewhat differently. Rapid induction frequently produces cardiac arrhythmia and ventricular arrest, but rarely ventricular tachycardia or fibrillation, as in cats. Prompt artificial respiration usually secures recovery, and then the arrhythmia does not return unless there is severe hypoxemia (O. S. Orth and Liebenow, 1946).

Early Stoppage of Heart.—Most fatalities with chloroform occur during the induction of the anesthesia, by sudden arrest of the heart. Experimentally, the heart will often resume if the vagi are promptly divided. In these cases the arrest is due to *stimulation of the vagus center.* This may be *reflex*, due to nasal, laryngeal, tracheal or pulmonary irritation by the chloroform vapor (Dastre; Morat; Brodie and Russell); but it may also occur when all reflex paths are eliminated, or on intravenous injection (Embley, 1902), thus indicating *direct stimulation* of the center. Its excitability is exaggerated by high concentrations of chloroform (about 2 per cent), by morphine and by asphyxia. Deep anesthesia dulls this vagus hyperexcitability, thus explaining why these accidents generally occur at the start. The administration of atropine would prevent this form of fatality. There is, however, another factor; for a normal heart cannot be stopped permanently by vagus stimulation, direct or reflex; with a chloroformed heart permanent arrest is easily produced (Desoubry and Magne, 1914). It follows, therefore, that the high concentration of chloroform vapor must have injured the heart. This increased sensitiveness of the heart may be fatal apart from the vagus: A. G. Levy, 1911, finds the cat's heart in early chloroform anesthesia very sensitive to high blood pressure (epinephrine), death in this case not being avoidable by vagotomy or atropine. This condition disappears in deeper anesthesia and was not seen with ether.

Socin, 1914, showed that chloroform renders the excised heart less resistant to venous engorgement or increased arterial resistance; *i. e.*, that it dilates more easily. Similarly, excitement may stop the heart of lightly chloralized cats (Sollmann, 1908). Embley, 1915, found that early chloroform death with cats is frequently due to ventricular fibrillation. With dogs, this was never witnessed, except as a terminal result of low blood pressure. Hering, 1916, also found the tendency to early death, in dogs and cats, parallel to excitement. The arrest is generally due to ventricular fibrillation from excessive excitability of the heart. Henderson, 1914, was inclined to attribute the early fatalities mainly to acapnia.

Vagus Response.—Chloroform decreases the intensity and duration of cardiac inhibition by vagus stimulation (E. Nobel, 1919).

The *cause of ventricular fibrillation* is presumably a shortened refractory period of the cardiac muscle, described by Sasaki, 1921. Higher concentrations of chloroform paralyze the muscle directly.

Direct cardiac depression by chloroform was demonstrated on the excised frog's heart by Clemens, 1850; on the exposed mammalian heart by Snow, 1852. The *excised mammalian heart* (Langendorff method; Sherrington and Sowton, 1903) shows strikingly the difference between chloroform and ether. The *quantitative difference* in the cardiac depressant action of these narcotics is illustrated by the results of Dieballa, 1894, on perfused frog's heart: if the fatal dose of chloroform be taken as 1, that of ethyl bromide would be 12; of ether, 48; of alcohol, 192. In perfused hearts, and doubtless also in living animals, the depressant action of chloroform is greatly increased by CO_2, and therefore by asphyxia (Sherrington and Sowton, 1906). With frogs' hearts, the depressant effects of anesthetics can be *antagonized by calcium* (Burridge, 1912).

Actions on the blood are not important in ordinary anesthesia. Ether and chloroform, like all fat solvents, produce *hemolysis* when added to shed blood; an insignificant degree of this action seems to occur during life, so that the resistance of the corpuscles is definitely lowered (C. D. Leake *et al.*, 1927). Some polycythemia may occur, especially under ether, due to diminution of the plasma, and to contraction of the spleen in ether anesthesia (amytal relaxes the spleen and so withdraws considerable corpuscles from the circulation; Haussner, Essex and Mann, 1938). The hemoglobin is reduced. Some corpuscles are destroyed entirely, others lose only part of their hemoglobin. Since a diminution of hemoglobin to 50 per cent is dangerous, it is never safe to use anesthetics on patients showing only 60 per cent of hemoglobin (Da Costa and Kalteyer, 1901). It is conceivable that this hemolysis explains partly the *anemia and icterus* which are sometimes seen; but these may be caused by hepatic changes. No methemoglobin is found in the blood after two hours of chloroform or three and a half hours of ether anesthesia (F. Jung, 1943). The *surface tension of the plasma* is lowered by the ether dissolved in it (Trabucchi, 1928). The *specific gravity* of the blood is somewhat increased during anesthesia and for several days after (Sherrington and Copeman). Buck, 1914, described marked decrease of the globulins after about two hours of chloroform or ether anesthesia. The *viscosity* of the blood is slightly increased in deep, diminished in light, anesthesia, but not to an important degree (Burton-Opitz, 1911). The *osmotic pressure* is a trifle increased by the molecular concentration of the dissolved anesthetic (Carlson and Luckhardt, 1908).

The *mineral constituents* of the plasma undergo considerable shift; during one hour of ether anesthesia in dogs, the K was reported to be decreased by 15 to 46 per cent, the Mg was also decreased considerably, Ca slightly, Na and Cl varied slightly and irregularly, with tendency to increase of Cl (Marenzi and Gerschmann, 1933). The *fat content* of the blood is increased by ether; chloroform has this effect only when the animal has been on a fat-rich diet (Bloor, 1914). The *cholesterol content* of the blood increases significantly in ether anesthesia, less so under chloroform, and practically not with ethylene or nitrous oxide. The rise is due partly to the excitement of the induction stage (Hospers, 1933), but it is also proportional to the rise of blood sugar and to the duration of the anesthesia, and may be prevented by the previous administration of insulin. Mahler, 1926, therefore attributed the rise of cholesterol to decrease of insulin output. During surgical ether anesthesia, a *leukocytosis* sets in slowly, usually after one to four hours. It concerns mainly the polymorphous, but the other forms are also increased. It appears to be due to stimulation of the bone marrow. The *phagocytic activity* is not decreased, even after four to six hours of anesthesia (F. C. Mann, 1916). *In vitro*, the motility of leukocytes is somewhat decreased by the concentration of chloroform which occurs in the blood in clinical anesthesia (Lowenburg, 1934).

The *coagulation time of the blood* is shortened in *ether anesthesia* by as much as 40 per cent (Rabinovich). *Chloroform and chloral* have no effect if the coagulation time is normal, but lengthen it if it is abnormally short. *Profound chloroform narcosis* diminishes or abolishes the coagulability of the blood owing to deficiency of plasma fibrinogen and prothrombin. This change is noticeable after thirty-five minutes of anesthesia. In extreme cases the fibrinogen may be completely absent. This effect is connected with the injury to the liver, similar to that of phosphorus, and is not produced by ether. The coagulability recovers with the repair of the hepatic lesions (M. Doyon, 1913; Whipple, 1915; E. W. Schultz *et al.*, 1925; H. P. Smith, Warner and Brinkhous, 1937).

The **pupils** furnish valuable information about the efficiency of the reflexes and asphyxia, and therefore of the depth and course of the anesthesia. In the *excitement stage*, they are dilated with the light reaction moderately decreased. This dilatation cedes with the approach of *anesthesia*. In man there is then actual constriction; the light reaction is diminished or abolished; the eyes are turned inward and upward as in sleep. The constriction persists throughout the anesthetic stage and into recovery. With ether, the diameter averages 3½ to 4½ mm.; with chloroform, 2 to 3 mm. Their behavior is easily modified by reflexes, respiratory embarrassment, and so forth, and should be occasionally ascertained by intentionally changing the depth of anesthesia. *Constricted pupils* usually mean that the anesthesia is light. *Dilatation* may mean either deep anesthesia, or asphyxia, or reflexes with light anesthesia. If the corneal reflex is present, dilatation should lead to more rapid administration; in the absence of reflexes, to lighter administration. *Sudden and extreme dilatation* generally signifies dangerous asphyxia. Morphine and atropine interfere with these reactions.

The effect of anesthesia is identical with that of sleep and is due to the abolition of the cerebral impulses which normally inhibit the constrictor tone of the oculomotor center. Asphyxia, on the other hand, increases this inhibition (Braunstein, 1894). The *pupillary reactions of animals* are somewhat different: all show the dilatation in the excitement and asphyxial stages, and the abolition of the light reflex during anesthesia; but the anesthetic miosis is witnessed only occasionally in dogs, never in cats or rabbits. In these animals the pupils assume a median position. The frog's pupil is not affected by anesthesia (Nakazawa, 1910). The *corneal and conjunctiva-reflexes* disappear late, as in all modes of death. *Nystagmus* under anesthesia occurs from the rhombencephalic supranuclear centers (E. A. Spiegel and Collins, 1940).

Gastro-Intestinal Tract.—Inhalation of the anesthetics generally results in *nausea* and often in *vomiting*, sometimes during the induction, and especially when the patient awakens. The mechanism is mainly central, but the local irritation and the swallowing of mucus may contribute. The degree of postanesthetic nausea depends on the depth and duration of the anesthesia. Ether is perhaps more nauseant than others, and this is exaggerated by its persistent taste, which acts by suggestion. Operative procedures, such as handling of the intestines, may also play a part.

During the surgical anesthesia, ether and, to a still greater extent, chloroform, by their peripheral action on the muscle and on the peripheral innervation, relax the tonus and arrest the movements of the entire digestive tract from the stomach to the rectum. The stomach relaxes, so that the division between fundus and pylorus largely disappears. Acute gastric dilatation is an occasional serious complication. Asphyxia does not overcome the depression. When the administration is discontinued, and if the anesthesia was not too profound or too prolonged, the small intestines and colon recover promptly, and may pass into a period of stimulation, increased colon tonus being especially notable. The stomach recovers more slowly; after deep narcosis, especially with chloroform, complete paresis of the stomach and intestines may persist for two hours, and incomplete paresis for twenty hours. The paresis that commonly follows laparotomies, however, is only partly attributable to the anesthetic, and mainly to the operative procedures (Cannon, 1911). *Other lipolytic narcotics* produce similar depression, but it is relatively slight with barbiturates, and practically absent with ethylene. With *nitrous oxide*, the asphyxial stimulation predominates. During the administration, peristalsis is increased and irregular. After the discontinuance of the administration, marked inhibition follows, but this largely passes off within an hour.

The above observations were made with the fluoroscope (Cannon, 1911; Baron and Barsony, 1914; Kuehlewein, 1921), and on permanent fistulas of the stomach, small intestines and colon (G. H. Miller, 1926). Bhatia and Burn, 1933, found the inhibitory effect of ether on the intestines and uterus much less in fully pithed cats, and therefore concluded that the inhibition is partly supraspinal.

Relative Effect of Different Anesthetic Agents.—Light surgical anesthesia of dogs prolonged the *gastric emptying time* by an average of 64 per cent with chloroform; 40 per cent with ether; 15 per cent with nitrous oxide; about 7 per cent with ethylene, cyclopropane and divinyl oxide. In young normal men, amytal, 0.2 Gm., shortened the emptying time by an average of 20 per cent. The effect on intestinal propulsion is probably similar (E. J. Van Liere, 1943). The *colon tonus and mobility* of dogs are decreased in anesthesia by chloroform, diethylether, divinyl ether; but cyclopropane, ethyl bromide, ethyl chloride and nitrous oxide produce immediate spastic contraction. Barbital has little effect (Van Liere *et al.*, 1944).

The *oral administration of ether and especially chloroform* causes considerable gastric irritation. In milder degree this produces a carminative and anodyne effect, which is useful in colic and dyspepsia (Spirit of Ether, 5 cc., 1 ʒ; Spirit of Chloroform, 2 cc., ½ ʒ; Chloroform Water, 15 cc., 4 ʒ). Spirit of Ether is also employed as a reflex "*diffusible stimulant.*"

If ether is taken into the stomach, it is rapidly volatilized and large quantities distend the viscus, sometimes so much as to interfere with respiration; it may even produce rupture of the organ. The duodenal injection of 2 cc. of ether, through the Einhorn catheter, has been used clinically for *reflex stimulation of pancreatic secretion* (G. Katsch and v. Friedrich, 1922). The spleen contracts actively in ether anesthesia. This is inhibited by nicotine. Barbiturates relax the spleen (Bhatia and Burn, 1933; Essex *et al.*, 1936; Haussner, Essex and Mann, 1938).

Anesthetics on the Parturient Contractions of the Human Uterus.—*Ether and chloroform* inhalations depress, in proportion to the depth of the anesthesia. The effects set in and pass off rapidly. Analgetic doses relieve the pain without materially weakening uterine contractions. Surgical anesthesia abolishes the contractions completely. Colonic ether-oil analgesia, with or without quinine, causes but little depression. *Avertin analgesia,* and *barbiturates* in amnesia dosage, have little or no effect on the contractions. *Nitrous oxide with deep oxygen* does not weaken the contractions even with deep surgical anesthesia. To the contrary, it has a spastic tendency.

Spinal anesthesia with procaine has little if any effect. Stovaine has a spastic tendency. *Morphine* has little if any effect. *Scopolamine* and *atropine* also have little effect, but tend to stimulate. *Quinine* usually has no effect, but it may stimulate or relax. *Epinephrine* tends to produce brief relaxation (Bourne and Burn, 1930; Dodek, 1932; Barlow and Jones, 1934). Similar results have been reported for parturient rabbits (H. Franken and Schossmann, 1928).

Ureter.—The contractions are depressed by chloroform in living animals, even by doses which do not affect the respiration or circulation (Lucas, 1906 and 1907). Inhalation of chloroform therefore relieves the ureteral spasm of *renal colic.* Ether stimulates the contractions.

Urinary Bladder.—Anesthetics (ether, pentobarbital) depress the stretch response and prevent sustained contraction when the bladder is completely filled, so that residual urine remains after micturition (in cats; Kolb and Langworthy, 1938). However, the paresis which may last for some days after abdominal operations is probably due to reflex disturbances, and not to direct effects of the anesthetic.

Skeletal muscle is depressed by the lipolytic narcotics, so that the excitation threshold rises, at first slowly, then rapidly when narcotic concentrations are reached, up to a hundred times the original value. Response to stimulation is slight, slow and localized, but persists until muscle is irreparably injured. Analogous effects are produced by exposure to acetylene, ethylene and nitrous oxide, but these require much higher concentrations (forty, sixty and eighty times, respectively, higher than ether). Nitrogen has little effect even at 10 atmospheres pressure (H. T. Graham, 1929). Potassium contracture is increased by chloroform in anesthetic and higher concentrations; less so by ether (C. Torda, 1944). Chloroform causes a specific *rigor* of the muscle when applied directly or injected into an artery (Kussmaul, 1858; Cl. Bernard). It also coagulates the extracted muscle proteins (Fuerth, 1896). Immersion in saline saturated with ether also results in irreversible rigor. Deep ether anesthesia produces moderate *depression of the motor endings* (Auer and Meltzer, 1914). Chloroform does not have this effect (Githens and Meltzer, 1914). Deep etherization of rats lowers the gastrocnemius muscle potential by an eighth; half of this is due to anoxia. Ether with intocostrin gives about a third greater depression of neuromuscular transmission than the sum of their separate actions (W. Schallek, 1946).

Peripheral Action on Nerves.—The direct excitability of nerves is not materially altered when the central nervous system is completely anesthetized (J. Bernstein, 1870). Direct application of solutions or vapors of the volatile anesthetics to a nerve lowers its conductivity and excitability, changes the polarization (Waller, 1896; Alcock, 1906; Bethe, 1908), and abolishes the action current (Forbes, McIntosh and Sefton, 1916). The sensory fibers succumb before the motor (Longet). The *conductivity of the nerve* is lowered, as well as its excitability; for if a nerve is exposed to ether vapor, stimulation at the proximal end ceases to be effectual much sooner than at the distal end; and with a long stretch of partly narcotized nerve, the response is the smaller, the farther from the muscle the stimulations are applied (Dendrinos, 1902). The excitability is recovered if the ether is washed off in time. With chloroform, recovery is more difficult. The concentrations required for these peripheral effects are greater than can exist in living animals; the motor and sensory nerves remain excitable even in profound anesthesia; nor is the conductivity lowered during life (Forbes, McIntosh and Sefton, 1916). Narcosis of a nerve diminishes its CO_2 production materially. Lower concentrations increase the CO_2 (Tashiro and Adams, 1914). The undiluted anesthetics when *injected directly into a nerve* produce a circumscribed neuritis, enjoining caution in subcutaneous or intramuscular injections.

Special Senses.—The *odor and sweet taste* of chloroform and ether show a peripheral stimulation of these sense organs.

The **urine output** is decreased during anesthesia and for some time after, but is generally compensated so that the twenty-four-hour output is about normal, both as to volume and solutes (Walton, 1933). The decrease is due to increased water loss by sweating, with diminished income because of the nausea; but there appears to be also a more direct action, for most anesthetics prevent diuresis from ingestion of fluid (Heller and Smirk, 1932).

Urine flow may be arrested reflexly by blowing anesthetic vapor (or amyl nitrite) upward through a tracheal cannula so that it passes into the larynx, but not into the lungs, and very little is absorbed.

Ether on Urine Flow.—This is *diminished* during the anesthesia. The oliguria is partly due to increase of blood concentration which is a constant phenomenon of ether anesthesia. Consequently, the decrease of urine can be prevented by increasing the water supply (Barbour and Bourne, 1924). Contraction of the renal vessels, with diminished kidney volume, occurs only in overdosage, and then as a part of the general circulatory disturbance (Buxton and Levy). In surgical patients, the urine output is often diminished by restriction of the water intake (Epstein *et al.*, 1916). As soon as the anesthesia is terminated, the flow *increases*, the output being above normal for several days. The specific gravity is also increased. This diuresis is proportional to the duration of the anesthesia (W. H. Thompson; Hawk, 1911, dogs; Pringle *et al.*, human, 1905).

Chloroform on Urine Flow.—This diminishes steadily during clinical anesthesia (Bobee, 1909), owing to the low blood pressure with diminished kidney volume (Thomson and Kemp, 1898). The *chloride excretion* is increased during and after the anesthesia.

Phenolphthalein Output.—The "functional capacity" of the kidney, as measured by this test, is generally somewhat decreased by ether anesthesia, the more the longer the anesthesia. The output is lowest soon after the operation, returning to normal in twenty-four to forty-eight hours. Exceptionally, there may be no decrease, but rather an increase; or the decrease may be large. It has no relation to albuminuria (R. H. Miller and Cabot, 1915; Epstein *et al.*, 1916). Whipple and Sped, 1915, found the phthalein output lowered after ether, paraldehyde, chloral, chloroform or alcohol anesthesia. They observed that Eck's fistula produced lowered output, as does phosphorus, and therefore attributed the effect to disturbance of liver functions.

Renal Irritation.—Postanesthetic *albuminuria* occurs in about one-fourth of ether anesthesias, and about one-third of chloroform (Wunderlich). Tube casts are common. With previously sound kidneys, the renal irritation usually disappears in a short time. In patients with chronic nephritis there may be fatal suppression of urine; but patients with some albuminuria are often etherized without bad effects. Chloroform is apparently somewhat more injurious than ether, but the difference is not very marked.

Relation of Renal Injury to Age and to the Lipoid Material of the Kidneys.—The renal epithelium of old animals shows greater histologic and functional injury after chloroform or ether, even though the kidney function appeared normal before the anesthesia. This is paralleled by increase of the stainable lipid of the epithelium, which is normally more abundant in old animals, and is further increased by anesthesia, especially in the old. Chloroform is distinctly more deleterious than ether (MacNider, 1921). Foulerton, 1921, attributed the lipid to infiltration from lipemia, owing to hepatic injury.

Anesthetics in Experimental Nephritis.—In dogs rendered polyuric and glycosuric by tubular uranium nephritis, MacNider, 1913, found chloroform anesthesia much more damaging than ether. In full-grown animals, chloroform promptly arrested the urine flow, so that it would not respond to diuretics; it made the histologic lesions more marked. The damage was less in young animals. Ether produced but little effect even in adults. (Young puppies are remarkably tolerant also to the other dangers of chloroform; Whipple, 1912.)

Nitrogen excretion is diminished during ether anesthesia (Pringle, 1905); it is then increased for twenty-eight to forty-eight hours, depending but slightly on the duration of the anesthesia. The total increase may amount to 45 per cent, but is generally smaller, and therefore much less than with chloroform (Hawk, 1908). Chloroform anesthesia *increases* the total nitrogen excretion (especially in carniverous animals), and the ammonia, allantoin, diamino acids, polypeptids, creatinine and organic sulfur. It *decreases* the excretion of urea and of monoamino acids (Lindsay, 1911). The increase persists for some days and may amount to 300 per cent. These changes are similar to those of phosphorus poisoning, and probably depend on the hepatic lesions.

Gaseous Metabolism and Blood Gases.—The production of CO_2 is decreased during anesthesia, by a third or a half; but the disturbances of respiration interfere with the gas exchange (Henderson), and thus raise the CO_2 concentration of the blood and lower the oxygen saturation.

The *CO_2 content of the blood* is increased from 25 to 36 per cent, the oxygen content reduced from 13.6 to 8.1 per cent (Gardner and Buckmaster, 1910). Chloroform depresses the gas metabolism of the *brain* by 60 to 90 per cent, proportional to the depth of the narcosis. With ether, the CO_2 falls less than the oxygen; the reverse is true of morphine (Alexander and Cerna, 1913). In *nerve fibers*, direct exposure to low (stimulant) concentrations increases CO_2 production, while anesthetic concentrations depress it (Tashiro and Adams, 1914). In *plants*, anesthetics first increase and then depress gaseous metabolism (Osterhout, 1918).

The *temperature* falls during anesthesia by ether and chloroform, partly through diminished heat production, partly through increased heat loss. The diminished production (Scheinesson) is reflected in decreased CO_2 formation, and is due to the decreased muscular movements and tone. The increased loss of heat is due to narcosis of temperature regulation, aided by exposure, and a little by the cooling action of the vapor. In ether narcosis (as after section of the spinal cord), cold reflexes fail to produce the normal protective blood concentration (Barbour and Bourne, 1924). In the paralytic stage, the dissipation of heat is also diminished by failure of the circulation, but the diminished heat production predominates in the collapse. The body becomes practically poikilothermal, and if the coma is of long duration, the temperature may reach a low level, unless heat is applied artificially.

Clinically, chloroform and ether cause about an equal fall of temperature. In ordinary operations on man the fall is from 1° to 4° F., averaging about 2.5° F. (H. A. Hare, 1888); much more in prolonged operations on animals (Moore, 1919). It is not markedly increased by the ordinary dosage of morphine. It can be prevented by external heat (the room temperature should be above 26.5° C. = 80° F.) and by keeping the skin dry (S. G. Davis, 1909). Excessive heat must be avoided, since temperature regulation is disturbed in all directions. Etherized dogs can maintain a constant body temperature only if the environing temperature is near 31° C. (Barbour and Bourne, 1924). *Precautions against loss of heat* are especially important, since chilling favors the occurrence of postanesthetic pneumonia. Warming the vapor has been advocated (Gwathmey, 1908), but the loss of heat from this source would be insignificant (Boothby, 1913).

Anesthetic hyperglycemia and glycosuria may occur temporarily in ordinary ether anesthesia (animals, Hawk, 1904; after intravenous injection, King, Maple and Haupt, 1913; human, Roehricht, 1905), and especially with chloroform (E. L. Scott, 1914). They are less with barbiturates (C. L. Evans *et al.*, 1931). Amytal and chloralose are said to cause the least disturbance of carbohydrate metabolism (Best, 1935). Ether completely inhibits the hypoglycemic action of insulin in dogs; the hypoglycemia sets in when the ether wears off (S. A. Peoples, 1943). The hyperglycemia involves extensive mobilization of liver glycogen (King *et al.*, 1912) which may fall by 60 per cent in the course of an hour's ether anesthesia (Evans *et al.*, 1931). Several factors are involved: asphyxia, through liberation of epinephrine and by acidosis; cooling; and perhaps direct stimulation of a diabetic center (Campbell and Morgan, 1933). The utilization of the mobilized dextrose may be normal or impeded (C. L. G. Pratt, 1938). The reducing action of the urine is partly due to ascorbic acid, especially in dogs, whose ascorbic acid synthesis is increased up to fifteen times the normal (Bowman, 1937); other reducing substances are perhaps present after chloroform (Hawk, 1911).

Ether hyperglycemia is more intensive in well-fed dogs than after fasting (Hawk, 1911). Chloroform diminishes the tolerance to galactose and levulose (Marshall and Rowntree, 1915). The *diastatic activity* of the blood increases in ether anesthesia, parallel to the rise of blood sugar (Killian, 1917). Ether and nitrous oxide increase the glycosuria and D ÷ N ratio in *phlorhizin diabetes*, the extra sugar being derived from glycogen, probably through tissue asphyxia (Sansum and Woodyatt, 1915).

Anesthetic hyperglycemia occurs after *division of the splanchnics* (King, etc., 1911), but only to a slight degree (Keeton and Ross, 1919). *Atropine* reduces the hyperglycemia considerably (Ross, 1919). It is checked by *barbiturates,* although these do not inhibit epinephrine or pituitary hyperglycemia (Campbell and Morgan, 1933). *Epinephrine output* is not indispensable to ether hyperglycemia, for this can readily be induced after excision of the adrenals (G. N. Stewart and Rogoff, 1920); but the *epinephrine store* is decreased by etherization; not by trauma (Stewart and Rogoff, 1920). Chloroform, ether and chloral decreased the output of epinephrine from perfused out suprarenal glands (Antischkow, 1927). Hawk, 1911, attributed the ether glycosuria to dyspnea. Grube, 1911, believed that the cooling is a factor, and this was confirmed by Tachi *et al.*, 1926. Ross and McGuigan, 1915, claimed a direct action of the ether, and that asphyxia and excitement are not essential.

Acidosis.—Inhalation anesthesia, whether by ether, chloroform or nitrous oxide, tends to produce some acidosis, with fall in *p*H and in the reserve alkali (bicarbonate) in the blood, and with the occurrence of acetone in the blood; but there is no evidence that it is of sufficient degree to be significant in clinical surgery (Menten and Crile, 1915; Austin and Cullen). The decrease of reserve alkali is greatest with chloroform (Morris, 1917).

With clinical ether anesthesia, compensated acidosis occurs in 30 to 85 per cent of routine operations; uncompensated acidosis in 15 to 20 per cent. The average reduction in plasma bicarbonate is equivalent to 5–15 cc. of CO_2 per 100 cc. The acetone substances of the blood are increased, accounting for at least 60 per cent of the bicarbonate decrease, and perhaps for all (Reimann, 1919). Killian, 1917, claimed that the *oral administration of sodium bicarbonate,* 20 Gm. per day, corrects not only the diminished alkali reserve, but also the hyperglycemia. It would be especially indicated if the CO_2 capacity of the plasma before operation is less than 58 cc. (Reimann and Bloom, 1918). The fall is not due to hyperpnea, for it occurs also under uniform artificial respiration. It is prevented by inhaling air with 3½ per cent of CO_2; 3 per cent is ineffective. MacNider, 1921, found the alkali depletion much more marked with old than with young animals; it was also greater with disturbed kidney function. W. E. Stone, 1938, found the *lactic acid content of the brain* decreased with barbiturate or ether anesthesia. Acetonuria is frequent after ether or chloroform anesthesia (Marshall and Rowntree, 1916; ethyl chloride, Telford, 1906; even after local cocaine, Gundrum). With ether, it is not much influenced by the duration of the anesthesia; fasting may be a factor (Chalfant, 1912). It is more common with the closed than with the open methods of administration. Children are more susceptible. J. J. Short, 1920, however, found the acetone substances in the blood and urine practically unchanged in patients who had been under ether for three-quarters of an hour; with more prolonged administration there was a slight increase.

Leake *et al.*, 1923, concluded that the *mechanism of the acidosis* is by withdrawal of base, and not by acid production, and that hyperventilation plays a very small part. Seevers, Stormont *et al.*, 1939, found that hyperventilation during clinical anesthesia produces marked alkalosis, with an average rise of 0.25 *p*H and lowering of CO_2 tension of arterial blood by 21 mm.

Alkali Reserve on Potency of Anesthetizs.—Tiffeneau *et al.*, 1930, reported that anesthetic potency is increased by administration of acid and decreased by alkali.

Delayed Chloroform Poisoning (Postanesthetic Toxemia).—The prolonged administration of chloroform may be followed by fatty degeneration of the liver, heart, kidneys, leading to profound toxemia, vomiting, prostration, icterus, and coma which is often fatal. Chloroform administration should, therefore, not be continued longer than half an hour. Postanesthetic toxemia is especially common with children and old people, in pregnancy, and in patients with acetonuria, diabetes, hepatic disorders (Hildebrandt, 1913), cyclic vomiting, rickets or wasting diseases. Anesthetics that do not contain chlorine and bromine are much less liable to toxic hepatitis. Avertin with amylene hydrate causes more liver damage than ether. Nitrous oxide, ethylene, evipan and cyclopropane are apparently free from this effect (unless there is anoxia), as are also local and spinal anesthesia (S. M. Rosenthal and Bourne, 1928; L. M. Morrison, 1943). Similar hepatic changes are produced by elementary phosphorus, by compounds of arsenic and of selenium, by tars, and by some bacterial infections. Abundant diet rich in carbohydrates (Graham, 1917; MacNider, 1929) and casein furnishes considerable protection against chloroform (and arsenical) hepatitis, while fat, and fasting, increase the susceptibility (W. C. Davis and Whipple, 1919, standardized dogs; L. L. Miller and Whipple, 1942; Ravdin *et al.*, 1943).

Symptoms.—The importance of late chloroform poisoning seems to have been first recognized by Bevan and Favill, 1905, although cases had been reported previously. The symptoms start after ten to 150, generally twenty-four to forty-eight hours, the intervening time being indistinguishable from the normal course. They consist in profuse, sometimes incessant, vomiting, first bilious, then blood-stained; excitement and delirium, alternating with apathy and prostration; dilated pupils; rapid pulse; icterus; unconsciousness deepening into coma. Death occurs in four to five days (Herb, 1911). *Necropsy* shows degenerative lesions in many organs, chiefly in the liver, brain, medulla, kidneys, suprarenals and heart; minor changes in the pancreas and gastro-intestinal tract; none in the ovaries, testes, lymph glands, spleen and thyroid (Risi, 1939; halogenated hydrocarbons, rats and mice, Abreu *et al.*, 1944). The *blood* generally shows retention of nonprotein nitrogen, urea and amino acids, similar to phosphorus poisoning, though less intensive (E. K. Marshall and Rowntree, 1915). All the current *liver function tests* reveal impairment by chloroform, carbon tetrachloride and other halogenated anesthetics (Drill and Ivy, 1943, bromsulfalein and serum phosphatase; L. M. Morrison, 1943, bile salt concentration in urine; Rosenthal and White, 1938, bromsulfalein and icteric index). Eight days are required for return to normal if the chloroform anesthesia lasted half an hour, and six weeks if it lasted two hours. The *anatomic lesions in the liver* consist in extensive vacuolization, fatty degeneration, swelling and necrosis of the cells, especially about the central veins (Nothnagel, 1866; Whipple and Sperry, 1909; Herb, 1911). Hypodermic injection of chloroform in paraffin oil leads to hepatic lesions similar to those of human Laënnec cirrhosis (Iwata and Inui, 1940). The fatty changes are perhaps due to infiltration and not to degeneration (Foulerton, 1921. Large doses of other anesthetics [urethane, Sollmann] cause similar degeneration). The icterus, the disappearance of fibrinogen from the blood; the diminution of liver lipase, with increase of plasma, kidney and muscle lipase (Quinan, 1915); the delay of the biliary excretion of phenoltetrachlorphthalein (Whipple and pupils, 1913); the changes in metabolism; and the occasional occurrence of leucin and tyrosin, are analogous to acute yellow atrophy and to phosphorus poisoning. In animals which recover, the liver changes tend to return to normal, even when there has been extensive necrosis (Whipple and Sperry, 1909). Mosiman and Whipple, 1912, found that puppies and fetuses are less subject to the hepatic necrosis; and that pigeons, frogs and terrapin seem to be immune. The *impairment of bile excretion* by chloroform, carbon tetrachloride and phosphorus is parallel to the histological changes of the parenchymal cells, and not of the stellate cells, suggesting that the latter are not concerned in bile pigment excretion (Wakabayashi, 1928). (The bromsulfalein retention test appears the most suitable indicator of hepatic dysfunction in animals; J. Casals and Olitsky, 1946.)

Protection against chloroform hepatitis is furnished in dogs by preliminary injection of casein digest, methionine, or sodium thioglycolate, not by sodium thiosulfate or glutamate, dextrose or gelatin. The common factor in the protection appears to be the -SH group (Brunschwig *et al.*, 1945). *Methionine* gives material protection if administered within three hours before the chloroform. It would probably also be of some value for treatment (3 to 5 Gm. daily; J. H. Eddy, 1945). It is chiefly responsible for the protective effect of casein and large amounts of meat. Cystine is also protective, but other amino acids are not (L. L. Miller *et al.*, 1940; Miller and Whipple, 1942). Protection is also furnished by hypodermic injection of *irritants*, such as sodium *xanthine* (Forbes and Neale), sodium ricinoleate or colloidal carbon. It has been suggested that the subcutaneous inflammation makes protein cleavage products available to the liver (Vars *et al.*, 1939). Administration of *liver extract* is somewhat protective in rabbits, chiefly but not entirely through its xanthine (J. C. Forbes, 1939). Davis and Whipple, 1915, obtained no protection from alkalis. Epinephrine and quinine appeared somewhat protective, the epinephrine, however, only after a day. The addition of other liver poisons did not markedly modify the effects of the chloroform.

Histologic lesions occur also in other organs, especially fatty and degenerative changes in the epithelium of the straight and convoluted tubules of the kidneys (Howland and Richards; Apperly, 1812); in the pancreas (Whipple and Sperry); in the suprarenal cortex and other glands of internal secretion (Scaglione, 1915). Involvement of the heart muscle sometimes dominates the symptoms. Degeneration of the cardiac ganglia has been described (Strassmann, 1898). Small hemorrhagic foci exist in the gastro-intestinal tract, mesentery, pleura and pericardium (Herb). These histologic lesions can be produced, especially in young dogs, by chloroform anesthesia lasting two hours (Whipple and Sperry, 1909; Whipple and Hurwitz, 1911). Repeated chloroform anesthesia, with rabbits, produces degenerative changes also in the central nerve cells and those of Auerbach and Meissner plexuses. So do many other poisons, but not ether (Lissauer, 1914). Cragin and Hull, 1911, pointed out the similarity of the late chloroform phenomena to *eclampsia*, and suggest that chloroform would be much more injurious than ether in this condition. McCrudden, 1912, reported that chloroform is more likely to produce fatty changes of the rabbit's heart after *nephrectomy*. Ether does not do this. *Encephalopathy* occurs occasionally after prolonged anesthesias. Necropsies show a great variety of degenerative lesions of the cortex and basal ganglia, probably due to anoxia (Steegmann, 1939).

Experimental hepatic cirrhosis occurs after repeated administrations of chloroform (Mertens, 1896; Herter and Williams, 1905). It is favored by the presence of bacterial infections and may then proceed to acute yellow atrophy (Opie, 1910).

Intravenous injection of ether (large doses in rabbits) causes destruction of liver tissue, with extensive thrombus formation (prevented by leech extract). The mechanism is evidently altogether different from ordinary chloroform degeneration (L. Loeb, 1906; Loeb and Meyers, 1910).

Other after-effects of anesthetics are mainly due to the irritant action, and may therefore occur with either anesthetic. They may be recapitulated as: *Gastric irritation, nausea and vomiting* are almost universal; less so with open methods; they vary with duration of anesthesia. *Tympanites* occurs especially after abdominal operations; the anesthetics are only contributory. *Renal irritation* is about equally frequent with either anesthetic. *Aspiration pneumonia* is more frequent after ether.

Protoplasmic Toxicity and Local Irritation.—The anesthetics, on direct application, narcotize all cells, of the lower organisms as well as of the higher. This is preceded, at least in some cases, by evidences of stimulation. The concentration required for irritation is greater than is reached from systemic administration. At the place of application, however, the irritation is marked. Chloroform is more irritant than ether, with equal concentration, and can be used as a rubefacient or even vesicant.

Cutaneous Irritation.—The evaporation of the volatile anesthetics cools the skin. Local anesthesia by freezing may thus be produced (see "Ethyl Chloride"). With ether and especially chloroform, the cooling is succeeded by a burning sensation and rubefaction. If evaporation is prevented, this may proceed to vesication. Chloroform is therefore used as an active counterirritant (chloroform 30, soap liniment 70). Local application of chloroform or of carbon tetrachloride relieves the itching of *insect bites* (W. A. Hoffman, 1941). The irritant action on mucous membranes is even more violent.

Hypodermic injection of ether is employed (1 to 2 cc.) as a rapid reflex stimulant in collapse, but it may lead to ulceration. It tends to produce slight and transient rise of blood pressure; but it fails in the severer grades of hemorrhage and shock, and in anesthesia (Lieb and Herrick, 1917). The *respiration* of normal rabbits is stimulated by the hypodermic injection of chloroform or ether; but these have little effects on deeply morphinized animals (Hanzlik, 1923).

Antiseptic Action.—Ether is quite ineffective for sterilizing the *skin* (G. T. L. Archer, 1945), but good results are claimed for ether in the *disinfection of wounds*, rinsing superficial wounds with liquid ether, or pouring 5 to 20 cc. into deeper wounds, repeating several times (Koristensky, 1930). In *perforating peritonitis*, 50 to 75 cc. are poured into the peritoneum (30 cc. for children). It is claimed that this diminishes the mortality without increasing the incidence of adhesions or pulmonary complications, or other untoward effects (Souligoux, 1913; Ducreux, 1938). *Chloroform* is fairly antiseptic (Strassmann, 1888; Salkowski, 1891). Chloroform water is used as a preservative.

Vermifuge.—Chloroform has been employed for the expulsion of tapeworms, but the effective doses are too irritant and toxic to make its use advisable. Alessandrini, 1915, advised it against hookworm and other parasites, 3 to 4 Gm. in olive oil or castor oil. Darling *et al.*, 1918, did not find it very effective. The **narcotic effects on infusoria** were observed by C. Bernard, 1876. The *action on fishes* is described by Clayberg, 1917, and utilized for bio-assays.

In plants the narcotics abolish protoplasmic movements; cause plasmolysis; suppress the gross movements of the Sensitive Plant (Mimosa pudica). Exposure to chloroform and especially to ether vapor hastens blooming (Keeble, 1906). The assimilation of oxygen is abolished by fairly low concentrations of chloroform; whereas CO_2 production is stimulated even by considerably higher concentrations Excessive concentrations, however, paralyze this also (A. A. Irving, 1911). Dry seeds resist high concentrations of anesthetics, because the dry envelopes of the seeds are impermeable. If these are removed or punctured, anesthetics become injurious (B. Schmid, 1901).

Ferments.—Pepsin, rennin, trypsin, diastase, invertase, catalase and other organic ferments, as well as metallic catalysts, are restrained by anesthetics in the same general order of efficiency as living cells.

CHOICE OF THE ANESTHETIC

This is determined by the particular conditions of the patient and of the operation. Safety should be the first consideration, but the depth and duration of anesthesia, the comfort of the patient, and the convenience of the operator are also important. The principal anesthetics which deserve consideration are: general anesthesia by ether, chloroform, nitrous oxide, ethylene, cyclopropane, vinyl ether or avertin; with or without morphine, scopolamine and barbiturates; seconal or pentothal; spinal anesthesia; and local anesthesia.

For *short operations*, local anesthesia by procaine or similar drugs should be preferred. Where these are not practicable, nitrous oxide or cyclopropane are used. Nitrous oxide is the safer. It is practically devoid of danger in short anesthesia. For *longer operations*, the advantages of general anesthesia often outweigh the disadvantages, as compared with spinal anesthesia. *Chloroform* is far more dangerous than ether, ethylene or nitrous oxide, although with practical experience the acute dangers may be greatly reduced. The chief immediate risks are in the induction period. The danger of postanesthetic toxemia makes its employment in prolonged operations almost inexcusable. *Cyclopropane* is more toxic to the heart. It has perhaps a special value in *shock*, as it tends *to raise blood pressure*. Nitrous oxide with oxygen and ether has variable effects on blood pressure, but is probably safer. Pentothal and spinal anesthesia lower blood pressure and so present a special risk (Crooke *et al.*, 1944).

Ether, ethylene and nitrous oxide are practically equally safe in ordinary cases. *Ether has several advantages:* it is easily administered; it gives more complete relaxation, less asphyxia, and less rise of blood pressure; so that the condition of the respiration and circulation are more nearly normal. Its administration is simple and does not require so much experience; ether is perhaps the safest anesthetic for long operations. The disagreeable features of its induction can be practically avoided by skillful administration. The advantages of nitrous oxide and ethylene appear especially in the cases in which ether is specifically contraindicated.

Contraindications to Ether.—The irritant action contraindicates its use (and also that of chloroform) in *renal disease* and in *acute respiratory disease* (colds, bronchitis). In these, nitrous oxide is preferred, although ether is often employed without damage. Chronic respiratory disease is not a contraindication, unless there is actual dyspnea (emphysema). *Children* are especially subject to ether irritation, resulting in respiratory embarrassment and choking. Ether *favors bleeding*, especially in parts in contact with the vapor; it is therefore not popular for operations of the mouth and larynx. In *brain tumor or atheroma*, ether and especially nitrous oxide may produce apoplexy; avertin, or local or spinal anesthesia, should be preferred. *Advanced heart disease* makes all anesthetics more dangerous. In this respect, ether and nitrous oxide are about equal; both should be preferred to chloroform and cyclopropane. The danger is proportional to the functional condition rather than to the valvular lesion; with fair compensation, ether can be used safely; indeed, the circulation may be rather improved during the anesthesia. In advanced fatty degeneration, it is better to employ local or spinal anesthesia. In *hot climates*, above 93° F., ether is vaporized so rapidly that its use by the ordinary methods is difficult.

Nitrous oxide is perhaps the safest anesthetic for short operations, and in sequence with ether. If the anesthesia lasts longer than an hour, it becomes somewhat more dangerous than ether even in the hands of experts; it is much more dangerous with limited experience. It is more pleasant to take; it causes no irritation, and but little excitement or gastric disturbance. There are practically no after-effects. It is especially preferred for short operations, and for excitable and neurotic patients. Old individuals are good subjects. Its *disadvantages* are, that the muscular relaxation is less complete; it causes more or less asphyxia and abnormal rise of blood pressure; and it requires special apparatus and special experience for its successful administration. Obese or anemic patients are also unsuited to all anesthetic methods which interfere with respiration.

Ethylene is in most respects intermediate between ether and nitrous oxide. It is discussed in a separate section.

Chloroform is convenient for patient and operator: its action is much more rapid than that of ether; it induces the most profound anesthesia and relaxation; it does not have the disagreeable taste, causes less suffocation, less excitement, and less postoperative nausea and vomiting. These disagreeable features of ether can be largely avoided by proper administration (preliminary nitrous oxide, and open-drop method). The dangers of chloroform may be risked in emergencies; when prompt anesthesia is imperative; in brain surgery, atheroma and aneurysm, where the lowered blood pressure is advantageous; and possibly on the battlefield to increase speed and lessen bulk. Chloroform has no advantage over ether in renal disease, and but little in respiratory diseases. *Specific contraindications to chloroform* are: advanced heart disease, Graves' disease, hemorrhage, prolonged operations, and conditions which favor acidosis.

Chloroform in Obstetrics.—It was generally believed that the use of chloroform in childbirth is relatively safe (J. Hill, 1916). This is explained partly by the lesser apprehension of the patients, and partly by the light degree of anesthesia, or rather analgesia, which ordinarily suffices. For deep anesthesia, it is as dangerous as for other patients, and presents the added disadvantage of delaying labor and thus favoring postpartum hemorrhage. The analgetic dosage does not cause serious delay. The anesthetics pass into the fetal circulation (Jung, 1914), and prolonged anesthesia is probably as injurious to the child as to the mother.

Statistics of Anesthetic Mortality.—Reliable statistics of sufficient extent will not be available until the reporting of *all* anesthesias, good and bad, is compulsory. Even then, the ratio of "bad risks" will be indefinite. Existing statistics give only a rough idea of the relative danger, but they agree fairly well. According to the various compilations, the acute mortality for *chloroform* is given as 1:1000, 1:2075, 2500, 3000, 3500, 3700, 5900; a fair estimate would seem to be 1:3500. This does not take account of the delayed deaths. For *ether*, the figures run 1:5100, 14,000, 14,600, 16,500, 16,800, 23,200; the average would be perhaps 1:16,000. For *A.C.E. mixture*, the ratio is 1:3370; for *ethyl bromide*, 1:5400; for *ethyl chloride*, 1:3000, 7000; for *nitrous oxide* in short operations (dentistry), less than 1:5,000,000. Beecher, 1938, gives 1:500 to 1:2000 for avertin, 1:2000 for chloroform, 1:3500 for cyclopropane, 1:5000 for ether, and 1:50,000 for nitrous oxide.

ADMINISTRATION OF GENERAL ANESTHETICS

Preparation of Patient.—A cleansing enema may be given on the evening preceding the operation, and an interval of five hours should have elapsed since the last meal, which should not be too heavy. The patient should be examined for cardiac, renal and pulmonary disease. He should be placed in such a position as to interfere to the smallest possible extent with respiration, the head preferably low and turned to the side. The clothing should be loosened and all foreign bodies—false teeth, and so forth, removed from the mouth. To prevent the local action of ether or chloroform on the skin, the mouth and nose may be anointed with petrolatum. Care should be taken to have the patient close the eyes.

Administration.—Inhalation is superior to all other methods in the convenience of its application, and in the facility with which the depth of anesthesia can be regulated to suit the needs of the moment. This depends on the concentration of the anesthetic vapor and can be adjusted either by using exactly dosed mixtures of anesthetic and air or, more simply and on the whole more efficiently, by watching closely the condition of the patient. The response of the respiration, pupils and other reflexes to changes in the concentration of the vapor must be observed. The concentration can be increased either by pouring the anesthetic more rapidly, by applying the mask closer to the face, or by limiting the supply of air. The mask should at first be kept fairly away from the mouth, until some narcotic effect is obtained, to lessen the feeling of choking from the concentrated vapor. The patient should be encouraged to breathe quietly and regularly. Counting is a good expedient for this purpose. If the patient holds his breath, struggles or coughs during the induction of the anesthesia, the concentration should be temporarily reduced, not increased. Rapid and deep breathing lessens the concentration of the anesthetic by dilution and cooling, when inhaled from gauze. Slow and shallow breathing gives more concentrated vapor.

Management during Recovery from Anesthesia.—The patient should not be left until he is fully conscious, since vomiting and inspiration of mucus may cause asphyxia. No nourishment should be given for at least four hours. If vomiting is persistent, a tumbler of hot water with a teaspoonful of bicarbonate may be given. Recovery is usually more speedy and satisfactory if the patient is placed on his side.

Regulation of Anesthesia.—Mechanical devices do not replace the sense of responsibility, the constant watchfulness and the quick reasoning of the experienced anesthetist. Anesthetization is not a physical experiment where the factors can all be foreseen; the condition of the patient may vary from moment to moment, and must be taken into account. The state of the respiration must be carefully watched: if the patient holds his breath, the mask must be held farther away, since the next respiration will be an especially deep one. When the respiration becomes slow and shallow, a sufficient amount has been taken, and the concentration may then be diminished. The aim is to give no more than is necessary just to keep the patient anesthetized. On the other hand, care must be taken to keep him thoroughly under the influence, for excitement, struggling, stoppage of respiration, shock and overdosage are much more common under partial or uneven anesthesia. Since the respiration and circulation react one upon the other, so that no change could occur in the latter without being noticed in the former, and since most accidents occur from stoppage of the respiration, it may be sufficient to watch this alone, as is advised by some. But as it is of the highest importance to discover beginning failure of the one or the other at the earliest possible moment, both should be carefully observed. *Severe hemorrhage*, exceeding 20 cc. per Kg., materially lowers the necessary dosage of the anesthetic (D. R. Wood and Jaco, 1943).

Closed and Open Methods of Administration.—The anesthetics may be administered with or without free access of air. In the closed methods, the patient rebreathes more or less from a permanent mixture of vapor through a fairly air-tight mask or cone. In the open methods, he breathes air freely through gauze (the usual chloroform mask), on which the anesthetic is poured. The closed methods are more rapid and economize the anesthetic, but from other standpoints they are rather objectionable. The open methods avoid asphyxia and are therefore pleasanter, safer and less subject to after-effects (mucorrhea, vomiting, and so on). The apparatus is simpler and more easily sterilized. Henderson, 1915, advised a closed method with ether vapor, claiming that this is scarcely more unpleasant than nitrous oxide and produces less nausea, vomiting, gas pains, and the like, than other methods. The skin should be kept pink, neither pale (acapnia) nor dusky (asphyxia).

Carbon Dioxide Inhalation.—In the induction of anesthesia, the stimulation of respiration by 5 per cent carbon dioxide hastens the attainment of equilibrium between the anesthetic vapor and the tissues, and therefore permits the use of lower concentrations. This should diminish local irritation (Haggard, 1924), and permits the use of more oxygen in gas anesthesia; for instance, the induction of anesthesia in rats or cats required 90 per cent of ethylene, leaving only a 10 per cent margin for oxygen; but it could also be attained with a mixture of ethylene, 75; oxygen, 15; and carbon dioxide, 10 (Kleindorfer, 1931). The carbon dioxide should not be unduly prolonged. Y. Henderson and Haggard, 1918, advised *postanesthetic inhalation* of air containing 1 to 8 per cent tension of carbon dioxide. This stimulates the respiration, and so promotes the more rapid elimination of the ether.

Administration of Ether by the "Cone" Method.—A special mask is used, which admits only a limited amount of air. About a tablespoonful is poured in the mask, and repeated as needed. The fact that the required concentration of ether is much greater than with chloroform leads to the temptation not to admit sufficient air. Concentrations of ether above 7 per cent irritate the mucosa so strongly that in imperfect anesthesia they cause reflex coughing, closure of the glottis and suffocation (Dreser, 1893).

Ether by the "drop" ("open" or "perhalation" method) avoids to a great extent the irritation, suffocation and excitement of ordinary ether anesthesia. This more than compensates for the disadvantages, the relative slowness, waste of ether, saturation of the room, and refrigeration of the inspired air. In this method, the ether is dropped rapidly (about 150 drops per minute) over the entire surface of an open (chloroform) inhaler, covered with some eight layers of gauze, and held an inch from the face. If the mask is closely applied, the vapor concentration may rise to 9.3 to 10.8 per cent; never above 12 per cent. (The method was originated by L. H. Prince, 1895.)

Administration of Chloroform.—This is dropped on a few layers of gauze, supported by a frame, and held some little distance from the face. The rate should never exceed 60 per minute, and usually should not be over 12. After the anesthetic stage has been induced, 6 drops per minute will usually suffice.

The *quantity of anesthetic* required for an ordinary operation varies. Some 40 cc. of chloroform or 150 cc. of ether by the ordinary method, or 250 cc. by the drop method, may suffice for an hour's anesthesia.

Other Methods of Administration.—Anesthetics may be administered by other methods, but these demand special experience, and generally special apparatus. In operations about the face, the anesthetic may be inhaled through a *nasal catheter;* in operations on the thorax, it may be administered by tracheal insufflation.

Intratracheal Insufflation.—The insufflation of air passed over the anesthetic was elaborated experimentally by Githens and Meltzer, 1913. It eliminates respiratory paralysis as a fatal factor. *Ether* is especially safe: excessive doses first stop the spontaneous respiration, but this is immaterial since the insufflation constitutes an efficient artificial respiration. The blood pressure declines slowly, and recovery is possible during an hour after the respiration is arrested, by simply stopping the ether. With *chloroform,* the respiration and circulation fail together, so that there is no reliable danger sign, and the zone of safety is much narrower. Unskillful insufflation presents various dangers (George, 1917). In *intrapharyngeal insufflation* ether vapor is driven through a nasal catheter, usually after anesthesia has been induced by the open method.

Rectal insufflation of the warmed ether vapor is useful in operations about the head; it also avoids excitement, struggling and gastric disturbance. It acts promptly (within six to fifteen minutes) and can be maintained indefinitely. However, it is uncomfortable; the dosage is more difficult; it is liable to be followed by severe, sometimes fatal, irritation of the colon, with gas distention, colicky pains and bloody diarrhea (Cunningham, 1920). The fatality is fairly high. Operative anesthesia may be produced by the rectal injection of a mixture of equal parts of *ether and oil.* Several fatalities have occurred, presumably because the dosage has not been satisfactorily worked out. *Gastric administration* of an alcoholic solution of chloroform is used in animal experimentation, but is too dangerous for man.

Intravenous administration of saline solutions of the anesthetics (ether, 5 per cent, Burckhardt, 1910; 7.5 per cent, Rood, 1911; chloroform, 0.6 per cent, Giani, 1910) produces anesthesia; but *a priori* one would consider the method both unsatisfactory and dangerous; and this seems to agree with the practical experience (Tyrode, 1910). The *solubility of ether in normal saline solution* falls with rise of temperature. A hundred cc. dissolve 11.2 Gm. at 5°; 6.9 at 20°; 5.3 at 30° (Bennett, 1912). The *intramuscular injection* of undiluted ether has been tried. However, the method is uncertain, painful and dangerous (see J.A.M.A., 1912, *59:*288).

Induction of anesthesia during sleep is of some medicolegal importance. It is difficult, but cases are reported (Brouardel, Les Asphyxies, p. 199). False accusations of criminal assault are often based on the mental confusion of the patient in the induction stage.

Administration for Analgesia.—Short operations can be performed in the stage of confusion before the patient becomes unconscious. This is also utilized in *obstetrics*, to deaden the pain without relaxing the uterine contractions; and to *check convulsions*, such as those of strychnine, tetanus or eclampsia. It is especially useful in the onset of these conditions. When the convulsions are fully developed, it must be used cautiously to avoid asphyxia. For the production of this light anesthesia, chloroform is preferred to ether, since it can be more easily regulated, and its effects are more lasting.

"One-minute Ether Anesthesia."—A teaspoonful of ether is poured into the cone, and the patient directed to count and take deep inspirations. The operation is done as soon as the counting becomes irregular.

Fixed Dose Self-Inhalation Chloroform Analgesia.—A single dose of 5 cc. of chloroform, poured on cotton and inhaled from the hand, produces effective analgesia, with slight confusion, but without unconsciousness, nausea or dangerous effects. The action is complete in five minutes and lasts about twenty minutes. The method has been used successfully for painful dressings and short operations (Sollmann, 1918; Sykes, 1919).

Obstetric Self-Inhalation of Chloroform.—Brunton's method may be used when an anesthetist is not available. The inside of a tumbler is covered with blotting paper. A few drops of chloroform are poured on, and this is given to the patient, with directions to hold it an inch from her mouth and inhale. This works automatically, for as the patient becomes narcotized she allows her hand to drop, and so removes the tumbler; and as soon as she becomes conscious and sensitive to pain, she replaces it.

Ether analgesia by oral administration has been employed for similar purposes. The action is more lasting, but not always as efficient. The dose consists of an ounce of a 50 per cent solution of ether in liquid petrolatum, sandwiched between two drinks of port wine. The petrolatum is intended to act as an automatic regulator for the evaporation and absorption of the ether vapor (Gwathmey and Karsner, 1917). A similar suggestion has been made for ethyl chloride (Baskerville and Hirsch, 1921).

Absorption and Excretion.—Chloroform and ether are absorbed almost instantly from the lungs, and excreted rapidly and almost quantitatively by the same channel. A small part is excreted by the urine. Absorption from the stomach and rectum is also prompt, and may be utilized for anesthesia.

Retention.—The percentage of the anesthetic in the expired air is at first much less than in the inspired. It begins to rise after two minutes, but remains considerably below the inspired even after ten minutes (Brodie and Widdows, 1906). This shows an actual retention of the anesthetic, which is reflected by its level in the blood (Buckmaster and Gardner, 1907). The *equilibrium between air, blood and tissues* depends on their relative solution-affinity for the anesthetic. The exchange is rapid at first, but slows as equilibrium is approached. Consequently, although a uniform concentration of anesthetic is inhaled, the concentration of the blood continues to increase for over eight hours; and when the anesthetic is discontinued, the excretion extends over the same period (Nicloux). The equilibrium between blood and tissues is probably established more promptly, for the concentration in the venous and arterial blood soon becomes equal. The anesthesia depends upon the concentration in the brain, and this on the concentration in the blood multiplied by their partition coefficient. The ether solubility in hashed brain is to that in blood as 0.92 to 1.31. The other tissues play the role of a buffer (Haggard).

Final Elimination.—When the anesthetic is discontinued, the greater part disappears rapidly from the blood.

Within five minutes, the percentage of ether or chloroform has fallen to one half. The final elimination is more gradual: with ether, there are traces in two hours, but not in four hours. With chloroform, the concentration falls to only a seventh in three hours, and traces are present even in seven hours (Nicloux). The excretion of volatile anesthetics through the lungs is a merely physical process, analogous to their evaporation from aqueous solutions. It depends more upon their solubility and affinity for water than on their boiling point (Cushny, 1910).

Ultimate Fate.—*Ether* is not oxidized in the body; 79 to 92 per cent can be recovered from the expired air, and practically all the remainder from the other excretions (Haggard, 1924). A small smount of *chloroform* is decomposed in the tissues, with the production of chloride (excreted by the urine; Zeller, 1883) and carbon monoxide. The quantity of the latter is too small to produce any effects. This decomposition occurs also in shed blood (Nicloux, 1910). The decomposition of various *bromine-containing anesthetics* is discussed by G. H. W. Lucas, 1928.

Concentration of Anesthetic in Inspired Air.—The anesthetics exist in the blood and tissues solely in physical solution: they are therefore absorbed and excreted by the alveolar blood in proportion to their concentration in the alveolar air, until the whole system of air-blood-tissues is in equilibrium. The absorption into the blood and tissues is not instantaneous, so that a given concentration in the blood can be reached the more rapidly, the more concentrated the anesthetic vapor, and the more effective the respiration (Haggard, 1924). With fairly uniform administration, the exchange is sufficiently rapid so that the quantity of anesthetic in the tissues at any given moment depends essentially on the concentration (partial pressure) of the anesthetic vapor in the inspired air (P. Bert). The action is determined by this concentration, or rather by the partial pressure, and only in a minor degree by the absolute dose of the anesthetic. The gas concentration in air may be expressed as volumes per cent, as mm. of pressure, or as mg. per liter. These may be converted into each other on the basis that 1 per cent by volume = 7.3 mg. Hg pressure at about 20° C., at sea level = 3.08 mg. of ether or 4.97 mg. of chloroform per 100 cc. of air.

The effective concentrations agree closely for all mammals, including man, provided that time is given to establish equilibrium (Bert, 1884; Dreser, 1893). In clinical practice, however, this is rarely the case. The administration is generally started with a high concentration to hasten induction, and this is gradually reduced as anesthesia is reached; the clinical concentrations are therefore variable, but almost always higher than at equilibrium. With *ether*, the maintenance concentration under clinical conditions is about 6 per cent by volume (18.5 mg. per 100 cc. of air, 44 mm. tension) for light surgical anesthesia; 10.5 per cent by volume (31 mg. per 100 cc. air, 73 mm.) for complete abolition of reflexes; and 11 per cent by volume for stoppage of respiration and eventual death (Kochmann, 1914). In surgical operations on man, T. K. Kruse, 1924, found the ether concentration under the mask to average 7 per cent after ten minutes of anesthesia. Boothby, 1916, found the "anesthetic tension" (the partial pressure of ether vapor which maintains anesthesia indefinitely, after it has been established) as 47 mm., equivalent to about 6.7 volumes per cent. In routine hospital practice, the alveolar air concentration of ether ranges from 3 to 7.2 volumes, according to the type of operation (R. N. Harger *et al.*, 1941). Experimentally, with induction sufficiently slow to secure equilibrium with the blood and tissues, satisfactory ether anesthesia is attained with 4 to 4.5 per cent by volume; and respiratory failure with 6.7 to 8 per cent.

For *chloroform*, the corresponding concentrations are, for light anesthesia, 1.35 volumes per cent (6.8 mg. in 100 cc. of air); deep narcosis, 1.65 per cent; fatal, 2 per cent (Kochmann, 1914). The *anesthetic zone* between the minimal anesthetic and the fatal dose is much wider for ether (*viz.*, 5 per cent) than for chloroform (0.65 per cent). This is one reason for the greater safety of ether. Another difference is that the deep anesthesia can be maintained almost indefinitely with ether, while chloroform kills within one or two hours (Rosenfeld, 1896). The *time factor* therefore plays a part especially with chloroform (also on account of the postanesthetic degenerations). On the other hand, the concentration may rise momentarily above the fatal limit, since the absorption, although rapid, is not instantaneous. Under clinical conditions 1 per cent chloroform vapor is insufficient to induce anesthesia; 2 per cent is generally effective; less than this must be used in pathologic conditions, but requires a longer time to establish narcosis. Even 3 per cent may be necessary in exceptional cases. The maximum limit of safety is placed at 2 per cent by Waller; at 1 to 1.5 per cent by Embley. Therefore, as soon as anesthesia is reached, the concentration must be gradually reduced to 1 per cent, and after half an hour even lower.

Even perfectly adjusted mixtures are not absolutely safe. In practice the inconveniences of exact vapor mixtures are generally held to outweigh their advantages. However, the above figures are fairly approximated in the ordinary methods of administration. *The air under the ordinary mask* has been found to contain generally from 1 to 2 per cent of chloroform, and with rapid application, up to 4 per cent.

The **distribution of the anesthetics in the blood and tissues** is in accordance with their relative solubility and vapor tension, if time suffices to establish equilibrium. *In vitro*, at body temperature, the stable distribution of ether between air and blood approximates 1:14.9 (Haggard, 1924). Ether is somewhat more soluble in water, making its quotient 1:15. In life this equilibrium is not reached even in the alveoli, and the quotient is nearer 1:10 (B. H. Robbins, 1934 and 1935). As long as the tissues continue to take up anesthetic from the blood, and this continues even to the end of three hours of anesthesia (van Mechelen, 1926), the concentration is higher in the arterial than in the venous blood, and this is higher than in the tissues. The left heart is therefore exposed to a higher concentration than the right, especially if the anesthetic is "pushed" (Pohl, 1891). When the administration is discontinued, the sequence is reversed, so that the concentration is highest in the tissues and lowest in the arterial blood.

The *distribution in the tissues* is influenced by their content of lipid material (Frison and Nicloux, 1907) especially of cholesterol and lecithin, for anesthetics with high lipid affinity such as chloroform. The proteins are also concerned. *With ether*, which has a relatively smaller affinity for lipids, the percentages in the plasma, corpuscles and in all the tissues are practically equal when equilibrium is reached (Nicloux); but the greater blood supply of the brain causes it to take up the anesthetic more rapidly, so that its concentration is temporarily higher than that of other tissues.

Ether Concentration in Venous Blood.—The following figures are representative for jugular blood of dogs (Robbins, 1935): light anesthesia without loss of reflexes, 113 mg. of ether per 100 cc. of blood; full anesthesia with suppression of lid and corneal reflexes, 150 mg; arrest of respiration, 187 mg.

The dangerous *concentrations of ether* in the blood were determined for cats by Schram, van Leeuwen and Made, 1916: 0.13 to 0.14 per cent, corresponding to deep anesthesia, cause marked fall of blood pressure by action of the vasomotor center and vagi; 0.17 per cent is fatal unless artificial respiration is used. With artificial respiration, 0.25 per cent is fatal if the vagi are active; 0.31 per cent if they were paralyzed; 0.44 per cent is fatal to the isolated heart-lung preparation, and 0.5 per cent to the perfused heart. The perfused heart is but little damaged by 0.17 per cent, *i. e.*, the concentration fatal to intact cats. During good anesthesia, the ether concentration in the *gases of the peritoneal cavity* reaches about 4 per cent (Y. Henderson, 1918). The *concentration of ether in the urine* approaches that in the arterial blood (Haggard, 1924). A *micromethod for the isolation of ether* is described by Gettler and Siegel, 1934.

With chloroform, blood absorbs considerably more than does salt solution; the percentage is two and one-half to eight times greater in the red corpuscles than in the plasma (Pohl, 1891; Nicloux, 1906; Buckmaster and Gardner, 1907). *Ethylene* also gives decidedly higher concentration in the plasma. The hemoglobin appears to be concerned in this, as well as the lipids (Nicloux). Data on the solubility of chloroform in blood, serum and water are given by Nicloux, Scolli and Foglieni, 1928.

The *concentration of chloroform in blood and tissues* was investigated especially by Nicloux, 1906 to 1908; Mansion and Tissot, 1906; Sicard, 1906. According to these, the *arterial blood* contains, with complete anesthesia by chloroform, 0.032 to 0.05 per cent (0.014 to 0.028 according to Buckmaster and Gardner). At death, the chloroform concentration averages 0.08 per cent (0.06 per cent, Pohl; 0.04 per cent, Buckmaster and Gardner). The *cerebrospinal fluid* also contains small quantities of chloroform when this is inhaled (Hald, 1921). The *chloroform content of the brain* is relatively high; that of the *liver*, low. In dogs killed by chloroform, Gettler and Blume, 1931, found 0.037 to 0.048 per cent of chloroform in the fresh brain; 0.035 to 0.048 in the lungs; and 0.019 to 0.028 per cent in the liver. Nicloux obtained similar figures. The white substance contains more than the gray, and peripheral motor nerves more than sensory, agreeing with their lipoid myelin content (McCollum, 1930). However, Guenter and Hoelscher, 1906, claimed that there is no difference in the percentage of chloroform in the blood, brain, liver and kidney, provided that the inhalation of a given concentration is kept uniform until equilibrium becomes established. *Adipose tissue* contains no more than does muscle (Nicloux), the walls of the fat cells being difficultly permeable to lipoid solvents. The distribution of chloroform in *hen eggs* exposed to the vapor was studied by Lallemand, 1932.

MIXED ANESTHETICS

Mixed Anesthesias.—Attempts to blend the actions of volatile anesthetics by mixing them are unsuccessful, because the ingredients do not volatilize with equal rapidity (Snow). The composition of the inspired anesthetic is therefore uncertain. As a rule, during the administration, the concentration of chloroform increases. The administration is further complicated by the different sequence of the disappearance of the reflexes with chloroform and ether (Storm van Leeuwen, 1916). These mixtures are therefore at least as dangerous as chloroform, and should be condemned (Kochmann, 1903).

The principal mixtures of this type are the *English A.C.E. mixture*, introduced by Harley (A_1; C_2; E_3);[*] *Billroth mixture* (A_1; C_3; E_1) *C. E. mixture of Hewitt* (C_2; E_3); *Schleich mixture* (benzine 1; C_3; E_{10}). Other mixtures containing ethyl chloride or bromide, and so forth, have also found advocates. The alcohol and benzine of these mixtures were intended mainly to raise or lower the boiling point, but benzine is not indifferent. There seems to be some combination between ether and chloroform, for on mixing equal volumes (25 cc.), the temperature is said to rise 14° C. (Marcelet, 1912).

Synergism of Ether and Chloroform.—Analysis of the concentration of the anesthetics in the blood shows that mixtures of the vapors do not exhibit a potentiated effect, but a rather imperfect summation of action (Madelung, 1910, and Buergi, 1910). Damkoehler, 1913, obtained different results for different depths of anesthesia.

Sequence Anesthesia.—A material advantage may sometimes be gained by using a sequence of anesthetic agents, particularly to induce anesthesia by the pleasant and promptly acting nitrous oxide-oxygen inhalation, and to continue with ether. These may be preceded by a sedative dose of morphine and a full hypnotic dose of a barbiturate, to produce a basic narcosis. This probably presents the nearest approach to an ideal anesthesia. Changing from full ether anesthesia to chloroform is dangerous (Hewitt).

Morphine, Scopolamine or Atropine Preliminary to Anesthesia.—One or several of these drugs may be injected hypodermically, half an hour before starting the operation. They diminish the anxiety of the patient and avoid some of the dangers of anesthesia. The doses given below may be combined.

Morphine (10 to 15 mg., $\frac{1}{6}$ to $\frac{1}{4}$ grain) is most effective in decreasing apprehension, excitement and struggling. Labbé and Guyon, 1872, were the first to use it clinically. It makes anesthesia prompter and smoother. It reduces materially the quantity of anesthetics (Claude Bernard), and thereby the gastric, pulmonary and toxic after-effects. The patient does not awaken so early. Since the morphine narcosis involves an entirely different mechanism, the side effects of both are relatively smaller. On the other hand, morphine depresses the excitability of the respiratory center, and the miosis interferes with the pupil danger signal. Morphine is contraindicated in pulmonary disease, in semicomatose patients, or when the operation would involve bleeding into the air passages.

---

[*] The proportions of all the mixtures are by volume. *A* stands for alcohol; *C*, for chloroform; *E*, for ether.

Morphine reduces the concentration of ether or chloroform vapor required for light anesthesia, but not that for deep anesthesia or death. The margin of safety is therefore widened considerably—60 per cent for chloroform, 50 per cent for ether (Kochmann, 1914). However, the respiration must be carefully watched with chloroform, for this also shows dangerous potentiation (W. Straub, 1913).

Atropine (0.3 mg., 1/200 grain) also diminishes ether salivation and bronchorrhea, thereby lessening the occurrence of ether pneumonia. The atropine mydriasis and tachycardia interfere with the use of the pupil and pulse as danger signals. The above dose should not be exceeded on account of occasional idiosyncrasies.

Scopolamine (0.5 mg., 1/120 grain) is often substituted for the atropine. It has the same peripheral actions on the pupil and glands, but intensifies the narcotic effects of morphine. On the other hand, it disposes to pronounced vasodilatation, so that the pressure may fall as deeply in ether anesthesia as with chloroform (Mayor, 1908). It sometimes intensifies the respiratory depression of morphine to a dangerous degree. Bevan, 1915, who opposed it strongly, believed that it also increases the percentage of vomiting and of bladder paresis.

The combined action of morphine or scopolamine with the hydrocarbon narcotics is far more than simple addition (Knell, 1907). Madelung, 1910, and Rappaport, 1911, found that one-half to two-thirds of the ordinary concentration of anesthetics suffices. *Scopolamine alone* does not reduce the concentration of chloroform or ether required for light anesthesia, but lessens somewhat that for deep anesthesia. Scopolamine and morphine together resemble morphine, except that they do not increase the zone of safety. The anesthesia is deeper, however; this may be practically important (Jochmann, 1914). *Bromides* give practically only simple summation with morphine or the aliphatic narcotics (Klammer, 1913).

Basal anesthesia is the extension of the preanesthetic sedation to the degree of confusion, sleep or stupor, as a foundation which is then brought to full anesthesia by an inhalation anesthetic agent. It is induced by fixed doses of rather potent, rather briefly acting narcotics, barbiturates or avertin, and is discussed more fully under these drugs. It is a sequence anesthesia, the sedative acting as a "back-log" of partial narcosis which avoids the fright and other difficulties of the induction period, and assures a smoother course, with much smaller quantities of the anesthetic; and on the other hand it obviates the inflexibility of fixed anesthetics. The respiratory depression, however, is additive and may be distinctly greater than with inhalation alone.

Ether-Magnesium Anesthesia.—The combined use of these anesthetics was proposed by Meltzer, 1913, for laboratory animals. Le Heux, 1919, showed that there is only simple summation between magnesium salts and ether, chloral and urethane. Gwathmey *et al.*, 1924, introduced a more complex *combination for obstetric analgesia.* They administer 0.01 Gm. of morphine hypodermically; one to three hypodermic injections of 2 cc. of 50 per cent magnesium sulfate; and a colon injection of ether 75 cc., quinine hydrobromide 0.6 Gm., and olive oil, to make 120 cc. It has been shown, however, that the magnesuim is quite inactive in this dosage (Shackell and Blumenthal, 1932), and the quinine does not serve any useful purpose. The inefficient magnesium has now been displaced by oral administration of pentobarbital (Gwathmey and McCormick, 1935).

The causes of death under anesthesia must be understood in order that accidents may be avoided. They differ according to the anesthetic, the stage of anesthesia, the character of the operations, diseases of the patient and other conditions. On this account clinical accidents may be different from the usual laboratory experiments.

Death Not Always Due to Anesthetic.—Patients died on the operating table before anesthetics were invented. One such case was of considerable importance in the history of anesthesia. When Simpson was about to try chloroform on a patient for the first time, the orderly who was carrying the bottle fell and spilled the chloroform. No other being obtainable, Simpson proceeded to the operation without anesthesia. The patient died with the first cut. Had the chloroform been given in this case, its introduction into practice might have suffered a long delay. Other similar cases are not unknown: a patient was to be operated upon and demanded chloroform. His condition, however, was so low that the surgeon feared to grant his wish, and to calm him held a cloth *without* chloroform before his face. Scarcely had the patient made four inhalations—of air—when he was dead. Many other cases of sudden death from the violent mental impression could be cited, besides deaths undoubtedly due to traumatic shock (Strassmann, 1898).

Impurities which may occur in ether and chloroform, mainly by decomposition, are rather unimportant. They contribute to the local irritation, but probably not to the dangerous effects. Anesthetic fatalities seem to be as frequent with the "pure" chloroform or ether as with that not specially treated. However, only U.S.P. quality should be used clinically. In the event of accident, inquiry should be made whether other patients have reacted abnormally to the same lot of anesthetic.

Ether, when kept in contact with air without special precautions, undergoes auto-oxidation, hastened by heat, light, moisture and other factors. This results in acetaldehyde, acetic acid, and an unidentified *"ether peroxide,"* which is explosive when ether is evaporated, and which is probably responsible for most of the aberrant pharmacological actions (G. Lindgren, 1946), although the irritant aldehyde is probably also involved. These chemical changes may be avoided or retarded by careful preservation, or by the addition of 0.02 per cent of diphenylamine, which is harmless in this concentration (Lindgren). Bruns, 1895, concluded from clinical observation that the ether impurities are mainly responsible for the bronchitis (R. B. Smith, 1913). Henderson, 1914, considered poor ether as more excitant, disposing to acapnia. Ether also generally contains some ethylene, which is probably unimportant. The effects of adding impurities to ether are reported by W. Browne, 1926. The presence of alcohol slows the rate of evaporation, and may be necessary when the ether is used in high altitudes or at a high temperature. The *impurities of chloroform* are also due to oxidation, accelerated by light and acids. The products vary with the conditions. The most constant are the irritant phosgene (carbonyl chloride) and hydrochloric acid.

Preservation.—The U.S.P. directs that *ether for anesthesia* must be stored in tight containers of not more than 3 Kg., and must not be used if the container has been opened longer than twenty-four hours. Carefully controlled clinical comparisons showed no difference, however, between ether so stored and that kept in bulk (Hediger and Gold, 1935; Dooley *et al.*, 1935; Morrison, 1938). No deterioration occurred within a month when a large tin container was opened daily and part of the contents removed (Hediger *et al.*, 1940). Lindgren, 1946, found that the peroxide tends to slow the induction time in animals and proposes that the peroxide, expressed as H_2O_2, should not exceed 5 mg. per 100 cc. Sunlight leads to rapid deterioration, and clear glass should not be used; amber glass is better, but tin is best (H. Gold, 1942). Chloroform should be preserved in sealed, dark glass bottles, and should contain 1 per cent of alcohol, which acts as a reducing substance.

"Idiosyncrasy," in the sense of allergy, probably does not exist for general anesthetics; nor are there marked differences in susceptibility toward equivalent concentrations of the anesthetic, even with refractory patients (Boothby, 1914). The greatest practical differences in the reaction of patients consist in the manner of "taking" the anesthetic. They are therefore most conspicuous in the induction of anesthesia, which is peculiarly difficult in alcoholic patients. Boothby, 1913, attributed their resistance to deep breathing, blowing the ether off the mask. Morphinists are said to be relatively insusceptible. Patients with Graves' disease may react badly. A patient may tolerate one anesthetic better than another. After the anesthesia is established, there is but little evidence of "peculiar" reactions, except such as may be foreseen in heart disease. Fatal accidents should therefore not be lightly ascribed to idiosyncrasy. The postanesthetic toxemias, however, are undoubtedly influenced by the individuality of the patient.

Range of Susceptibility.—In a series of *dogs,* the amount of ether required to produce analgesia ranged from 0.4 to 1.1 cc. per Kg. of body weight (median 0.65 cc.); the smallest amount that stopped respiration was 1 to 3.3 cc., median 1.65 cc., per Kg. The margin of safety was five times greater in some than in others (R. W. Whitehead and Draper, 1936), but this refers to the amount inhaled, not to the concentration. *Very young mice* are materially more resistant to arrest of respiration by ether than those somewhat older; in an ether concentration which killed mice older than twenty days in four and one-half minutes, mice less than four days old survived about one hundred minutes (Barrows, 1933). *Starved animals* are much more susceptible to chloral, paraldehyde and morphine, but not to alcohol, amylene hydrate, or urethane (Mansfeld, 1905). *Dextrose administration* previous to ether anesthesia of pregnant animals tends to stabilize their acid base equilibrium, and to guard them against kidney injury. It is more effective in young animals than in old, and in early more than in late gestation (MacNider, 1926). *Alcoholic intoxication* of dogs materially increased the toxicity of prolonged chloroform inhalation, even when the alcohol had been administered three or four hours previously and its visible effects had practically disappeared (S. M. Rosenthal, 1930). *Hyperthyroidism* induced in guinea pigs by feeding thyroid gland rendered them more susceptible to heart block by chloroform, but not by ether (Herzfeld, 1926).

Death during the induction of anesthesia is fairly common with chloroform, rarer with ether. In a series of twenty *chloroform deaths* in which the time was noted, a third occurred within five minutes, and a half between six and fifteen minutes after the start of the administration (quoted from Brouardel, "Les Asphyxies," 1896). The usual sequence of events is sudden suspension of the respiration from acapnia or muscular spasm; the asphyxia leads to cardiac dilatation, vagus stimulation and finally asphyxial failure of the heart. The failure is especially rapid with *chloroform*, because this adds the direct cardiac action of the drug. In light chloroform narcosis, the cardiac muscle is hyperexcitable, and any excitement is likely to induce ventricular fibrillation and death (G. Levy, 1913; G. R. Brown, Long and Beattie, 1930). The respiration may resume temporarily after the heart has stopped, but the heart itself cannot usually be revived. Failure of the circulation therefore commonly precedes the final arrest of respiration and is the real cause of death. Prompt artificial respiration generally restores the heart, and the arrhythmias do not return when chloroform is resumed, unless there is severe hypoxemia (Orth and Liebenow, 1946).

With *ether*, similar fatalities are rarer, but may occur early or somewhat later—in either event owing to faulty administration during incomplete anesthesia. The error may have been committed an hour before actual death: In light ether anesthesia, the excitability of the respiratory center is increased. If this state is prolonged by excessively slow, incomplete or intermittent anesthesia (*f. i.*, in throat operations), acapnia results. When the anesthesia deepens and the center becomes depressed, the acapnia (deficiency of CO_2) leads to arrest of respiration and injury to the heart (Henderson, 1911). Stoppage of respiration by *ether* is less dangerous, because the more vigorous heart generally beats until the respiration has resumed. Experimentally, the heart may also be stopped reflexly by vagus stimulation, but clinically this seems to be exceptional. At any rate, the phenomena occur with little warning. The *danger signs* are sudden dilatation of the pupils, pallor and change of facial expression. Too high concentration of the vapor is the immediate cause of these actions. Fright, excitement, struggling, irregular respiration and idiosyncrasy are contributing factors. Crying in children is especially dangerous. These accidents are avoided by beginning the administration with very dilute vapor, and increasing the concentration gradually. Morphine helps to prevent acapnia and fear. Atropine eliminates the vagus reflex.

Epinephrine-Chloroform Syncope.—Epinephrine is valuable for resuscitation when cardiac arrest occurs in deep narcosis; but in *light* anesthesia, its injection may produce dangerous arrhythmias and fatal ventricular fibrillation, especially with the halogenated narcotics, chloroform (A. G. Levy, 1911 and 1913), methyl and ethyl chloride and bromide, trichloroethylene, carbon tetrachloride, and large doses of avertin. Cyclopropane (see Index) renders the heart subject to epinephrine fibrillations. With chloroform the fibrillation does not occur if the epinephrine is injected *before* the anesthesia, nor in *deep* anesthesia. It is most marked in vagotonic patients, and is much greater in cats than in dogs. It is due chiefly to excessive irritability of the chloroformed heart muscle to adventitious stimuli, such as epinephrine, acceleration, stimulation, abrupt and excessive changes of blood pressure, and sensory reflexes. It may be prevented or suppressed by quinine, quinidine, procaine, cocaine and barbiturates (review, W. J. Meek, 1941).

Death in deep anesthesia is usually due to paralysis of respiration, generally with more or less involvement of the circulation. With *ether*, the circulation is usually fairly good when the respiration stops. The arrest may be due to exaggerated response to inhibitory reflexes, especially from the vagus or superior laryngeal (Mann). With *chloroform*, there is progressive fall of blood pressure, then failure of the respiration, and finally cessation of the heart; but the pulse is generally imperceptible before the respiration stops. Since the paralytic phenomena develop gradually, with ample warning, these deaths are generally due to inexperience of the anesthetist. The *danger signals* are: increasingly shallow or irregular respiration; very slow or very rapid pulse, cyanosis; dilatation of pupil. These accidents may be avoided by carefully watching for these signs, by maintaining the anesthesia evenly, and no deeper than complete muscular relaxation and absence of the sensitive reflexes. The *autopsy* in acute chloroform or ether deaths shows nothing beyond the ordinary phenomena of death by asphyxia—heart distended, veins congested, and so forth.

Late Ether Convulsions.—Dangerous epileptiform convulsions, setting in during deep anesthesia by ether or other anesthetics, have been noted occasionally, especially in England (R. V. Payne, 1936). They are rare, but occur especially in children and young women, particularly in those with febrile conditions. They are quite distinct from nitrous oxide jactitation, and from the "ether clonus" that develops before full anesthesia is obtained. They start with dyspnea and cyanosis, soon followed by generalized convulsions which begin in the eyelids and spread to the facial muscles and over the entire body. The temperature rises very high. Nearly a third of the patients die, usually within one-half to three-quarters of an hour, by arrest of respiration (Lundy, 1937). Many of the patients have abnormal electroencephalogram records, indicating latent epileptic liability which would be a predisposing factor (D. Williams and Sweet, 1944). A. Smith, 1944, reports that the convulsions may be arrested by raising the patient to a sitting position, thus lowering the intracranial pressure. Seevers *et al.*, 1938, attributed the convulsions to depletion of alkali reserve, by respiratory depression, rebreathing and fever, and found that CO_2 potentiates similar ether convulsions in animals. Oxygen variations had little effect. *Experimental catatonia from gases* always results if white mice inhale N or CO_2; inconstantly with CO and N_2O; not with acetylene (de Jong, 1934).

Swallowing of chloroform usually produces immediate vomiting and sometimes defecation, followed by narcosis (Schoenhof, 1914). The acutely *fatal dose* is not known; an ounce or more would be dangerous. Recovery may be succeeded by fatal gastritis or icterus and the other phenomena of late chloroform poisoning. The treatment would be as for inhalation. Gastric lavage with oil has been advised (Wirth, 1909).

Treatment of Accidents.—The *tongue* may fall back and interfere with respiration, as denoted by noisy breathing. If this occurs, "place the index finger of each hand upon the corresponding cornua of the hyoid bone, while the middle fingers rest upon the angle of the jaw, and then press forward and upward, the same force serving to extend the head upon the neck; if this fails to open the glottis, by means of a tenaculum, thrust far back into the base of the tongue, draw it forward" (H. C. Wood). If the mucus accumulates, it should be removed with a cloth (Mayor suggests the dental saliva siphon).

Serious accidents should be treated with the first warning of danger; the anesthetic should be stopped at once. The head of the patient should be lowered to give the medullary centers and heart the full benefit of any remaining circulation. A few rhythmic compressions of the epigastrium may be tried, but if these do not succeed quickly, *artificial respiration* by any of the methods should be begun at once. This prevents asphyxia and eliminates the poison. The cardiac region should also be compressed strongly at the rate of 40 times per minute, since this aids the action of the heart and supplies a mechanical stimulus. A liter of saline solution and 1 cc. of 1:1000 solution of epinephrine may be at the same time injected into the cardiac end of an artery. The chances of success are proportional to the promptness with which they are applied. Gunn and Martin, 1915, recommended the combination of intrapericardial injection of epinephrine with cardiac massage. This may be successful even when the heart is arrested and when either measure alone would fail. Various stimulants are usually tried, at present especially metrazol, but their efficacy is questionable.

Reflex stimulation, by the inhalation of diluted ammonia or by any strong sensory stimuli, is sometimes remarkably effective in early anesthesia, but may depress respiration and blood pressure if the anesthesia is deep. *Metrazol* varies for different anesthetics (in dogs); under ether it produces marked tremors and convulsions, with little or no respiratory stimulation; under evipal it causes marked stimulation of the respiratory center without convulsions; under trichlorethylene it has both effects (D. E. Jackson, 1934). Draper and Whitehead, 1939, found that intravenous injection of 5 mg. per Kg. in late surgical ether anesthesia had a distinct tendency to prevent arrest of respiration. Coramine did not counteract respiratory arrest by either chloroform or ether, nor did it facilitate resuscitation (Whitehead and Draper, 1938). Strychnine, caffeine, digitalis and nitrites are probably useless.

Explosion Hazard.—Most anesthetic vapors are highly inflammable and explosive, especially if mixed with oxygen. Chloroform is not explosive, but forms dangerous irritant oxidation products. Nitrous oxide is not easily explosive and lowers the explosiveness of other gases. Ether ignites and explodes readily; ethylene and cyclopropane are especially liable to explosion. The occasions for anesthetic explosions are open lights, cautery and static electric sparks. Moist air furnishes more efficient protection against these than does grounding. Open ether administration offers little danger of explosion, as air taken 2 inches from the mask is not inflammable (Coste and Chaplin, 1937). However, the flame of an open light may leap over considerable distance, especially if there are drafts. If an open light is unavoidable, it should be placed high above the patient, since ether vapor is heavier than air.

Statistically, the hazard of explosion is small; a questionnaire covering over two million administrations gave the rate, per 100,000 as 1.73 for ether, 2.44 for hylene, 3.85 for cyclopropane (P. D. Woodbridge 1939). The *approximate limits of inflammability of ethylene and ether* are reported by Coward and Jones, 1931, as: ethylene in air, 3 to 30 per cent; in oxygen, 3 to 80 per cent; ether in air, 1.7 to 50 per cent; in oxygen, 1.7 to 40 per cent; in nitrous oxide, 3.8 to 26 per cent. Coste and Chaplin, 1937, state the inflammability limits of ether vapor as 2 to 8 per cent in air, 1.5 to 16 per cent in nitrous oxide and in oxygen.

Chloroform, if used with an open light, is partly oxidized into phosgene gas ($COCl_2$, carbonyl chloride), chlorine and hydrochloric acid, which cause considerable irritation—cough, dyspnea, collapse (Langenbeck, 1888). Fatality to the spectators has been reported (see Gerlinger, 1902).

PREPARATIONS.—***Chloroform,** U.S.P., contains at least 99 per cent $CHCl_3$ and 0.5 to 1 per cent of alcohol. Heavy, colorless, volatile liquid; boils at 60° to 61° C. Characteristic odor, sweet hot taste. Not inflammable, but in presence of flame produces noxious gases. Slightly sol. in water (1:210); freely miscible with alcohol, ether and oils. Dose, 0.06 to 0.3 cc., 1 to 5 minims. *Chloroform Water*, U.S.P., is a saturated aqueous solution. Dose, 15 cc., 4 drachms. *Chloroform Liniment*, U.S.P., is a mixture of 3 volumes of chloroform and 7 volumes of camphor and soap liniment. It deteriorates with age.

***Ether,** U.S.P. (Aether; Sulfuric Ether), contains 96 to 98 per cent ethyl oxide, $(C_2H_5)_2O$. Light, volatile liquid; sp. gr., about 0.715; boils at 35° C. Characteristic odor. Highly inflammable; vapors explosive. Sol. in water (1:12) and in all proportions of alcohol and oils. Dose, 1 cc., 15 minims. *Ethyloxide*, U.S.P., is a less pure product, used as solvent, and not for anesthesia. *Spirit of Ether*, B.P. (Hoffmann's Drops), contains 33 per cent of ether. *Compound Spirit of Ether* (Hoffmann's Anodyne) is an antiquated preparation of about the same strength as the spirit, containing additional ethereal products ("ethereal oil").

NITROUS OXIDE

Nitrous oxide, N_2O, nitrogen monoxide or protoxide, "laughing gas," was the first of the inhalation anesthetics. When inhaled undiluted, it rapidly produces unconsciousness and anesthesia, partly by a direct narcotic action, and partly by exclusion of oxygen. The asphyxia limits its use to short operations, such as the extraction of teeth. It has the advantages of prompt action and recovery, absence of irritation and of after-effects, and is practically devoid of danger. By the addition of oxygen, the asphyxial factor may be removed. The anesthesia also becomes slower and lighter, but by carefully adjusting the percentage of oxygen a satisfactory degree of surgical anesthesia can be maintained for longer periods without letting the asphyxia attain dangerous proportions. Nitrous oxide is especially valuable in the "Gas-Ether Sequence," by avoiding the unpleasant features of the induction of ether anesthesia. Asphyxia by undiluted nitrous oxide is used in the treatment of schizophrenia.

Historical.—Nitrous oxide was first prepared by Priestley about 1776. The discovery of its anesthetic properties by Humphry Davy and by Wells is described under "Ether and Chloroform." Elsworth (Boston Med. and Surg. Jour., 37) in January, 1843, amputated a thigh under successful nitrous oxide anesthesia. Its administration with oxygen was introduced by E. Andrews of Chicago in 1868. *Gas-ether sequence* was suggested by Clover, 1876.

Inhalation of Undiluted N_2O.—For short operations, as in dentistry, the gas is administered through a tight-fitting mask, so that all air is excluded. The symptoms run a rapid course: the *preliminary effects* consist in a sweetish taste; numbness; exhilaration (laughter); confusion; deeper and quicker respiration; and fuller pulse. *Partial anesthesia*, with loss of consciousness, ensues in twenty to thirty seconds. The patient is subject to dreams. The reflexes are preserved and excitement may be present, especially if the patient is disturbed. The respiration is still regular, deep and quickened; the pulse full and rapid; the pupils are enlarged; the face is dusky, livid or pallid; the eyelids twitch and are slightly separated. *Complete anesthesia* occurs in fifty to 120 seconds, averaging fifty-six. Its onset is denoted by a change in the respiration, which becomes slightly irregular and noisy. The pulse is quickened by about 30 per cent and is small. The blood pressure shows a large asphyxial rise (Kemp, 1897). The vasoconstriction diminishes the urine flow. The limbs are relaxed, but individual muscles exhibit clonic or epileptiform contractions. The pupils are almost invariably dilated. The face is cyanosed. Relaxation of the sphincters occurs rarely.

Operative Period.—As soon as this stage is reached, the gas is removed. The pulse at once becomes slower and fuller; the respiration also recovers rapidly; and the asphyxial symptoms disappear. The anesthesia lasts some twenty-two to thirty seconds after the gas is removed; and it is during this period that the operation must be performed. The total time between the beginning of the administration and complete recovery is therefore a hundred to a hundred and fifty seconds. The duration of the after-anesthesia increases with the duration of the administration. This may be prolonged to several minutes by giving the patient an occasional breath of pure air (every fifth inhalation); or by admitting a little air into the mask. The admission of air, however, makes the anesthesia uneven and unsatisfactory. *After-effects* are generally absent with short administrations. Sometimes the patients complain of giddiness, headache, lassitude and drowsiness. Nausea is exceptional.

Accidents are rare with short administrations (less than 1 to 5,000,000), because of the wide margin between the first danger sign (noisy and irregular respiration) and death. In patients with grave cardiac lesions, the pulse may become feeble and the respiration shallow before anesthesia is established. If the administration is continued too long in healthy individuals, the asphyxial phenomena become emphasized, with violent inspiratory, then forced expiratory movements; then shallow and intermittent and finally arrested respiration, in two to four minutes (Haggard, 1910). The violence of ordinary asphyxial convulsions is mitigated by the narcosis. Cyanosis is intense. The heart continues to beat for some time, so that *restorative measures* are generally successful. They should consist in artificial respiration, preferably with oxygen.

Contraindications.—Undiluted nitrous oxide should not be used in cardiac lesions, valvular or myocardial; in elderly patients especially with advanced arteriosclerosis or high cerebral pressure; and in operations on the brain. It is often ineffective in hysterical, obese, muscular or alcoholic patients (S. G. Davis, 1909).

Nitrous Oxide with Oxygen.—The respiratory disturbances, convulsive features and cyanosis produced by undiluted N_2O are purely asphyxial. If the gas is mixed with a sufficient proportion of oxygen (15 to 20 per cent), these asphyxial phenomena are absent, and the anesthesia can be prolonged indefinitely. With smaller percentages of oxygen, the symptoms are intermediate. The dilution of the gas with oxygen lowers its concentration in the blood to a corresponding degree, so that the narcotic action is not so prompt or deep. The concentration necessary for complete surgical anesthesia varies considerably in different individuals; most patients require at least 90 per cent of nitrous oxide and 10 per cent of oxygen; but 80:20 suffices sometimes, especially with morphine (Seevers and Waters, 1938). Ordinarily the 80:20 mixture inhaled at atmospheric pressure produces only confusion with incomplete loss of consciousness. Subanesthetic concentrations are definitely analgetic (Seevers, Bennett *et al.*, 1937); 20 per cent of nitrous oxide with 80 per cent of oxygen produces analgesia equivalent to 15 mg. of morphine (heat radiation test, W. P. Chapman *et al.*, 1943). *Morphine-scopolamine* greatly increases the efficiency of nitrous oxide, so that with these alkaloids, a mixture of 80 per cent with 20 per cent of oxygen at atmospheric pressure induces operative anesthesia (Kochmann 1914). Basal narcosis with barbiturates is serviceable.

Hewitt found that 6 per cent of oxygen is required to prevent the convulsive features and noisy respiration; 11 per cent to prevent lividity. Above 10 per cent, the reflexes and movements of the patient were more pronounced. Jackson, 1917, confirmed that the addition of more than 10 per cent of oxygen greatly delays or even prevents the loss of consciousness.

The *administration of the mixed gases* requires special apparatus for adjusting the two gases in any proportion. This is connected with a close-fitting mask. To hasten the anesthesia, the administration may be started with a mixture containing only 2 per cent of oxygen. This is gradually increased to 10 to 20 per cent. If the oxygen content is less than 13.7 per cent, by volume, the arterial oxygen tension falls below the dangerous asphyxial levels of 30 mm. (McQuiston *et al.*, 1943). Since asphyxial susceptibility varies unpredictably in different persons, Barach and Rovenstine, 1945, proposed that nitrous oxide should never be administered with less than 20 per cent of oxygen. If this proves insufficient, other anesthetic technics should be substituted.

Phenomena.—The primary symptoms are the same as with pure gas. The respiration is at first stimulated, so that the patient feels that he can breathe with less effort (Jackson, 1917). The *anesthetic stage* is usually reached in a few minutes. It is characterized by regular, calm, somewhat snoring respiration; slightly dusky face; and medium pupils. The pulse is moderately quickened; the blood pressure, somewhat high; the blood, rather venous.

Convulsive phenomena are absent. The reflexes and muscular tone are greatly decreased, but not abolished as with ether; the anesthesia is not so profound.

The stimulant effects of nitrous oxide on the respiration and circulation of dogs, like those of cyanide and lobeline, arise by reflexes, the respiration from the carotid body, the circulation from the aortic body (Comroe, 1938, 1939). Nitrous oxide has no action on other tissues and is harmless to them. Dogs anesthetized continuously for three days with a mixture of N_2O and oxygen recovered without any damage.

After-Effects.—When the administration is stopped, the patient awakens fully within two or three minutes. Nausea is exceptional, but more common than after short inhalations.

The *advantages* consist mainly in the greater comfort of the patient, the smaller danger and the absence of irritant side effects. The gas would therefore be especially indicated in renal and acute pulmonary diseases, or when the patient dreads the other anesthetics. Crile, 1910, claimed that it diminishes the danger of shock and infection. The *disadvantages*, contraindications and limitations were discussed under the undiluted gas. Its application is further limited by the rather shallow anesthesia, incomplete relaxation, high blood pressure and venosity of the blood, the expense of the gas and apparatus, inconvenience, and the need for specialized experience. Fatalities from the surgical use of nitrous oxide are perhaps fairly numerous, but reliable statistics are not available (*cf.* J. F. Baldwin, 1923). Prolonged inhalation of nitrous oxide with less than 15 per cent of oxygen leads to anoxic sequels similar to those described under carbon monoxide (Courville, 1936).

Nitrous oxide analgesia in obstetrics has been advocated as much safer than scopolamine-morphine "twilight sleep." It does not weaken the uterine contractions and has no bad effects on mother or child (Webster; Lynch; Davis, 1915).

Direct Narcosis and Anoxia.—Nitrous oxide depresses sensation directly, as shown by the analgesia and confusion in the presence of normal oxygen concentrations. Frogs which preserve their reflexes for hours when placed in pure hydrogen lose them promptly in undiluted oxide. The direct action is not sufficient, however, to produce complete unconsciousness, even with 2 atmospheres of nitrous oxide, if the partial pressure of oxygen is kept at the normal ⅕ atmosphere, 156 mm. (W. E. Brown *et al.*, 1927). It must therefore be concluded that the depth of the anesthesia depends mainly on anoxia; but that the nitrous oxide causes an additive analgetic depression, which permits a somewhat higher and safer oxygen ratio, enough to make the anesthesia practically feasible, and certainly less unpleasant.

No one has been able to confirm the statement of Paul Bert, 1880, that full anesthesia is produced in dogs by a mixture of 85 parts of N_2O and 15 parts of oxygen, at an excess pressure of ¼ atmosphere.

Anesthesia in dogs requires reduction of the oxygen of the inspired air to 11.5–3.6 volumes per cent, varying with individual animals and with the degree of anesthesia, which is generally light with 8 to 9.5 per cent of oxygen and moderate to deep with 4.9 to 5.2 per cent, the degree in a given animal increasing with the oxygen reduction (C. W. Greene and Currey, 1925). However, reduction of oxygen to less than 6 per cent soon produces unconsciousness even without nitrous oxide.

Blood Gases in Nitrous Oxide-Oxygen Anesthesia.—Nitrous oxide is very soluble in blood, to 45 per cent by volume (Bert). Greene *et al.*, 1925, found close to 23.3 volume per cent (18.9 to 26.8) in the blood during anesthesia, independent of the percentage inhaled (85 to 96) or the degree of anesthesia. On the other hand, the anesthesia showed a close inverse relation to the *oxygen* of the arterial blood, which ranged from 2.1 to 18.8 volumes per cent. Anesthesia was not satisfactory until the oxygen saturation had fallen to 80 per cent, from the normal of 92 per cent; but the anesthetic level of oxygen is somewhat higher than in pure anoxemia. Lucas, Henderson and Foster, 1931, also found the oxygen in nitrous oxide-oxygen anesthesia as 6 per cent (volume) in the arterial blood, 3 per cent in the venous blood, and 23 per cent in aerated blood. Anoxemia occurred with the inhalation of $N_2O:O_2::90:10$, even with the most careful administration.

Significant differences from typical narcotics are shown in the incompleteness of the narcosis if oxygen is adequate, and in the failure of nitrous oxide to narcotize *excised tissue* (muscle or heart) and *invertebrates.* On these, it acts merely as an indifferent gas. H. Wieland, 1922, therefore ascribed its effects (as also those of acetylene) to interference with oxidative processes in the central nervous system. Their partition coefficient is on the lipid side: 1.89 for N_2O; 1.39 for acetylene, contrasting with 4.5 for ether. Humphry Davy believed that nitrous oxide acts like oxygen on the blood, but Frankland showed that it is not decomposed. Nitrous oxide probably does not combine with *hemoglobin.* The *blood catalase* is diminished by nitrous oxide, as in other forms of anesthesia (Burge *et al.*, 1918).

High Pressures of Nitrous Oxide.—These are fatal above 3 atmospheres, even when inhaled with adequate oxygen. The symptoms consist in narcosis, convulsions and finally depressed respiration. The heart remains strong (Bock, 1913).

PREPARATION.—***Nitrous Oxide,** U.S.P. (Nitrogen Monoxide, Oxidum Nitrosum), N_2O, is a colorless gas; slight characteristic odor; somewhat sweetish taste. One volume dissolves in about 1.5 volumes of water. It is marketed, compressed into a liquid, in steel cylinders. It returns to the gaseous state when the pressure is released.

◆

MISCELLANEOUS HYDROCARBON ANESTHETICS

A large variety of volatile and soluble hydrocarbons have properties which would make them available for anesthesia, and a large number of these have been studied pharmacologically and clinically, as is indicated in the reviews of Seevers and Waters, 1938, and M. Kochmann, 1936; the latter also includes the toxicology of industrial fat solvents. Only those that have achieved some practical prominence will be considered here.

Experience has confirmed the prediction of Brown and Henderson, 1926: "The *methane series* will probably not yield an anesthetic gas." The useful agents are ether, olefine (ethylene) series, cyclic hydrocarbons, and halogenated compounds. *Volatility and solubility* favor the action, the volatility because it facilitates penetration into the lungs; the solubility because it favors quick absorption and tends to slow elimination.

ETHYLENE ANESTHESIA

Ethylene, $CH_2:CH_2$, is employed to produce gas anesthesia. Since its clinical introduction in 1923, mainly through Luckhardt, Carter and Lewis, the published reports have been almost uniformly favorable.

Historical.—The stupefacient phenomena of ethylene, and their resemblance to those of nitrous oxide, were recognized by the toxicologist L. Hermann in 1864. The effects on animals were described about as they are known today by Eulenberg, 1876, and Luessem, 1885, but it was not tried for surgical anesthesia on man. No further work on animals appeared for the next thirty-three years, when Malisoff and Egloff, 1919, did some further toxicity experiments. Meanwhile, it had been found by Crocker and Knight, 1908, that ethylene vapor in the high dilution of 1:2,000,000 has a toxic effect on plants, which was further studied by E. M. Harvey, 1914. This great toxicity for plants led Luckhardt and Carter, 1923, to study its effects on animals; its low toxicity but rapid action on animals led them and their co-workers (Luckhardt and Lewis, 1923) to develop its successful clinical application. Nearly at the same time and in ignorance of their work, W. E. Brown, 1923, also reinvestigated the effects of ethylene on animals and men, with more knowledge of the older work, and with a direct view to surgical anesthesia; but he did not proceed to the clinical application.

Anesthetic Effects.—Ethylene is an aliphatic narcotic with relatively low potency, but with rapid action and recovery, due to its high volatility. Its effects may be conceived as analogous to a rapid ether anesthesia; but because of their rapidity, the phenomena appear more similar to those of nitrous oxide. It acts more powerfully and more promptly than the latter. Full anesthesia, which requires 90 per cent (volume) of ethylene and 10 per cent of oxygen, is established in about half the time required for the ordinary nitrous oxide-oxygen induction; the anesthesia and relaxation are deeper, and adequate for major operations; the recovery is more rapid, the patient being usually awake with clear mind within two minutes after discontinuance of the anesthetic. The percentage of ethylene may be gradually reduced toward 80 per cent in prolonged anesthesia. The rapid action and recovery demand close attention on the part of the anesthetist.

Mechanism of Action.—As with the other aliphatic narcotics, this appears to be connected with a high partition coefficient (= 13.2; Luckhardt and Carter, 1924).

Effective Concentration.—Mammals are generally only slightly depressed by mixtures containing 80 to 85 per cent of ethylene diluted with oxygen; with 90 per cent, the anesthesia becomes complete in twenty to thirty minutes (Luckhardt and Carter, 1923); 25 to 35 per cent produces analgesia; consciousness is sometimes lost with 40 per cent, generally with 50 to 60 per cent (Seevers and Waters, 1938). Continued inhalation of 85 to 86 per cent is slightly toxic, with slow fall of blood pressure and respiration; 89 per cent is quickly toxic; 93 to 95 per cent is acutely fatal (W. E. Brown and Henderson). Frogs are anesthetized by the 85 per cent mixture in twenty minutes, while 85 per cent illuminating gas produces no marked effects in thirty minutes (Luckhardt and Lewis, 1924).

Special Phenomena.—The *induction* is not disagreeable to the patient. The gas has a rather unpleasant odor, but it is not noticed after a half-dozen inhalations, because of the mental confusion. Talking and excitement are relatively slight and often absent. Analgesia occurs before the full anesthesia.

During established anesthesia, the respiration is practically normal. The excitability of the medullary centers is not lowered; they tend rather to be slightly stimulated by the lowered oxygen concentration, and hemorrhage is accordingly somewhat increased during the anesthesia; but the asphyxia is slight and does not progress to cyanosis. The respiration is slow and regular and the pulse scarcely changed. Sweating and salivation are slight or absent, and the temperature fall is relatively slight. Renal efficiency (phthalein excretion and saline diuresis) is not impaired; pulmonary irritation also appears to be absent. Postanesthetic vomiting is only half as frequent as with ether (30 per cent of the ethylene anesthesias as against 77 per cent of ether anesthesias, in the series of Luckhardt and Lewis), and when it occurs it is less severe and less persistent. Gas pains, in the same series, occurred in only 4 per cent of the ethylene, against 37 per cent with ether; they are no more troublesome than after local anesthesia. In obstetric use, it does not materially reduce the uterine contractions, and permits prompt respiration to the delivered child (Heaney, 1924).

Morphine is not required even for deep anesthesia, but it facilitates the administration, and permits the use of somewhat lower concentrations (Luckhardt and Lewis, 1924).

Respiration, Circulation and Temperature.—In animals, the CO_2 production is depressed only in proportion to the muscular relaxation. The respiratory center is not depressed by anesthetic doses, the rate and depth being increased in proportion to any anoxemia. The *blood pressure* rises about 10 mm., showing that the vasomotor center is not injured. The temperature falls but little. *Excised frog or mammalian heart* is not injured by saturating the perfusion fluid with ethylene (Bouckaert, 1924).

Digestive Tract.—The gastric secretion and motility (emptying time) are depressed clinically, but less than with ether (R. L. Johnson and Ivy, 1926). In animals also, when ethylene is administered to produce ordinary surgical anesthesia, the gastric movements are slightly depressed; but the movements of the small and large intestines are stimulated, in contrast to other inhalation anesthesias. In deep anesthesia, these are also highly depressed (Miller and Plant, 1925). Excised intestines of rabbits respond with slight and transitory decrease of tonus and some increase of amplitude of the contractions (S. A. Peebles and Phatak, 1934).

Hydrogen-Ion Concentration of the Blood.—Ethylene lowers the actual alkalinity of the arterial blood considerably less than ether or chloroform, and about the same as nitrous oxide. If anoxemia occurs, this causes a preliminary alkalosis (always with nitrous oxide; Leake, 1924).

Fatalities.—None are likely to occur with clinical concentrations. If the concentration is pushed much beyond 90 per cent in animals, death results mainly from anoxemia, *i. e.*, by respiratory failure. The circulation is not affected directly by the ethylene, so that resuscitation is relatively easy. *Impure ethylene*, of peculiar odor, produced cyanosis, imperfect relaxation, and subsequent prolonged emesis (Luckhardt, 1924).

The *advantages over ether* are principally: the easier, more pleasant, prompter and safer induction; the diminution of emesis and gas pains; the more rapid recovery; and the minimizing of renal and pulmonary irritation. *Advantages over nitrous oxide* consist in the practical absence of asphyxia; the deeper anesthesia and more complete relaxation; the lesser excitement and struggling; and the prompt recovery.

Disadvantages.—The principal drawback is the explosiveness of the ethylene-oxygen mixture, which demands the careful exclusion of electric sparks (static or other), open flames and cautery. This precaution is equally essential, however, with ether vapor: W. Bourne, 1934, found records of twenty ethylene explosions in operating rooms; and in the same period, thirty-nine explosions of mixtures of nitrous oxide, ether and oxygen (but this would make the percentage of ethylene explosions much higher than for the ether mixtures, since the latter were doubtless administered much more frequently).

Ethylene gas in encephalography appears to have some advantages over air, in that the subsequent headache is less severe and much less persistent (H. Newman, 1937).

Plants.—Ethylene gas is used to hasten the maturation of fruits and vegetables; it is indeed said to be produced in these processes.

***Ethylene, U.S.P.** (Aethylenum), contains 99 per cent, by vol., $CH_2{:}CH_2$. A colorless gas, somewhat lighter than air, of slightly sweet odor and taste. Sol. in water (1:9) at 25° C. Usually furnished in compressed form in metallic cylinders. Inflammable and explosive.

OTHER OLEFIN GASES

The introduction of ethylene anesthesia gave impetus to the study of other gases of the series $C_n H_{2n}$, but they are probably not sufficiently valuable (Seevers and Waters, 1938). The literature is cited by L. K. Riggs, 1925. The experiments of the latter on rats show that the activity of the lower members increases in nearly geometric ratio; *i. e.*, the concentration of gas required to produce anesthesia is, for ethylene, 90 per cent (volume); for propylene, 40 per cent; for butylene, 20 per cent; and for amylene, 6 per cent. With butylene and amylene undesirable side actions appear (exaggerated excitement stage; respiratory disturbances).

Diethylene.—Intravenous injection of 0.05 cc. into decerebrate cats raises blood pressure by stimulation of the vasomotor center. It has little effect on the respiration, heart or blood vessels directly (Bijlsma and van Esveld, 1929).

Propylene gas ($H_3C.HC{:}CH_2$) acts similarly to ethylene, but is more powerful, so that 50 per cent (volume) induces unconsciousness in two minutes, in man, and concentrations of 37 to 40 per cent suffice for anesthesia. This would permit considerable economy in oxygen as well as in the anesthetic. Its administration is not unpleasant, and recovery is rapid. In animals, toxic phenomena appear slowly with 65 per cent, rapidly above

70 per cent (W. E. Brown, 1924; Halsey, Reynolds and Prout, 1926). In dogs and cats, propylene may cause *ectopic ventricular beats*, the number increasing with the concentration of the gas. They disappear when the administration is stopped (C. R. Caine and Reynolds). Repeated prolonged propylene anesthesia of mice results in less visceral degeneration than with ethylene, and about the same as with nitrous oxide and ether. *Isolated uteri and intestine segments* are little affected by either propylene or ethylene. *Isolated frog and turtle hearts* survive longer in oxygen containing anesthetic equivalents of propylene than of ether (C. Reynolds, 1926).

Cyclopropane,  , an isomer of propylene, was proposed by G. H. W. Lucas and Henderson, 1929, as a promising anesthetic. It has been used clinically with good results in a considerable number of anesthesias, especially in Wisconsin and Montreal (Waters and Schmidt, 1934; W. Bourne, 1934; review, Council on Pharmacy and Chemistry, 1941, J.A.M.A., *116*:2502). Its actions and uses are intermediate between those of ether and ethylene, but its administration requires special experience, since the signs of anesthesia differ from those of other anesthetics. Its chief *advantage* is the quick and pleasant induction and the minimal side effects, so that it is preferred by patients. The most serious *disadvantage* is the liability to cardiac arrhythmia and ventricular fibrillation, which is even greater than with chloroform. Sympathomimetic drugs should not be employed with it. A number of explosions have occurred in its use; these are greatly feared, although its explosibility is perhaps no greater than with other anesthetic-oxygen mixtures.

***Cyclopropane,** U.S.P. (Trimethylene), is a colorless gas, with a characteristic not unpleasant odor, boiling at −32.9° C., inflammable and explosive similarly to ether (explosive range in air, 3 to 8.5 per cent; in oxygen, 2.5 to 50 per cent). It has a high oil:water partition coefficient (64.4 at 35° C., as compared with ether, 2.5; ethylene, 13.2; acetylene, 2.1; Henderson and Lucas, 1930). It is soluble in water to 20.4 volumes per cent, in oxalated blood to 45.7 per cent; the corpuscles dissolve 2½ times as much as the plasma. It is likely to polymerize on standing and to contain propylene and cyclohexane as impurities, but this is not practically important.

Course.—Unconsciousness occurs in one or two minutes. Excitement is present in only 3 per cent. Recovery is rapid, but slower than with other gases. The most important difference from ethylene and nitrous oxide is that it produces anesthesia in much lower concentration, 15 to 25 per cent by volume, so that the oxygen intake is easily kept at the normal level. The muscular relaxation is therefore much better than with nitrous oxide, although not so complete as with ether. Postanesthetic nausea, however, is more frequent than with nitrous oxide. Pulmonary complications are no more frequent than with the other anesthetics. It does not appear to cause liver degeneration. It is administered in a closed system with carbon dioxide absorption, to economize the gas. The oxygen is maintained at 20 per cent. There is no cyanosis, and the criteria of other anesthetics do not apply. The decisive danger signal is cardiac irregularity, extrasystoles, bradycardia or tachycardia. Premedication interferes with these signs; but ordinary doses of morphine reduce the concentration required for a given level of anesthesia by 10 to 12 per cent (Seevers and Waters).

Effective Concentrations.—Prolonged inhalation of 3 to 5 per cent produces analgesia; 6 per cent causes unconsciousness in many subjects (Seevers, Bennett *et al.*, 1937). In clinical cases the concentration in the mask averaged 7.4 volumes per cent for mild anesthesia, 13.1 per cent for the majority of abdominal operations, 23.3 per cent for deep anesthesia, 43 per cent for arrest of respiration. With dogs, complete muscular relaxation occurs with 20 to 25 per cent; respiratory paralysis usually with 40 per cent; cardiac arrhythmias with 46 per cent, and cardiac paralysis with 60 to 80 per cent, the latter notwithstanding artificial respiration and adequate alveolar oxygen tension (Seevers, Meek *et al.*, 1934). The blood concentration with dogs averaged 16.8 mg. per 100 cc. for abdominal relaxation, 20.6 mg. for loss of lid reflex, 25.5 mg. for costal paralysis, 28.2 mg. for arrest of respiration (B. H. Robbins, 1936, 1937).

Respiration.—Cyclopropane does not irritate in clinical concentrations, and does not produce induction disturbances. Anesthetic concentrations depress the respiration, progressing to arrest with toxic dosage (Waters). The CO_2 content of the blood and tissues rises accordingly. Statistics indicate a low incidence of pulmonary complications (Burford, 1938). Massive atelectasis may occur by rapid absorption of oxygen behind localized bronchial obstructions (Coryllos and Birnbaum, 1932; O. R. Jones and Burford, 1938). *Salivation* is somewhat greater than with nitrous oxide or ethylene, but less than with ether or chloroform.

The blood pressure is practically unchanged in smooth anesthesia, but may rise through asphyxia or reflexes. The blood vessels are relaxed and capillary bleeding appears to be increased.

Cardiac irregularities develop readily under certain conditions, although full anesthesia can generally be obtained without arrhythmia or other electrocardiographic change. In the absence of other medication they set in about the time when respiration ceases, with concentrations of 35 per cent or higher in dogs (Seevers *et al.*, 1934); but they occur even when the blood is fully oxygenated by artificial respiration, and in perfused hearts they are proportional to the dissolved cyclopropane; this, therefore, *acts directly* (W. V. Lee *et al.*, 1943).

The irregularities in intact animals generally disappear promptly when the concentration of the cyclopropane gas mixture is decreased. They do not render the heart more subject to overdistention by saline injection, indicating that it is not seriously injured (Meek and Volpitto, 1936). *The susceptibility to cyclopropane arrhythmia* is increased by anoxia, by morphine (cyclopropane tends to augment the morphine bradycardia in dogs; Robbins *et al.*, 1939); and particularly by epinephrine and related sympathomimetic amines. Partial protection is furnished by atropine, barbiturates, procaine, quinine, quinidine and other cardiac depressants (J. H. Baxter and Robbins, 1939).

Injection of epinephrine during light cyclopropane anesthesia produces ventricular tachycardia which readily passes into ventricular fibrillation. This is less liable to occur in deep anesthesia; it does not occur in decerebrated dogs. C. R. Allen, Stutzman and Meek, 1940, suggested that cyclopropane increases the irritability of the heart by sympathetic stimulation through a brain center above the pons. *The same effect* is produced by arterenol, epinine, kephrine, and cobefrine; not by ephedrine, propadrine, benzedrine, synephrine, neosynephrine (O. S. Orth *et al.*, 1944). Brief ventricular fibrillation is easily reversible. It is prevented by procaine, 16 mg. per Kg. by vein; but this is ineffective after the fibrillation has set in, even if injected intracardially within thirty seconds (Stutzman *et al.*, 1945). Barbiturates are not very effective (Meek and Seevers, 1934).

Nausea and vomiting are not frequent. In 10,000 clinical anesthesias recorded by Waters, these symptoms occurred in 56.5 per cent of ether administrations, 39 per cent of cyclopropane, 33 per cent of ethylene, 23 per cent of nitrous oxide. *Intestinal motility* has given somewhat discordant results. In fistula dogs, Weisel, Youmans and Cassel, 1938, observed decrease of tonus and inhibition of movement, returning to normal promptly after discontinuing inhalation. Burstein, 1938, reported increased tonus and contractions in light anesthesia; in deep anesthesia the contractions were diminished, but the tonus remained high. Excised segments from rabbits responded with increased tonus and contractions (Peebles and Phatak, 1935). The *urine output* is decreased during anesthesia with compensatory increase some hours later, as with ether and ethylene. Inhalations lasting an hour and repeated daily did not impair the *liver* function tests or produce any histological changes in dogs (Raginsky and Bourne, 1934).

Fate.—Cyclopropane is not converted into its isomer propylene in the animal body. It is absorbed and eliminated more rapidly than ethylene if the gases are injected under the skin or into the peritoneum (Seevers, de Razio and Evans, 1935).

Methyl (mono, di and tri) cyclopropanes are unsuitable for anesthesia, as they produce more cardiac irregularity and fall of blood pressure (V. E. Henderson and MacDonald, 1937; W. A. Lott *et al.*, 1938).

ACETYLENE

Anesthesia by the purified gas, HC:CH, has not become popular, perhaps because its advantages do not appear to be sufficiently great to balance the disagreeable odor. Its introduction, like that of ethylene, resulted directly from experiments undertaken primarily for theoretical "academic" purposes (review, Seevers and Waters, 1938).

Clinical Application.—Gauss, 1923, used a gas mixture of 40 per cent (by volume) of acetylene and 60 per cent of oxygen, flavored with oil of pine. The effects are similar to those of ethylene. It is necessary to employ a purified gas, as ordinary acetylene contains toxic impurities, such as H_2S (Wefers, 1917), which were largely responsible for the effects described by earlier observers.

Mechanism of Action.—Wieland, 1922, believed that nitrous oxide and acetylene differ from ordinary narcotics in that they do not appear to anesthetize organisms and processes that do not require free oxygen (ascaris; the contraction phase of muscle, and so forth). He also found that acetylene anesthesia greatly reduces the carbon dioxide production in higher animals.

Anesthetic Action on Animals.—The susceptibility appears to vary rather widely (Wieland). C. N. Jordan, 1923, required about 80 per cent for dogs. He emphasized the rapid recovery, and the absence of after-effects, even with a four hour anesthesia. The *blood pressure* rises and the pulse is slowed by stimulation of the vasomotor and vagus centers, even when ample oxygen is present. Spinal reflexes are depressed (Bollert, Eichler and Hildebrandt, 1927).

Effects on Man.—B. M. Davidson, 1925, found that human subjects were rendered unconscious in five to six minutes by 33 to 35 per cent; 30 per cent was not sufficient. Repeated inhalations (three times within a week) decreased the susceptibility; while 33 per cent acetylene abolished consciousness in six minutes at the first inhalation, it required nine minutes at the second, and more than thirty-three minutes at the third. A similar diminution was produced in the rapidity and degree of the minor disturbances of the psychic functions by lower concentrations, which she studied in some detail. Inhalation of 10 per cent of acetylene is used for *determining the cardiac output* (Grollman, 1929); 4 per cent ethylene is used similarly. These have some advantage over the ethyl iodide method of Richard, 1926.

VINYL ETHER (VINETHENE)

The actions of divinyl oxide, CH_2:CH.O.CH:CH_2, are intermediate between those of ethylene and ordinary ethyl ether. It differs from the latter chiefly by greater rapidity and brevity of action, due largely to its greater volatility. It is a colorless fluid of ethereal odor, boiling at 28.3° C., specific gravity 0.77 at 20° C. Anesthesia is promptly induced and easily maintained, with quick recovery. The rapid course requires special caution in its administration, but renders it useful for short operations, such as extraction of teeth, reduction of fractures, obstetric operations; and for induction to other anesthetics. The excitement is much less than with ethyl ether; salivation is moderate, but persists even after atropine; nausea and vomiting occur in about 5 per cent of the patients; muscular relaxation is satisfactory, although not so complete as with ethyl ether; the blood pressure is unchanged; postoperative complications are infrequent. The liability to liver injury is between ether and chloroform, and must be guarded against, although it has not been reported clinically (Ravdin, Eliason *et al.*, 1937). It may occur in prolonged inhalation in animals, even when the oxygen supply is abundant (Goldschmidt *et al.*, 1934;

von Brandis). The explosion hazard is about the same as for ethyl ether. Vinyl ether may be administered for short operations by dropping on an open or semiclosed mask; if the administration exceeds forty-five minutes, it is better to give it with oxygen. Normal respiration is the best guide to its use. Eye signs are not reliable. If cyanosis should develop, or if anesthesia is in any way unsatisfactory, the vinyl ether should be stopped and another anesthetic substituted.

Anesthesia requires a *blood concentration* of $\frac{1}{7}$ that of ethyl ether for man, $\frac{1}{4}$ for animals (28 mg. against 116 mg. per 100 cc.); the fatal concentration is about half that of ethyl ether (68 mg. against 155 mg.); Goldschmidt *et al.*, 1934. This would give a wider margin of safety, but this is offset by the lower total concentration, especially in view of the rather wide variability of response (Ruth). Several clinical deaths have been reported. In dogs the anesthesia is complicated by disturbing running movements. The *intestinal tonus and movements* are decreased in all stages of the anesthesia (fistula dogs; Burstein, 1938). The excised intestine of rabbits may react with increased tonus (Peebles and Phatak, 1934).

Historical.—Divinyl ether was first investigated as a possible anesthetic agent by Leake and associates, 1933 and 1934, and has been applied clinically especially by W. Bourne, 1934 and 1935; S. Goldschmidt, 1934; Waters, 1934; Shipway, 1935; and Lundy, 1935. A review by the Council on Pharmacy and Chemistry is published in the Journal of the American Medical Association, 1937, *109*:656.

Vinyl Ether, U.S.P. (Divinyl Oxide, Vinesthene), contains about 4 per cent of alcohol and not more than 0.025 per cent of harmless preservative phenyl alphanaphthylamine to delay polymerization. Slightly sol. in water, readily in alc. and in oils. It should not be used for anesthesia if the original container has been opened longer than twenty-four hours. Decomposition products include formic acid and formaldehyde.

Cyclopropyl vinyl ether ("*Cyprethylene Ether*"), administered by inhalation, approximates the anesthetic potency of divinyl ether and of chloroform. The heart activity is normal with anesthetic concentrations. Functional liver damage was demonstrable in monkeys (J. C. Krantz, Evans *et al.*, 1942).

Isopropenyl vinyl ether ("*Propethlene*") approximates chloroform in potency and lowers blood pressure, but does not produce hepatic or other visceral injury (Krantz, Carr *et al.*, 1943).

Isopropenylmethyl ether ("*Isoprome Ether*") produces good anesthesia in animals, with complete muscular relaxation (Krantz, Carr *et al.*, 1943).

Propenyl ethyl ether produces effective anesthesia in animals with relatively high factor of safety, but irritates the upper respiratory tract (Krantz, Carr *et al.*, 1943).

Dimethyl Ether.—W. E. Brown, 1924, found 65 per cent (by volume) to produce anesthesia, but it is unpleasant to take and the recovery is slow.

n-Propyl methyl ether compares favorably with ethyl ether in animals (J. C. Krantz, Evans *et al.*, 1946).

Methane.—W. E. Brown, 1924, found that this has a narrow zone of safety; unconsciousness occurs with 87 per cent (by volume), and death with 90 per cent. Its effects are mainly asphyxial.

Methyl Formate Vapor.—With guinea pigs, 0.15 per cent produces nasal and conjunctival irritation, retching, narcosis and death, apparently by pulmonary irritation; autopsy shows congestion and edema of the lungs and hyperemia of the liver, kidneys and brain surface. Death occurs in two and one-half hours in 1 per cent, in one-half hour in 5 per cent vapor (Schrenck, Yant *et al.*, 1936).

Ethyl acetate ("acetic ether") inhalation produces acute pulmonary edema and congestion of the liver and kidneys. Chronic poisoning results in secondary anemia, leukocytosis, and cloudy swelling and fatty degeneration of the viscera (Blina, 1933).

Iso-amyl acetate ("Banana oil solvent") is used as a cellulose solvent. It causes local irritation of the eyes, upper respiratory tract and other exposed tissues, but it is not dangerous systemically (Hamilton, 1915, 1917; Smyth and Smyth, 1928). *Secondary amyl acetate* appears to be more irritant, narcotic and toxic (F. A. Patty *et al.*, 1936).

"Methyl cellosolve" has been reported to produce encephalopathy and profound depression of the bone marrow or granulopenic anemia in exposed workers (Parsons and Parsons, 1938).

Lacquer Solvents.—H. F. Smyth and Smyth, 1928, who investigated the toxic effects of the inhalation of these vapors, group them as to safety as follows: (1) Usable safely in concentrations ordinarily attained in brushing and spraying, or sometimes higher: ethyl acetate, amyl acetate, perhaps butyl acetate. (2) Safe in ordinary concentrations, but to be increased only with caution: gasoline, turpentine, xylol. (3) The present spray concentrations cannot be safely exceeded: toluol and butyl alcohol. "*The Toxicity of Industrial Solvents,*" E. Browning, 1938, contains a review of all classes of these solvents, prepared on behalf of the British National Research Council. They are also reviewed by von Oettingen, 1942, and M. Kochmann, 1938.

HALOGENATED ANESTHETICS

The introduction of halogen atoms increases the anesthetic potency and the toxicity of the aliphatic narcotics, up to nearly complete replacement of all the H atoms, but diminishes again somewhat if no H remains. The toxicity also increases with the length of the carbon chain. Chloroform, $CHCl_3$, was discussed with ether; carbon tetrachloride with the anthelmintic agents (see Index).

Data on the *comparative toxicity* of the chlorine derivatives of the aliphatic series are given by Barsoum and Saad, 1934, and by Alice Hamilton, 1943. The chlorine derivatives of cyclopropane were investigated by V. E. Henderson, 1938.

Fate.—Methyl chloride, bromide and iodide are decomposed in the body into methanol and the halogen acid.

Severe methanol poisoning may result from prolongep exposure to subanesthetic concentrations. The corresponding ethyl compounds form ethanol. *Di, tri and tetra halogen compounds* are virtually not decomposed. The decomposition of various *bromine-containing anesthetics* in the body is discussed by Lucas, 1928, and Glaser, 1928.

Ethyl Chloride.—On account of its high volatility, the anesthesia appears and disappears promptly, and is therefore especially adapted for minor surgery. It has the same *dangers* as chloroform: relatively small doses may cause sudden stoppage of the heart, though less frequently than chloroform. Larger doses paralyze the heart muscle directly; and are even more dangerous than chloroform, because of the extreme suddenness and rather indefinite signals (E. D. Brown and Large, 1905; Wood, 1910). Its main *advantages* consist in the rapidity with which anesthesia is induced; in the consequent absence of struggling, excitement and unpleasant sensation; in the prompt and complete recovery. Its administration is often followed by headache, nausea, vomiting, and sometimes collapse. The muscular relaxation and abolition of reflexes are incomplete, and a little experience is required to recognize the proper time for operating. It has occasionally failed in alcoholic patients. Administering ethyl chloride by his special closed-circulation apparatus, D. E. Jackson, 1916, found its effects to be intermediate between those of nitrous oxide and ether. The concentration of ethyl chloride in the blood and tissues during narcosis was investigated by Camus and Nicloux, 1908, and E. Frey, 1912.

The main use of ethyl chloride is for *local anesthesia*, freezing the tissues by a fine spray of the liquid; the tube is held about 3 feet away. The impossibility of dissecting the frozen tissues restricts its use to simple incisions (opening boils); the analgesia is imperfect, and the thawing rather painful.

Ethyl Chloride, U.S.P. (Monochlorethane), C_2H_5Cl, is a colorless, extremely volatile liquid, of sharp, sweet taste and peculiar odor. Inflammable. Boiling point, 12° to 13° C. Sparingly sol. in water, readily in alc. or eth. Dispensed in special glass or metal containers. Used for freezing and for general anesthesia.

Methyl chloride boils at —24° C. It has been tried for anesthesia by inhalation and as a refrigerant spray, but the latter may produce vesication. Its chief use is in domestic refrigerators, and poisoning may be produced by the escape of the vapor. H. M. Baker, 1927, reviewed twenty-one cases. The *symptoms* consisted in vertigo, drowsiness, anorexia, slight nausea, visual disturbances from slight blurring to diplopia, but without changes in the eye ground. There is also a characteristic gait. Formate is found in the urine. The breath for several days has a peculiar odor, probably either methyl alcohol or acetone (Weinstein, 1937). A further group of twenty-nine cases, ten of them fatal, was reported in Chicago by Kegal, McNally and Pope, 1929. *Postmortem examination* showed pulmonary edema, cardiac dilatation, degenerated areas in the liver and kidneys, and scattered petechial hemorrhages. A special committee of the American Medical Association made recommendations to decrease the hazards (J.A.M.A., *94*:1832), which appear to have been fairly effective. The minimal *fatal concentration* for guinea pigs, with seventy-two hours of exposure, is 75 parts per million of air (J. L. White and Somers, 1931). Daily exposure of dogs and monkeys to 500 ppm becomes extremely dangerous within two weeks (W. W. Smith and von Oettingen, 1947). Eight cases of industrial poisoning are reported by W. D. McNally, 1946. Poisonous effects from absorption into food and drink are not likely, as the marked taste would prevent the consumption of toxic quantities (Yant, Shoaf and Chornyak, 1930).

Allyl chloride is the most toxic of the halogenated aliphatic hydrocarbons, its vapor being strongly irritant and causing death by pulmonary irritation. Animals that survive recover completely (E. M. Adams, Spencer and Irish, 1940).

Vinyl chloride was investigated by Patty, Yant and Waite, 1930.

Ethyl bromide resembles ethyl chloride closely (Weber, 1906), but has a higher boiling point, 38° to 40° C. It is used for short anesthesia, or rather analgesia. It must not be pushed to the disappearance of reflexes, since the respiration is paralyzed about the same time. The zone of safety is therefore narrow. Pain is abolished before consciousness, and the operation must be made before consciousness is entirely gone. The proper time for operating is somewhat difficult to choose, and the drug is dangerous in unskilled hands. With experience, the danger seems to be slight. The proper amount (for adults, 8 cc.; for children not more than 1 cc. per year) is poured on a folded towel or cone, and administered to the exclusion of air, until the proper degree of anesthesia is reached. It is then removed. It is only suitable for short operations (tonsillectomy, and so on). The administration requires twenty to forty seconds; the anesthesia lasts about two minutes. Recovery occurs at once. Inhalation of ethyl bromide in high concentration (6 to 18 per cent) for short periods produces acute pulmonary congestion and edema in animals; low concentrations (0.32 to 2.4 per cent) inhaled for a longer period produce the same effects, and also acute parenchymatous nephritis (C. P. Waite and Yant, 1928). It should be protected from light and heat. After a bottle has been opened, the contents cannot be used again, as they deteriorate rapidly. The drug must not be confused with *ethylene bromide* ($C_2H_4Br_2$), which is more toxic.

Ethyl iodide also resembles ethyl chloride in action (Weber, 1906), but boils at 72° C. It is inhaled for determining the cardiac output (Richard, 1926). Its excretion after inhalation of 1 to 3 cc. was studied by Blumgart, Gilligan and Swartz (1931): About 45 per cent is exhaled during the inhalation, and a further 9 per cent during the first two hours afterwards; 31 per cent is excreted by the urine (85 per cent of this in the first twenty-four hours); the remaining 15 per cent is presumably eliminated by the intestines, skin and sputum. Within therapeutic limits, the percentage retained is independent of the quantity inhaled.

Methyl bromide is a gas at ordinary temperature, boiling at 45° C. It is supplied liquefied by pressure. The vapor does not explode readily. It is used as a *fumigant* for the extermination of lice and bedbugs, and for the eradication of certain insects in food materials. Some remains tenaciously adsorbed in the latter, but not enough to produce deleterious effects (H. C. Dudley and Neal, 1942). It is also employed extensively as refrigerant, as fire extinguisher, and as methylating agent in chemical industry. It is a highly toxic and insidious agent and must be handled cautiously (review and bibliography, von Oettingen, 1946; industrial poisoning, H. Wyers, 1946). In animal experiments it is more toxic than methyl chloride, producing local irritation, pulmonary edema and pneumonia. Longer exposures to lower concentrations cause excitement, convulsions, paralysis, with cerebral congestion and visceral degenerations. *Industrial poisoning* is characterized by peculiar nervous after-effects. The immediate relatively slight narcotic symptoms pass off promptly, but are followed after several hours or even days by motor, sensory and psychic disturbances—aphasia, amblyopia, and so forth, lasting usually about two weeks and then regressing slowly; or they may persist for years. Some patients develop an epileptiform syndrome; others show congestion of internal organs (Duvoir, Fabre and Layani, 1937; R. N. DeJong, 1944). Animal experiments show that the methyl bromide has largely or entirely disappeared before these effects develop (E. Glaser, 1928). They are apparently due to neurodegenerations similar to those of carbon monoxide and manganese, perhaps from decomposition products.

Bromoform ($CHBr_3$) is not sufficiently volatile to be used as an anesthetic. It is employed as an antispasmodic in whooping cough, but is of doubtful value. It is a heavy liquid, resembling chloroform. Slightly soluble in water; miscible with alc., chlorof., eth., and fixed or volatile oils. Slightly volatile, not inflammable. Dose, 0.2 cc., on sugar dissolved in alcohol and glycerin.

Trichloroethylene, $CHCl{:}CCl_2$, a highly volatile, noninflammable liquid, boiling at 88-90° C., produces prompt analgesia and anesthesia on inhalation, resembling chloroform, but more rapid in action and less potent. It is used as analgetic (1 cc. self-inhaled from gauze until the odor has disappeared, three or four times daily, for four to six weeks) to relieve the pain of trigeminal neuralgia (M. A. Glaser, 1931), angina pectoris (where it acts solely as analgetic, and has no effect on the coronary vessels; Krantz *et al.*, 1938), and migraine (Geiger and Goodman, 1937).The patient should recline, since there is sometimes vertigo and drowsiness, although not general anesthesia. This dosage appears to be practically nontoxic and may be repeated if necessary, but generally not more than 4 cc. in a day. Patients should be warned against overdosage and addiction.

Its use originated in an observation of Plessner, 1915, that accidental inhalation in industries, where it is used as fat and varnish solvent, produced bilateral loss of sensation of the trigeminal distribution. It appears now that this is due to neuritis, and not to functional anesthesia. Following a suggestion of Oppenheim, 1915, Plessner applied it to trigeminal neuralgia.

Inhalation of 1 to 2 cc. from gauze produces a momentary choking sensation, then dizziness, confusion, inebriation and markedly diminished sensitivity to pain, exactly as in the analgetic stage of other inhalation anesthetics. It is not confined to the trigeminal distribution. Tactile acuity (tested by von Frey hairs) is not decreased (Council on Dental Therapeutics, 1931). *Addiction* to trichlorethylene, for inebriation and elation, has been reported in several cases. Eichert, 1936, described two patients who finally used 120 to 180 cc. within a few days, with marked mental changes, which cleared up on discontinuing. Other cases are reported by Jordi, 1937, and by N. K. Rickler, 1945.

General anesthesia by trichloroethylene (under the name of "*trilene*") became rather popular in England. The claimed advantages are ease of administration, absence of local irritation and of superficial oozing from cut surfaces, and relative safety (C. L. Heiver, 1942), but acute fatalities are fairly frequent (A. R. Hunter, 1944). It requires more oxygen than ether. Too rapid administration causes respiratory depression (H. F. Griffiths, 1942). It is somewhat more difficult to achieve complete muscular relaxation. It does not usually produce significant *electrocardiogram* changes clinically, but larger doses cause marked slowing of the heart rate, ectopic beats and changes in the P and T waves in animals (Mallach *et al.*, 1943). Disturbed automaticity is sometimes seen in man (Waters *et al.*, 1943). Its pharmacology was investigated by Joachimoglu, 1921.

Its clinical administration by closed apparatus may result in persistent trigeminal and other *cranial palsies*, attributed to toxic degradation products, dichloroacetylene, phosgene and carbon monoxide, formed by interaction with the soda lime of the absorber system. Dichloroacetylene produces encephalitis in rabbits (J. H. Humphrey and McClelland, 1944; S. Carden, 1944).

Chronic industrial poisoning with trichloroethylene results in some local irritation and dermatitis (L. Schwartz, 1939), and in systemic effects, headache, vertigo, anoxemia and nervous disorders, due to severe polyneuritis, including paresthesia and disturbed sensibility in the extremities (H. J. Pearson, 1934), paralysis of the trigeminal nerve, disorders of vision by optic nerve atrophy, and permanent blindness from retrobulbar neuritis (Isenschmidt and Kunz, 1935). These neuritic phenemena are probably caused by impurities.

Chronic Effects on Rats.—Acute exposure to 0.2 per cent of vapor produces slight narcosis; 0.3 to 0.5 per cent results in deep anesthesia. With chronic exposure (six hours per day, five days per week, up to six months), 0.3 per cent generally proved fatal in less than six months; with 0.2 per cent and less, the rats survived (as also did dogs), without noticeable deleterious effects. Their growth curves were similar to those of the control animals, and no histologic abnormalities were found in the liver, kidneys, lungs or other organs (H. Taylor, 1936).

Trichloroethylene, U.S.P., is a clear, colorless, volatile liquid, of specific gravity 1.46, with an odor similar to that of chloroform. A small amount of ammonium carbonate may be added as preservative. On exposure to air it forms small amounts of the irritant phosgene, hydrochloric acid and dichloracetyl chloride. It is very soluble in alcohol, practically insoluble in water, soluble in organic solvents. It is generally sealed in thin glass tubes containing the usual inhalation dose, 1 cc. Oral administration of 0.25 Gm., in gelatin capsules, three times daily has been suggested (Seelert, 1932), but has not become popular.

Tetrachloroethylene and **carbon tetrachloride** are considered with the anthelmintics; see Index.

Dichloroethylene (*acetylene dichloride*), $CHCl.CHCl$, is also used industrially as a cleansing agent. Exposure to the vapor produces nausea and vomiting, weakness, tremor, epigastric cramps. Dermatitis develops in skin exposed directly to the liquid. The blood sugar level is low, the white count high. There was no evidence of renal damage. Intravenous injection of calcium gluconate relieved the cramps and vomiting (Wirtschafter and Schwartz, 1939).

Ethylene dichloride (*dichloroethane,* Dutch Liquid), $CH_2Cl.CH_2Cl$, a colorless oily liquid, is used industrially as a solvent, particularly for rubber. Digestive derangements, drowsiness, tremor and nystagmus are reported from chronic exposure to its vapor (W. D. McNally and Fostvedt, 1941). It is one of the more toxic of the halogenated hydrocarbons. High concentrations in air produce narcosis and pulmonary congestion. Many animals develop hemorrhagic necroses in the adrenal cortex. Kidney and liver injury is less than with chloroform or carbon tetrachloride. Various chemical agents confer some protection, especially methionine and choline (Heppel *et al.,* 1946). Dogs and foxes, but no other animals tried, develop bilateral swelling and turbidity of the cornea with concentrations that had no other ill effects. It generally clears when exposure is discontinued (Heppel *et al.,* 1944).

1, 2-Dichloropropane (*Propylene Dichloride*), $CH_2Cl.CHCl.CH_3$, used as a solvent substitute for carbon tetrachloride, is one of the most toxic of the halogenated hydrocarbons. The liver injury is greater with low protein, choline-deficient diets, and some protection is furnished by dl methionine and by choline plus l cystine (L. A. Heppel, Highman and Porterfield, 1946).

Tetrachloroethane (acetylene tetrachloride), $CHCl_2—CHCl_2$, was employed in the airplane industry as a solvent for cellulose acetate, but has been displaced largely by less dangerous solvents. It is also used in dry cleaning. Its inhalation produces hepatic degeneration with symptoms analogous to those of phosphorus or chloroform poisoning (Alice Hamilton, 1917, bibliography). H. A. Coyer, 1944, reported seven cases, one fatal. They developed hepatic cirrhosis, hemorrhagic diathesis with bleeding into the intestinal tract, and frequently ascites.

Trichloroethanol resembles avertin in action, and has a wider margin of safety. It is more soluble and more stable in water. It is excreted in the urine, partly unchanged, partly conjugated as glycuronate (G. Lehmann and Knoefel, 1939).

Carbon disulfide, CS_2, resembles the chlorinated methanes in its effects. It is a volatile liquid (boiling at 46° C.) with highly explosive vapor, extensively used in the manufacture of viscose rayon, and in the rubber industry as solvent for sulfur chloride. It has about the same acute toxicity as chloroform and produces similar effects, including vomiting, weakness, convulsions and unconsciousness. Chronic poisoning is much more common and leads to nervous and mental disturbances, based on extensive anatomical changes in the peripheral nerves and in the ganglion cells of the cerebral cortex.

Chronic poisoning **is especially common in the viscose rayon industry. Susceptibility differs greatly, but most** workers exposed to the vapor present some deleterious symptoms, psychotic in about 3 per cent. They may not appear for several weeks and progress slowly. They begin with disturbed sensation (formication, headache, vertigo) and gastro-intestinal catarrh; then insomnia, fatigue, listlessness, loss of initiative, melancholia, erethismus, loss of memory, hysterical manifestations, exaggerated and then diminished libido and complete impotence (but chronic poisoning in guinea pigs did not result in functional or anatomic changes of the sex organs, male or female; Passerini, 1933). The symptoms usually disappear in a few weeks if exposure is discontinued. If it is not, polyneuritis develops, with tremors, muscular weakness, sometimes areas of anesthesia, and blindness from involvement of the optic nerve (Haas and Heim, 1911). Extension to the cerebrum results in encephalopathia, erethismus, apathy, hallucinations, mania, epileptic attacks. Ataxia has been reported. Marked marasmus develops. Death does not occur till late (F. J. Braceland, 1942; F. H. Lewey, 1941). Degenerative *histologic changes* are found in the blood (hemolysis, mononucleosis, anemia; no methemoglobin formation; H. Briegers, 1941), and in the nerve cells and dendrites, liver (vacuolization), kidneys and lungs. The fluid or vapor causes conjunctivitis and other local inflammatory changes in the eye; and *dermatitis,* with erythema, vesication, degenerative changes in the peripheral nerve endings, and even third degree burns on prolonged contact (J.A.M.A., *112:*2086). Poisoning in rubber works was described by A. L. D. Delpech, 1856; it is reviewed by A. Hamilton, 1915; Gordy and Trumper, 1938.

Dogs exposed to 400 ppm, eight hours daily for fifty-one days, developed similar symptoms and anatomic changes. Thiamine apparently conferred some protection (Alpers, Belett *et al.,* 1941).

Fate.—The solubility of carbon disulfide is so low that the tissues soon become saturated and no more can be absorbed, no matter how high the concentration inhaled, except as it is oxidized and excreted into the urine. About 85 to 90 per cent is oxidized to sulfate and organic sulfur compounds (R. W. McKee *et al.,* 1943). None is converted to hydrogen sulfide.

Enzymes.—The *succinic oxidase* system, which is important in nerve metabolism, is inhibited *in vitro,* but only with relatively large quantities of carbon disulfide. There is no inhibition of pyruvic oxidase or decarboxylase, nor of lactic dehydrogenase (McKee *et al.,* 1943).

Fluorine Derivatives of Chloroform.—The substitution of F for Cl decreases the toxicity of chloroform progressively: Booth and Bixby, 1932, found the concentration of the vapors which kill guinea pigs in ten minutes as 7 per cent for $CHCl_3$, 21 per cent for $CHCl_2F$ and 63 per cent for $CHClF_2$; so that each F lowers the toxicity by a third.

The pharmacology of *saturated fluorocarbons,* with one to six carbon atoms, was studied by Struck and Plattner, 1939. They are irritant and narcotic.

Dichlorodifluoromethane, CF_2Cl_2, *"Freon,"* CCl_2F_2, boiling at −29° C., is the preferred refrigerant in refrigerating machines, and is used in "bombs" for spraying insecticides. Its toxicity is relatively low. Inhalation of 20 per cent vapor produces analgesia and confusion, but not unconsciousness. Tremors are prominent, and convulsions may occur with high concentrations (Brenner, 1937). Recovery is complete in ten minutes. Animals survive exposure to 20 per cent for 120 hours, and to 80 per cent for fifteen minutes, but not for thirty minutes. It is noninflammable, but in the presence of flame it may be partly decomposed, producing phosgene, chlorine and volatile acid.

Trichlorofluoromethane, $CFCl_3$, is also less toxic than chloroform. It boils at 24° C., while chloroform boils at 60° C.

TRIBROMOETHANOL; AVERTIN

Tribromoethanol,  $\begin{array}{l}\mathrm{C{\equiv}Br_3}\\ \mid\\ \mathrm{CH_2{-}OH}\end{array}$, was introduced under the name "aver'tin" as a fixed-dose anesthetic for rectal administration, to produce a somewhat evanescent surgical anesthesia. Its chemical structure is that of ethyl alcohol, with the substitution of three bromine atoms. This greatly intensifies the narcotic effect, analogous to the relation of chloroform to methane. It is improbable that the bromine plays a direct part in the narcosis. Tribromoethanol is soluble in water (1:30 at 40° C.), but solution occurs slowly, and aqueous solutions are prone to decompose, with formation of hydrobromic acid and dibromacetaldehyde, which is very irritant. It is therefore marketed as "Solution of Tribromoethanol" ("Avertin with Amylene hydrate;" formerly "avertin liquid"), a solution of the substance in amylene hydrate, corresponding to 1 Gm. of tribromoethanol and 0.5 Gm. of amylene hydrate in 1 cc. of the solution. The amylene hydrate renders avertin more rapidly soluble, but it also modifies the action, for it is itself narcotic, and increases the depth and especially the duration of the anesthesia, and adds to the respiratory depression. Tribromoethanol solution has attained considerable vogue for producing rather *deep basal anesthesia.* It is also used against tetanus and other convulsive conditions. The rather prompt recovery of consciousness is sometimes advantageous. In neurosurgery it is preferred because it lowers the intracranial pressure (which is generally raised in inhalation anesthesias). Full anesthesia is dangerous. Even the basal anesthesia should not be employed by those inexperienced in its use. The effects and the fatalities approach rather closely those of chloroform, except that hepatitis is not so common, perhaps because it is not used for prolonged anesthesia. Visceral diseases, infections and chronic alcoholism are cited as contraindications (Petermann, 1930).

Patients prefer tribromoethanol anesthesia; they drowse off promptly and awaken in about half an hour, with the whole ordeal over. There are practically no disagreeable sensations and no nausea, because the action passes off rapidly and completely. The *disadvantages* are inherent in fixed-dose anesthesias, which preclude control of the effect once the dose has been administered. The response of the patients varies considerably, owing in part to differences of the distribution of the enema in the colon. There may be some rectal irritation, but with proper use this is trivial. Respiratory depression is liable to complicate and prolong the induction of supplementary inhalation anesthesia. Some patients react with alarming early depression, usually transitory (H. K. Beecher, 1938). Postanesthetic sleep may be prolonged from six to thirty hours, or there may be prolonged delirium, requiring close surveillance. Patients often require catheterization. Avertin is not advisable for *obstetric amnesia,* since uterine atony results from doses above 50 mg. per Kg. (H. Killian, 1929). Special contraindications are numerous.

Historical.—Tribromoethanol was introduced by Willstaedter and Duisberg, 1923, 1926. Eichholtz, 1927, 1929, investigated its anesthetic action on animals and clinically. Its pharmacology was studied by Straub, 1928, and its clinical introduction promoted by Bützengeiger, 1927 (reviews, Council on Pharmacy and Chemistry, 1937, J.A.M.A., *109*:952).

Administration.—Tribromoethanol solution is administered exclusively by rectum, dissolved in warmed distilled water (not to exceed 40° C., to avoid decomposition), in the ratio of 2.5 cc. in 100 cc. of the dilution, so that each cubic centimeter contains 25 mg. of tribromoethanol and 12.5 mg. of amylene hydrate. It should be tested with congo red just before injection; acid solutions should be discarded. A cleansing enema is given on the preceding evening and another three hours before the operation. Half an hour before operation, the avertin solution is instilled into the rectum during five to seven minutes. It produces some local irritation followed by local anesthesia. Morphine, 10 mg., is often administered before the tribromoethanol, but is not necessary and it increases the risk of respiratory failure (Barlow and Duncan, 1933), as do also other sedatives.

Dosage.—The ordinary dose is 50 to 80 mg. of avertin (with 25 to 40 mg. of amylene hydrate) per Kg. of body weight. This quantity should not ordinarily be exceeded for basal anesthesia, although for young and vigorous subjects it may be increased up to 100 mg. of tribromoethanol (with 50 mg. of amylene hydrate). Serious toxic effects in the early clinical use were due chiefly to excessive doses and to ignorance of the contraindications, but even 100 mg. per Kg. occasionally causes complete anesthesia with circulatory and respiratory depression. The total dosage should not exceed 9 to 10 cc. of avertin with amylene hydrate for men, or 6 to 8 cc. for women, regardless of body weight.

Sequence Anesthesia.—The ordinary doses often fail to produce complete unconsciousness, and with half the patients they require to be supplemented by ether (Petermann, 1930) or N_2O. The effects of these are additive (ether, I. G. Karber and Lendle, 1929; nitrous oxide, rats, O. W. Barlow, Duncan and Gledhill, 1931).

Contraindications (relative or absolute, depending on the condition of the patient) include liver or kidney dysfunction, severe cardiac disease, old age, shock or dehydration, sepsis, toxemia, severe pulmonary tuberculosis, empyema, marked hypothyroidism, obesity, asthenia, cachexia, ileus, tumors of the colon, enteritis and acidosis (N.N.R.). Acute renal insufficiency is an absolute contraindication, as it increases the toxicity by interfering with the elimination. *Hyperthyroidism* (or thyroxin administration sufficiently in advance) is said to hasten the destruction and therefore to decrease the efficacy of tribromoethanol.

Administration in Tetanus.—The spasticity and convulsions may be controlled within ten minutes by 25 to 50 mg. per Kg., supplemented by 10 to 15 mg. per Kg. every fifteen to thirty minutes as needed. A light narcosis should be continued for two or three weeks, until convalescence is definitely established (R. Spaeth, 1940). Tetanus antitoxin should be administered in the meantime.

The course of the narcosis is rapid and brief after rectal administration of the ordinary doses. They reach their maximum in ten to twenty minutes, are distinctly decreased by forty to forty-five minutes, and consciousness has returned completely in sixty to ninety minutes after the injection. With larger doses, this is followed by prolonged sleep (H. Killian, 1929). In rabbits and rats, full consciousness is usually restored in thirty to fifty minutes after a full narcotic dose. Good *analgesia* in the sense of indifference to pain is obtained, as with chloroform, when the patient is partially conscious and able to appreciate sensations (clinically, M. Rodecurt, 1929; rats, O. W. Barlow, Duncan and Gledhill, 1931). Muscular relaxation is also good. Postanesthetic nausea is less than with ether.

Postoperative Events.—Shortly after regaining consciousness, the patients generally fall into a quiet sleep, lasting several hours (sometimes even for a day), from which they can, however, be readily roused. Continuous vigilance is necessary to maintain an open airway and to prevent cyanosis and respiratory failure. Postoperative excitement and delirium are not common, and generally yield to morphine. There is often considerable amnesia of the events of the next twenty-four hours. Severe headache ensues exceptionally and persists for one to three days. Cough is present for two or three days in about 5 per cent of the patients.

Fatalities.—Tribromoethanol produces serious fall of blood pressure and depression of respiration which may be fatal. Early collapse, marked cyanosis and persistent unconsciousness indicate a bad prognosis. The therapeutic margin is narrower than with ether (L. Lendle, 1928). The danger is increased by the variability of absorption and excretion. The clinical mortality approaches that of chloroform (1:500 to 1:2000; Beecher, 1938). A large proportion of the recorded deaths (reviewed by F. Eichholz, 1930) occurred with doses of 75 to 100 mg. per Kg.

Treatment of Untoward Effects.—Barlow *et al.* found picrotoxin with ephedrine the most effective treatment, but they do not greatly decrease the mortality. Ephedrine, caffeine, cocaine, nicotine and carbon dioxide were practically ineffective. Ephedrine, however, interrupts or shortens the narcosis clinically and in animals (Raginsky and Bourne, 1931). Riedel, 1930, claimed that administration of sugar diminishes the toxicity.

The fatal dosage for animals is reported by Barlow *et al.*, 1931. Lendle, 1933, found that *young rats* are somewhat more tolerant than adults, both as to narcosis and fatality.

Individual Functions.—The *narcotic effects* are similar in animals and in man. Rabbits, *f. i.*, when injected rectally with 0.3 to 0.5 Gm. of avertin per Kg. show excitement and prompt narcosis (Herzberg, 1928). Rats are tranquillized so that they do not struggle when tied in the supine position, after injection with 47 per cent of the M.L.D. of avertin with amylene hydrate, as compared with 37.5 per cent of the M.L.D. of avertin crystals, and 78.5 per cent of amylene hydrate (Barlow and Gledhill, 1933).

Site of Narcotic Action.—H. Cushing, 1931, concluded that tribromoethanol depresses the diencephalon, for patients in tribromoethanol anesthesia fail to give the normal severe reaction to the injection of 1 to 1.5 cc. of pituitrin into the third ventricle. However, Chauchard and Monod, 1931, showed that the action extends also to the cortical centers.

The *respiratory center* is depressed in tribromoethanol anesthesia, even more than with chloroform. The ordinary clinical dosage causes marked respiratory slowing, diminished response to carbon dioxide, and sometimes fatal respiratory arrest (F. B. Parsons, 1929; Hoepfl, 1930). With rabbits, the respiration rate is decreased to a fourth by the dosage required for full anesthesia. The depression is enhanced by morphine (G. Karber and Lendle, 1929; H. Killian, 1930). In rats, respiratory depression occurred with 46 per cent of the minimal tranquillizing dose of avertin with amylene hydrate, with 25 per cent for avertin crystals, with 75 per cent for amylene hydrate. Morphine potentiated the respiratory depression more than the sedative action (Barlow and Gledhill, 1932).

Circulation.—Ordinary doses of tribromoethanol generally produce considerable *fall of blood pressure*, usually of short duration (maximum in eight minutes), and not directly dangerous (C. C. Greer, 1930; W. P. Kennedy 1930). This involves depression of the heart and of the vasomotor center; direct action on the blood vessels, similar to that of alcohol, and decrease of the blood volume approaching that of severe hemorrhage. The *heart* is depressed directly, both by tribromoethanol (H. Guggenheimer and Fischer, 1927) and by amylene hydrate (E. Harnack and Meyer, 1894). Clinically, however, there is little effect on the heart, even with doses considerably higher than those used in clinical anesthesia (Raginsky, Bourne and Bruger, 1931). Electrical changes are exceptional and slight (Morton, 1935). Much higher concentrations, in animals, slow the heart, diminish the output and increase the coronary flow. Tribromoethanol anesthesia sensitizes the heart to epinephrine irregularities. Avertin *lowers the intracranial and intra-ocular pressure*, during fifteen or twenty minutes. Gas and ether anesthesia increase these pressures (Seevers *et al.*, 1931; W. Bourne, 1934). While these and other anesthetics dilate the pial vessels in cats, tribromoethanol decreases their diameter (Finesinger and Cobb, 1935).

Gastro-intestinal motility is considerably depressed even by hypnotic doses of tribromoethanol, the stomach more than the ileum, and this more than the colon; but the effect passes off as the patient awakens (Quigley, Barlow and Himmelsbach, 1934).

Parturition.—The uterine contractions are slowed (Dodek).

The *urine output* is suppressed for two hours in nearly 75 per cent of the human clinical anesthesias, chiefly by the fall of blood pressure, and is still low after twenty-two hours. The urea output is likewise lowered. In dogs the urine secretion is suppressed for one or two hours by anesthetic doses (Bruger *et al.*, 1930), and large doses produce definite histologic lesions. Human kidneys appear more resistant, but albuminuria and hemorrhagic nephritis are seen occasionally. Acute renal disease materially slows the excretion of tribromoethanol, and its toxicity is correspondingly increased.

Metabolism.—The *temperature* falls; the *blood sugar* rises. The alkali reserve is lowered, the blood bicarbonate being diminished. The *acidosis* approaches that of chloroform, but is less marked in man than in dogs (M. Bruger *et al.*, 1930).

Liver.—Moderate doses appear to have little effect on the normal liver, no more than amytal or ether (P. Kaczander, 1930; Bruger *et al.*, 1930). Impaired liver function is reported in 1 or 2 per cent of clinical administrations. It is generally slight and transient, but ordinary doses may exceptionally produce severe hepatitis and nephrosis, similarly to chloroform (D. H. Andersen, 1945). Large doses or with liver disease produce toxic hepatitis in dogs (E. Heinecke, 1930; Bourne and Raginsky, 1931).

Rectal Irritation.—Tenesmus and bloody stools sufficient to be mentioned in the record occur in about 1 per cent of clinical anesthesias; about a fourth of these are fairly severe. They occur both without and with amylene hydrate. The latter is more irritant in dogs. It is advisable to flush the rectum after the anesthesia is no longer needed. The rectal inflammation, with various visceral lesions, is generally responsible for delayed fatalities in rabbits (A. H. Maloney, 1942).

Absorption, Fate and Excretion.—These explain the rapid course. With rectal injection of tribromoethanol, 50 per cent may be *absorbed* in ten minutes, 75 per cent in twenty-five minutes, and the remaining 25 per cent very slowly (A. Speigel, 1930). The absorption is rather variable, however. The addition of amylene hydrate increases the speed of absorption in dogs (Quigley, Barlow and Himmelsbach, 1934).

The *excretion* occurs by the urine, almost as rapidly as the absorption, so that the sojourn in the body is brief; 70 to 80 per cent may be excreted in twenty to thirty minutes, and 95 per cent in the first two hours (D. A. Wood, 1930). When renal function is impaired, the toxicity may be considerably increased (Veal, Phillips and Brooks, 1931). The greater part is *detoxicated by conjugation* with glycuronic acid before it is excreted (Endoh, 1924; Welsch, 1929). The bromine remains in the molecule and is not ordinarily excreted as ion (Straub, 1928), but a case of bromide rash has been reported. In rabbits, the *tissue concentration* of avertin decreases in the order: liver, heart, brain, kidneys, lungs, spleen, blood (Fischer and Hüppmann, 1934). The concentration in the blood reaches its maximum in twenty to thirty minutes after the rectal injection. Narcosis occurs with 6 to 10 mg. per 100 cc. of blood; awakening with 2 or 3 mg. (review, Anschütz, 1930). G. A. Emerson and Morrison, 1942, report on the Br distribution in cats receiving tribromoethanol, tribromoacetaldehyde (bromal) and tribromoacetic acid.

Amylene Hydrate, dimethylethylcarbinol, tertiary amyl alcohol, $(CH_3)_2C_2H_5COH$, contributes a little to the narcosis and somewhat more to the respiratory depression (Barlow and Duncan, 1932). It has been used as a hypnotic, ranking between chloral and paraldehyde, in doses of 1 to 2 Gm. Its maximal hypnotic dose for man is generally stated as 4 Gm.; this is the amount contained in 8 cc. of avertin with amylene hydrate, which is the ordinary therapeutic dose. The fatal dose for animals is about 1 or 2 Gm. per Kg. The pharmacology of amylene was studied by E. Harnack and Meyer, 1894.

Amylene Hydrate, U.S.P.; a clear, colorless, volatile liquid of aromatic odor and taste. It is soluble in 8 parts of water, and freely soluble in alcohol. It forms acicular crystals on cooling.

Derivatives.—The hypnotic and lethal doses of various trihalogenated alcohols and their derivatives were investigated for rats by Burtner and Lehmann, 1938. They report that *trichloroethanol* has a wider margin of safety than tribromoethanol (avertin).

Trialkylmethanols are all narcotic, but much less so than tribromoethanol (Rice, Glenn *et al.*, 1938).

PREPARATIONS.—***Solution of Tribromoethanol,** U.S.P.; **Avertin with Amylene Hydrate.** Bromethol. Each cubic centimeter of the fluid contains 1 Gm. of tribromoethanol and 0.5 Gm. of amylene hydrate.

Tribromoethanol, U.S.P., a white crystalline powder of slightly aromatic odor and taste. It is volatile and unstable in air, slightly soluble in water (about 1:35). It melts at 79° to 82° C. It contains 84.8 per cent of bromine. Average dose (also for avertin), rectal, 60 mg. per Kg. of body weight, the total not to exceed 8 Gm. for women, 10 Gm. for men, regardless of weight.

ALIPHATIC HYPNOTICS

Sleep is one of the earlier phenomena of light narcosis and may be induced by small doses of any of the aliphatic narcotics. With many of these, however, the hypnotic stage is too brief, passes too easily into general anesthesia, or is complicated by undesirable side actions, stimulation, local irritation, and so on. Clinical somnifacients may be conveniently grouped into those which induce sleep promptly, and those which maintain it; evipal and barbital illustrate the extremes.

Historical.—The somnifacient properties of alcohol and of opium were known and used in antiquity. The first addition to these was bromide, introduced by Laycock in 1853, as a sedative in epilepsy, but not used as hypnotic until 1864, by Behrend. Five years later (1869) Liebreich added chloral hydrate. This was twenty-three years after the discovery of ether anesthesia. There was again a gap of thirteen years, followed by the introduction of paraldehyde (Cervello, 1882), urethane (Schmiedeberg, 1885), and sulfonal (Baumann and Kast, 1888); another gap of fifteen years, then barbital (E. Fischer and Mering, 1903); another gap of nine years, then phenobarbital against epilepsy (1912). Since then other barbiturates have been introduced in large numbers which, because of their potency, relative safety and comparative freedom from untoward actions, have largely displaced the other hypnotic drugs.

Chemical Grouping.—The hypnotic hydrocarbons and their halogenated derivatives may be grouped under the principal headings: (1) Oxygen substituents of hydrocarbons— alcohols (avertin, isopral, amylene hydrate), aldehydes (paraldehyde, chloral), ketones (sulfonals), ethers and esters (urethane). (2) Ureides acyclic (carbromal) and cyclic (barbiturates, hydantoins) and tetrahydropyridines. The ethyl group and the next higher homologues seem to be especially valuable in conferring hypnotic action, and are most effective in the presence of aldehyde or ketone radicals. Alcohol radicals weaken the action, so that glycerin, *e. g.*, is not narcotic. The compounds must resist oxidation sufficiently to make their action lasting.

Role of Chlorine.—The narcotic effect is greatly enhanced by the introduction of chlorine, as shown by the comparison of acetaldehyde and chloral, and by the methane derivatives, the efficiency of which increases for each additional chlorine atom from methane to carbon tetrachloride. This peculiar property of the chlorine compounds has not been explained.

Actions.—Small doses of these drugs depress sensory and intellectual processes, so that the perception of external stimuli is lowered (Kraepelin, 1892). The subject is thus put into a condition favorable to natural sleep. This should be the aim in their therapeutic use. Larger doses produce an actual stupor and eventually coma.

Other functions behave as in natural sleep:

The blood pressure and pulse are somewhat lowered. The skin vessels are moderately dilated. The brain vessels are also dilated (Berezin, 1916). The visceral vessels are constricted. The secretion of sweat is increased; the urinary, lacrimal, salivary and gastric secretions are decreased, the movements of the empty stomach are increased (Carlson). The chlorinated hypnotics (chloral) in large doses have a direct depressant effect on the medullary centers, especially the respiration, and on the heart muscle. All the members are hemolytic when added directly to blood (L. Herrmann).

Relation to Sleep Centers.—The narcotic action of the hypnotic drugs may be conceived as protecting the sleeping center against awakening impulses. Since all kinds of somnifacient drugs induce sleep in animals whose hemispheres have been removed, indeed often more effectively than in normal animals (Morita, 1915; Esser, 1931), their action must be chiefly on the basal centers, but this does not exclude that part of their action may be cortical in intact animals. These remarks apply to all the hypnotic drugs, and a division into "*cortical* hypnotics" (alcohol, paraldehyde, morphine, bromides, urethane, magnesium) and "*basilar* hypnotics" (barbiturates and chloretone) does not appear sufficiently justified (review, M. Kochmann, 1936).

Older views conceived sleep purely as a passive process, somewhat as a profound degree of inattention to the external and internal impressions of consciousness. The rhythm of awakeness and sleep persists, however, in animals deprived of hemispheres and cerebellum. This would leave the brain stem, the region of the basal ganglia, the corpora striata and mammilaria and the optic thalamus as the focus of sleep regulation. This is confirmed by the observations that this is the seat of degenerative lesions in the persistent sleep of lethargic encephalitis, and experimentally, by the production of orderly sleep of apparently normal type, by electrical stimulation of the floor of the third ventricle in cats (Hess, 1932, 1933; Marinesco) or by injection of 4 or 5 mg. of calcium chloride into this region, in cats (A. V. Tonkikh, 1941). Transection of the brain stem behind the third cranial nerves also produces in cats a condition apparently identical with natural or barbital sleep, which persists indefinitely and includes extreme miosis and suppression of olfactory and ophthalmic reflexes (Bremer, 1935). All these experiments create artificial conditions, and it may therefore be questioned whether they are conclusive for ordinary sleep; but they are currently accepted and sleep is accordingly conceived as an active process provoked by stimulation of the "sleep centers" in the basal ganglia, which in turn blocks the access to them of the awakening impulses from the cerebral cortex (cerebral sleep); or (somatic sleep) from autonomic "awakening centers," situated somewhere more posteriorly, in the vicinity of the oculomotor center, whose electrical stimulation may awaken sleeping cats (Economo). Progressive transections of the brain stem in rats indicate that the caudal area of the hypothalamus is concerned with keeping awake, the preoptic area with sleep, perhaps by inhibiting the caudal area (Nauta, 1946).

The classification of cortical and basilar hypnotics was based chiefly on the ambiguous potentiation between the hypnotics (Molitor and Pick, 1926), and on the report of Keeser, 1929, that the concentration of the barbiturates is higher in the mesencephalon than in the brain generally. The distribution has been contradicted by Koppanyi and Dille, 1935, but it would not be very cogent since it would depend on the ratio of white and gray matter rather than on selective action. Gensler, 1915, found the concentration of hypnotics in the whole brain somewhat higher than in the other tissues, including the blood. A. E. Laidlaw and Kennard, 1940, report that India ink injections show numerous dilated capillaries in the hypothalamic nuclei with barbiturate anesthesia, but few with ether.

Direct injection of phenobarbital into various cerebral areas results in sleep from the infundibular regions, not from the telencephalon, rhinencephalon or cerebellum (Sahlgren, 1934). The effects of intracisternal injection of hypnotics were reported by Borbely, 1935 (animals); and Urban, 1935 (human) and by S. J. Weinberg, 1934.

Neurohistological degenerations after long-continued use of fairly large doses of barbiturates occur throughout the central nervous system, but especially in the cerebellum, midbrain and spinal cord (Mott, Woodhouse and Picksworth, 1926). It is improbable that these have any relation to the hypnotic action.

The *antagonism and synergism* of the various hypnotics with stimulants of the mesencephalon, such as tetrahydronaphthylamine (Morita, 1915), coramine and ephetonin (Moritsch, 1932), for normal and decorticated rabbits is complex and confusing. The "basilar" hypnotics render the cortex more susceptible to ether and other anesthetics, so that they probably also have a cortical action, especially with large doses.

Brain potentials have been studied especially with barbiturates. These result in the large regular alpha waves characteristic of normal sleep or cerebral transection, interpreted as disconnecting the cerebral cortex from the disturbing impulses of the awake state. However, barbiturates also render the cortex much more susceptible to the abolition of the waves by ether, indicating direct cortical depression; and anesthetic doses of barbiturates (or avertin) abolish the waves even without ether (Bremer, 1936; Berger, 1934; Derbyshire *et al.*, 1936).

Blood Lipids.—The influence of continued administration of aliphatic hypnotics was investigated by Waser, 1915.

Inflammation.—Chloral, urethane, and presumably the other aliphatic narcotics, inhibit the migration of leukocytes from the inflamed frog's mesentery (Ikeda, 1916).

Glucose Tolerance Test.—Clinical doses of chloral, barbital, pentobarbital and morphine lower and shorten the hyperglycemia (H. Tod, 1935).

Comparison of Aliphatic Hypnotics.—Chloral, the oldest member of the group, is a good somnifacient, but it has been largely displaced by the newer hypnotics, perhaps not quite deservedly. Its action is certain, prompt, but sufficiently lasting, and easily graduated by the dosage. It is readily soluble, and not cumulative. It has an unpleasant taste and is somewhat irritant to the stomach. It is not effective against pain. The large doses originally employed sometimes produce dangerous cardiac and respiratory depression. It is doubtful whether these effects need be feared with doses of 1 Gm., but it is generally advised to be cautious in its employment in the presence of depression of the medullary centers, or of vascular, cardiac, renal, pulmonary or gastric disease. *Paraldehyde* is milder than chloral, but acts promptly. It does not affect the respiration or heart, but as unpleasant to take. *Barbital* (veronal) is about as effective, but not quite so prompt, is chloral. It is less disagreeable to taste, and is not so toxic; but full doses have caused severe and fatal poisoning, and therapeutic doses may produce cumulative effects. *Phenobarbital* (luminal) is more active and more toxic than barbital, but small doses are merely calming and sedative, like bromides, so that it has found a special field in epilepsy and in thyroid disease. *Amytal* and especially *pentobarbital* induce sleep more promptly, but do not maintain it so long, and leave less of a mental fog. *Carbromal* (adalin) and *bromural* act rather feebly, and *like the bromides* are suitable mainly for mild nervous insomnias. *Sulfonal* and *trional* are fairly powerful, but act slowly and produce considerable after-depression; they also irritate the kidneys and cause dangerous cumulative effects.

The *relative clinical effectiveness of various somnifacients* may be estimated from the data of Grabfield, 1931, and expressed as the average dosage (in Gm.) required to assure a good night's sleep to hospital patients indiscriminately, as follows, in ascending order (the more important drugs are in italics): *Codeine,* 0.0175 (*Pentobarbital,* 0.046, assumed as one-half of amytal); neonal, 0.058; *phenobarbital,* 0.072; ipral, 0.085; *amytal,* 0.94; phanodorn, 0.11; *chloral,* 0.155; *barbital,* 0.16; chlorbutanol, 0.18; butylchloral, 0.21; sabromin, 0.32; bromural, 0.41; carbromal, 0.43.

Comparison with Other Groups.—Morphine is ordinarily less effective than chloral, but is superior when insomnia is due to pain. *Scopolamine* is used especially in psychic insomnia and insanity. *Apomorphine* is said to be superior in acute alcoholism. *Bromides* are effective only in mild nervous cases, worry, and the like.

Mixtures of Hypnotics.—Urethane and opiates give only simple summation of action in animals (Le Heux, 1919). The older work, which claimed potentiation, appears open to criticism (Storm van Leeuwen, 1919).

Experimental criteria of hypnotic action are difficult, as this is influenced greatly by external conditions, such as fatigue or freshness, quiet and excitement. The *depth of sleep* may be measured quantitatively by the rise of carbon dioxide tension in the alveolar air (Regelsberger, 1934). The daily activity may be recorded by automatic devices; *f. i.*, by suspending an aluminum cage from a spiral spring (Schlaginweit, 1928). Sedation may be tested against excitement induced by cocaine (for mice, 1 mg. per 100 Gm. of body weight, hypodermically; Modrakowski and Rusiecki, 1937); with rats, by the quieting of the struggles when the animal is kept tied in the supine position.

Therapeutic Indications.—Hypnotics are used to procure sleep in insomnia, especially when more physiologic measures (removal of the cause, and so forth) are not applicable, and to break incipient habits of insomnia, by promoting the confidence and equanimity of the patient. Their continued use generally leads to tolerance and often to dependence and addiction. They should be avoided if possible. Full doses often produce acute poisoning. Doses only large enough to induce sleep indirectly by quieting the patient are rarely dangerous, and can be used temporarily without apprehension. When the hypnotic needs to be continued for a long time, it is well to change occasionally to a hypnotic of another type, and to return to the first later.

The *consumption of hypnotic drugs* has attained astonishing proportions, especially since the introduction of the convenient and relatively safe barbiturates. Five million ounces of these were sold in the United States in 1940, equivalent to more than four million sleeping doses per day (Klumpp).

Toxicology.—Suicide by hypnotic drugs, especially the barbiturates, becomes increasingly frequent, especially in large cities, where barbiturates are the means of 2 to 17 per cent of all suicidal deaths from poisons (exclusive of carbon monoxide) (W. E. Hambourger, 1939). Some of the suicides are accidental, the whole supply of drug being consumed by "automatism" in the twilight zone induced by the first dose (Richards, 1934). The *symptoms* are similar for all hypnotic drugs, passing through deep sleep, stupor and coma, often lasting for several days. Death occurs from narcosis of the respiratory center or from low blood pressure and temperature fall, or subacutely from lung complications (deglutition pneumonia) or nephrosis. The renal damage is often much greater than the urine findings would suggest. Oliguria may be marked. Edema is not common. Glycosuria occurs with normal blood sugar level, so that it is renal. Liver injury, from slight jaundice to acute yellow atrophy, has been observed with chloral and with nirvanol. *Recovery symptoms* after severe poisoning are similar to those after anesthesia, but with a slower course. Fever is common. The *treatment* should begin with gastric lavage. Activated charcoal may be useful. Severe cases may be treated by full doses of picrotoxin or metrazol with ephedrine (see under Barbiturates). Lumbar puncture has been advocated to relieve the high cerebrospinal pressure.

Efficiency of Respiratory Stimulants against Poisoning by Aliphatic Hypnotics.—Metrazol and coramine are fairly effective in rabbits (O. Gros, 1936), but are improved by the addition of epinephrine (Barlow *et al.*). The quantitative differences of various analeptics were studied by Chakravarti, 1939.

Largest Doses from Which Recovery Has Been Reported Clinically.—Leschke gives these as 8 Gm. for hedonal; 15 Gm. for bromural, adalin (carbromal) and phanodorm; 16 Gm. for trional; 26 Gm. for amylene hydrate; 30 Gm. for sulfonal; 150 Gm. for paraldehyde. Further data will be found under the individual drugs.

Addiction to soporifics is not uncommon, in the sense of indefinitely continued use from dread of insomnia. Some individuals respond with euphoria or inebriation, and use the drugs for this purpose, often with increasing doses. They can be fairly easily withdrawn, without marked abstinence symptoms. The immediate dangers are similar to those of abuse of alcohol, doubtless including greater automobile accident hazard. Severe addiction may lead to mental deterioration, similar to progressive paresis, sometimes with a parkinsonian syndrome.

CHLORAL HYDRATE

Chloral hydrate, $CCl_3.CH(OH)_2$, is the hydrate of *trichloraldehyde*, $CCl_3.CHO$. It was discovered by Liebig in 1832, and was introduced as a hypnotic by Liebreich in 1869. Chloral forms analogous compounds with alcohol and glycerol, with quantitatively identical actions.

Therapeutic Uses.—Chloral is used especially in insomnia of psychic origin. In ordinary nervous insomnia it should be given in small doses of 0.3 to 1 Gm. (5 to 15 grains), sometimes with 1 Gm. of sodium bromide. It may be administered in milk or in Orange Syrup, but its taste is not easily disguised. Larger doses are needed in mania and in delirium tremens. In the latter condition, the large doses have caused collapse. It is not very effective against febrile delirium or pain. The addition of morphine is said to secure a stronger effect than if either were used alone (Knell, 1907). Chloral is effective against the *convulsions* of strychnine, tetanus (Dreyfus, 1914), eclampsia, and the like. Fairly large doses are needed, and it has been displaced by the barbiturates. Chloral is also used in *asthma* and *seasickness*, but the benefits are uncertain. Chloral *by rectum* is rather more effective than by mouth. It cannot be used hypodermically because of its irritant action. *Locally*, it is sometimes employed against neuralgia and pruritus, as an ointment (15 per cent) or as *chloral camphoratum*, N.F. (the liquid resulting by triturating equal parts of chloral and camphor).

Ordinary somnifacient doses, 1 or 2 Gm., produce drowsiness in ten or fifteen minutes, and quiet, sound sleep within an hour, mainly by diminishing attention to external stimuli. The sleep lasts at least several hours, but the patient can be easily and completely aroused, and awakens refreshed, generally without depressant after-effects. It does not easily create tolerance. Exceptionally, chloral produces excitement and even delirium. It is irritant and disagreeable to take and should perhaps be avoided in gastric and intestinal derangements. Emptying of the stomach is somewhat hastened by 0.6 Gm. of chloral, as also by sedative doses of amytal (Northup and Van Liere, 1946). A few patients develop lacrimation. The respiration and pulse are somewhat slowed and the blood pressure and temperature slightly lowered, but little more than in ordinary sleep (Alstead, 1936). In respiratory and especially in circulatory diseases, these depressant effects may be rather more pronounced, and may perhaps lead to some cyanosis with the larger doses. In fact, however, the fear of respiratory and cardiac depression is based essentially on faulty deductions from animal experiments. There is no good clinical evidence of cardiac depression; while the danger is greater in cardiac diseases, it has often been given without bad effects (Cushny, 1914). The experimental evidence also indicates that the depressant dose is considerably larger than the therapeutic hypnotic dose (Gunn, 1914).

Larger doses, 2 or 3 Gm., produce deep sleep, which, as the dosage is increased, passes into stupor and coma, with complete muscular relaxation. The other depressant effects become much more important. The depression of the medulla makes itself felt by *slowing of the respiration* and *fall of blood pressure*. The vasomotor paralysis is so prominent that chloral is used in the laboratory to secure paralysis of this center. The pulse is also slowed through direct depression of the cardiac muscle. *Dilatation of cutaneous vessels* is quite marked and causes fall of temperature with large doses, aided by diminished production of heat from muscular relaxation and depression of the heat-regulating centers. The temperature regulation in deep chloral coma resembles that of cold-blooded animals (Sollmann and Hatcher, 1908). *Skin eruptions* sometimes follow. Death is ordinarily caused by paralysis of the respiratory center, although it may take place by paralysis of a weakened heart.

The cardiac effects are similar to those of chloroform. They consist in shortening of the refractory period and depressed contractility. With *stimulated ventricular segments*, the shortening of the refractory state leads to superposition of contractions and tetanus, and because of the depression, the tetanic contraction may be lower than the normal single twitch. The threshold of stimulation is not materially raised (Sasaki, 1921). Applied to the *exposed heart* of frogs or turtles, chloral produces progressive slowing, diminished contractility, lessened systole, and diastolic standstill. The arrested heart at first responds easily to stimuli, but cannot be started by atropine (Razewski, 1870; Harnack and Witkowski, 1879). Further details are described by W. H. Schultz, 1906. The *excised* frog heart (Straub arrangement) shows marked lengthening of the refractory period (K. Gies, 1927). Similar depressant effects are seen in the *mammalian heart* (Bock, 1898; Gunn, 1915). The depressant concentration is at least 1:1000; the fatal, 1:400. The oxygen consumption of the heart is decreased, but not so much as its activity (Rohde and Ogawa, 1912). *Sudden stoppage of the heart* may occur from relatively small doses, in cats, under the influence of excitement (Sollmann, 1908). This resembles some of the human cases. The *accelerator mechanism* is generally depressed by chloral (Fredericq, 1913).

Excised Intestines.—The movements are increased by 0.05 per cent, and diminished by stronger concentrations. This may be preceded by stimulation. Later, there may be occasional slow but strong contractions (Sembdner, 1913).

The *urine flow* is diminished during the narcosis (Ginsberg, 1912), as is also the phenol-s.-phthalein output (Whipple and Speed, 1915). The uric acid excretion is somewhat increased (Abl, 1913). The output of nitrogen and neutral sulfur is increased; but in *distinction to chloroform*, this is delayed for several days after administration (Harnack and Remertz, 1893); nor is the disturbance so great as with chloroform. Doses so large as to maintain anesthesia over twenty-four hours may not produce the characteristic effects of prolonged chloroform administration on the *liver and kidneys*, or only occasionally and to a slight degree (Hopkins, 1912). Severe chloral coma, however, is followed by prolonged anorexia, marasmus and loss of weight (Sollmann and Hatcher, 1908). Lissauer, 1914, found changes in the cardiac ganglia in rabbits (which are specially susceptible).
